Par. 212 *d* For furnaces over 38 in. in outside diameter of vertical fire-tube boilers and other types of furnaces and combustion chambers not covered by special rules in this Code, which have curved sheets subject to external pressure, that is, pressure on the convex side, the staying, both circumferential and longitudinal, shall be provided for in accordance with the following formula:

$$P = \frac{CT^2}{p^2} + 250\frac{T}{R}$$

where p and the value of C are as given in Par. 199, p shall not exceed $2T$, and p^2 shall not exceed $0.008\ CTR$.

The stress per sq. in. in staybolts shall not exceed 7500 lb., based on a total stress obtained by multiplying the product of the circumferential and longitudinal pitches by $\left(P - 250\frac{T}{R}\right)$.

Second Revision of A.S.M.E. Boiler Code, 1923

A HEARING is held by the Boiler Code Committee at least once in four years, at which all interested parties may be heard, in order that such revisions may be made as are found to be desirable, as the state of the art advances. The year 1922 became the period of the second revision and the Boiler Code Committee held a Public Hearing in connection with the recent Annual Meeting of the Society in December, 1922, to which the membership of the Society and everyone interested in the steam-boiler industry was invited to attend and present their views.

For the convenience of every one interested, a printed schedule of the various proposed revisions had been published and distributed to all those who were invited to attend the Public Hearing and the opportunity was given thereat for the most careful consideration of all of the proposed revisions. As a result of the suggestions received at the Public Hearing, a number of modifications of the previously announced revisions were offered and in addition suggestions were received for still further revisions of the Code. All of these suggestions for modifications and new revisions have been carefully considered by the Boiler Code Committee and the result in modifications of revisions and additional revisions are here published.

It is the request of the Committee that these revisions be fully and freely discussed so that it may be possible for anyone to suggest changes before the rules are brought to final form and presented to the Council for approval. Discussions should be mailed to C. W. Obert, Secretary to the Boiler Code Committee, 29 West 39th St., New York, N. Y., in order that they may be considered by the Boiler Code Committee.

The revisions here published are limited to the paragraphs appearing in the 1918 Edition of the A.S.M.E. Boiler Code, and the paragraph numbers refer to the paragraphs of similar number in that edition. For the convenience of the reader in studying the revisions, all added matter appears in small capitals and all deleted matter in smaller type in brackets.

Modifications of Revisions

PAR. 9 ADD THE FOLLOWING TO THE REVISED FORM PRINTED IN THE JULY 1922 ISSUE OF MECHANICAL ENGINEERING:

SEAMLESS TUBES OR LAP-WELDED PIPE MAY BE USED FOR DRUMS OR OTHER PRESSURE PARTS OF A BOILER PROVIDED SUCH TUBES OR PIPES CONFORM TO THE SPECIFICATIONS FOR WELDED AND SEAMLESS STEEL AND WROUGHT-IRON PIPE, AND PROVIDED ALSO THAT THE OUTSIDE DIAMETER OF THE TUBES OR PIPES DOES NOT EXCEED 20 IN.

PAR. 19 CANCEL PROPOSED REVISION OF THIS PARAGRAPH PRINTED IN THE DECEMBER 1922 ISSUE OF MECHANICAL ENGINEERING.

PAR. 21 REPLACE REVISED FORM PRINTED IN DECEMBER 1922 ISSUE OF MECHANICAL ENGINEERING WITH THE FOLLOWING:

21 *Tubes for Water-Tube Boilers.* The maximum allowable working pressures for STEEL OR WROUGHT-IRON tubes used in water-tube boilers, shall be for the various diameters and gages measured by Birmingham wire gage, as given in Table 2. REDRAWN PIPE NOT TO EXCEED $1^1/_2$-IN. STANDARD PIPE SIZE WHICH MEETS THE PIPE SPECIFICATIONS, MAY BE USED FOR WATER-TUBE BOILERS FOR A WORKING PRESSURE NOT TO EXCEED 200 LB. PER SQ. IN., WHEN SCREWED IN THE SHEET, PROVIDED THE WALL THICKNESS IS AT LEAST 50 PER CENT GREATER THAN THE WALL THICKNESS REQUIRED BY TABLE 2. THE MAXIMUM ALLOWABLE WORKING PRESSURES FOR COPPER TUBES USED IN WATER-TUBE BOILERS SHALL BE FOR THE VARIOUS DIAMETERS AND GAGES MEASURED BY BIRMINGHAM WIRE GAGE AS GIVEN IN TABLE $2^1/_2$, BUT NOT TO BE USED FOR PRESSURES TO EXCEED 250 LB. COPPER TUBES SHALL NOT BE USED WITH SUPERHEATED STEAM.

TABLE $2^1/_2$ MAXIMUM ALLOWABLE WORKING PRESSURES FOR COPPER TUBES FOR WATER-TUBE BOILERS

For Different Diameters and Gages of Tubes

Outside diam. of tube, in. D	Gage—B. W. G. 12	11	10	9	8	7	6	5	4
2	170	231	250	250	250	250	250	250	250
$3^1/_4$	...	...	101	142	215	250	250	250	250
4	...	...	...	...	128	173	242	250	250
5	...	...	...	...	...	...	143	184	218

$$P = \left(\frac{t - 0.039}{D}\right)12000 - 250$$

Where P = Maximum allowable working pressure, lb. per sq. in.
t = Thickness of tube wall, in.
D = Outside diameter of tube, in.

PAR. 185 ADD THE FOLLOWING TO THE REVISED FORM PRINTED IN THE DECEMBER 1922 ISSUE OF MECHANICAL ENGINEERING:

WHERE PLATES ARE PLANED OR MILLED DOWN IT SHALL BE FOR THE ENTIRE CIRCUMFERENCE OF THE JOINT, AND THE FILLET AT THE EDGE OF THE PLANING SHALL BE NOT LESS THAN 1 IN. RADIUS.

PAR. 194 REVISE PARAGRAPH AS PRINTED IN AUGUST 1922 ISSUE OF MECHANICAL ENGINEERING TO READ AS FOLLOWS:

194 The longitudinal joint of a dome 24 in. or over in inside diameter shall be of butt and double-strap construction or made without a seam of one piece of steel pressed into shape, and its flange shall be double-riveted to the boiler shell. IN THE CASE OF

NOTE:—Matter in caps.—added matter; Matter in smaller type in brackets—to be deleted.

a dome less than 24 in. in diameter, for which the product of the inside diameter and the maximum allowable working pressure does not exceed 4000 in. lb., its flange may be single riveted to the boiler shell and the longitudinal joint may be of the lap type provided it is computed with a factor of safety not less than 8.

When a dome is located on the barrel of a locomotive-type boiler or on the shell of a horizontal-return-tubular boiler, the diameter of the dome shall not exceed six-tenths the diameter of the shell or barrel of the boiler.

All domes shall be so attached that any water which enters the dome along with the steam can drain back into the boiler.

Flanges of domes shall be formed with a corner radius, measured on the inside, of at least twice the thickness of the plate for plates 1 in. thick or less, and at least three times the thickness of the plate for plates over 1 in. in thickness.

When boiler shells are cut to apply steam domes, the net area of metal, after rivet holes are deducted, in flange and liner, if used, must not be less than the area required by these rules for a length of boiler shell equal to the length removed. The height of vertical flange equal to three times the thickness of the flange shall be included in the area of the flange (see pars. 187 and 188).

Par. 195 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Insert the word "unstayed" before the word "dished," the first word of the fourth section of this paragraph.

Par. 212*a* Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Omit the words "except handholes" in the 9th and 16th lines.

Par. 216 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Change the figure "1.25" at the beginning of line 11, to "1.5."

Par. 218 Change the first sentence of revised form printed in December 1922 issue of Mechanical Engineering as follows:

218 When stays are required the portion of the heads below the tubes in a horizontal-return-tubular boiler shall be supported at the front head by through stays with nuts inside and outside and at the rear head by attachments which distribute the stress.

Par. 230 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Insert the word "determined" after the word "length" in the 9th line.

Par. 231 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Insert the words "or rivets" after the word "staybolts" in the 16th line.

Par. 239 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Add the words "or flame" to section a-4.

Par. 247 Replace the revised form printed in July 1922 issue of Mechanical Engineering with the following:

247 Where no rules are given and it is impossible to calculate with a reasonable degree of accuracy the strength of a boiler structure or any part thereof, a full-sized sample shall be built by the manufacturer and tested in a manner to be prescribed by the boiler code committee and in the presence of or more representatives appointed to witness such test.

Par. 253 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Revise fifth line of the first section to read: Diameter for [thicker] material [not] more than $^5/_{16}$ [$^5/_8$] in. thick.

Insert the word "such" before the first word "holes" in the second section.

Par. 260 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Omit the words "when used" in the first line.

In Fig. $20^1/_2$, turn this figure upside down and cross-hatch and revise so that the cross-section of flanged manhole frame will have a curved line representing the lower edge of plate around hole.

Par. 261 Replace the revised form printed in December 1922 issue of Mechanical Engineering with the following:

261 The strength of the rivets in shear on each side of a [manhole] frame or ring reinforcing manholes or other openings such as those cut for steel nozzles and boiler flanges over 3 in. pipe size shall be at least equal to the tensile strength of the maximum amount of the shell plate removed by the opening and rivet holes for the reinforcement on any line parallel to the longitudinal axis of the shell, through the manhole, or other opening.

Par. 268 Revise first section of form printed in December 1922 issue of Mechanical Engineering to read as follows:

268 *Threaded Openings.* All pipe threads shall conform to the American Pipe Standard and all connections 1 in. pipe size or over shall have not less than the number of threads given in Table 8. For smaller pipe connections there shall be at least four threads in the opening.

Par. 269 Revise first sentence of form printed in December 1922 issue of Mechanical Engineering to read as follows:

269 *Safety Valve Requirements.* Each boiler having more than 500 sq. ft. of water heating surface or in which the generating capacity exceeds 2000 lb. per hour, shall have two or more safety valves.

Par. 273 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Replace the word "body" in the 4th and 5th lines with the word "casing."

Par. 274 Revise first section of form printed in December 1922 issue of Mechanical Engineering as follows:

274 The minimum aggregate [total] relieving capacity of all of the safety valve or valves required in a boiler shall be not less than that determined on the basis of 6 lb. of steam per hour per sq. ft. of boiler heating surface for water-tube boilers. For all other types of power boilers, the total relieving capacity shall be not less than that determined on the basis of 5 lb. of steam per hour per sq. ft. of boiler heating surface, for boilers with maximum allowable working pressure above 100 lb. and on the basis of 3 lb. of steam per hour per sq. ft. of boiler heating surface for boilers with maximum allowable working pressures at or below 100 lb. per sq. in. In many cases a greater relieving capacity of safety valves will have to be provided than the minimum specified by this rule and in every case the requirement of par. 270 shall hold.

Revise added matter at end of second section as follows:

Where the operating conditions are changed, the safety valve capacity shall be increased, if necessary, to meet the new conditions and be in accordance with Par. 270.

Par. 278 Revise added matter of form printed in December 1922 issue of Mechanical Engineering as follows:

Each valve shall have an open drain through the casing below the level of the valve seat. For valves exceeding 2 in. pipe size, the holes shall be tapped for drip pipe. In the case of fire-tube boilers, the boiler openings for safety valves shall be not less than those corresponding to an evaporation of 5 lb. of steam per hour per sq. ft. of heating surface and to safety valves having the intermediate lifts and corresponding relieving capacities given in table 15.

Par. 280 Revise last line of form printed in December 1922 issue of Mechanical Engineering as follows:

diameters of [all of] the safety valve connections and shall also meet the requirements of par. 278.

Par. 281 Revise second sentence of form printed in December 1922 issue of Mechanical Engineering as follows:

To close after blowing down not more than 4 per cent of the set pressure, except for working pressures of 50 lb. per sq. in. or less, in which case the blow down shall not exceed 2 lb. per sq. in.

Par. 287 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Replace the word "body" in the first line, with the word "casing."

Par. 289 Revise second line on revised form printed in December 1922 issue of Mechanical Engineering as follows:

heated steam, shall have a casing of steel, steel alloy, or equivalent heat-resisting material, including all parts which

Insert the words "(see Par. 12)" after the word "outlet" at the end of the third line, ending the sentence. Begin new sentence with the words the valve shall have a flanged, etc.

Par. 321 Add the following sentence to form printed in December 1922 issue of Mechanical Engineering:

For steam pressures of 200 lb. and over, the water connections shall be of steel pipe or tubing, wrought-iron pipe or the equivalent.

Par. 324 Note the following on revised form printed in December 1922 issue of Mechanical Engineering:

Insert the word "or" before the word "over" in the second line.

Par. 332 Replace the revised form printed in December 1922 issue of Mechanical Engineering with the following:

332 Each boiler shall conform in every detail to these Rules, and shall be distinctly stamped with the symbol as shown in Fig. 23, denoting that the boiler was constructed in accordance therewith.

After obtaining the stamp to be used when boilers are to be constructed to conform with the A.S.M.E. Boiler Code, a state inspector, municipal inspector, or an inspector employed regularly by an insurance company which is authorized to do a boiler insurance business in the state in which the boiler is built and in the state in which it is to be used, if known, is to be notified that an inspection is to be made and he shall inspect such boilers during construction and after completion. At least two inspections shall be made, one before reaming rivet holes and one at the hydrostatic test. In stamping the boiler after completion, if built in compliance with the code, the builder shall stamp the boiler in the presence of the inspector, after the hydrostatic test, with the A.S.M.E. Code stamp, the builder's name and the serial number of the manufacturer. A data sheet shall be filled out and signed by the manufacturer and the inspector. This data sheet together with the stamp on the boiler shall denote that it was constructed in accordance with the A.S.M.E. Boiler Code.

In cases where boilers cannot be completed and hydrostatically tested before shipment, the proper stampings shall be applied at the shop and two data sheets signed as herein provided by the same or different inspectors covering the portions of the inspections made at the shop and in the field, the data sheets each to be separately sent to the proper destination.

Each boiler shall be stamped adjacent to the symbol as shown in Fig. 24, with the following items with intervals of about one-half inch between the lines:

1 Registered number

2 A.S.M.E. [Manufacturer's] serial number which may be the manufacturer's serial number.

[2 State in which boiler is to be used.]

[3 Manufacturer's State standard number.]

3 Name of manufacturer.

4 Maximum working pressure when built.

5 Water heating surface in sq. ft.

[5 State's number.]

6 Year put in service.

Items 1, 2, 3, 4, and 5 to be stamped at the shop where built.

Item 6 is to be stamped by the proper authority at point of installation.

Portable boilers of 100 hp. or less shall have the stampings as herein provided applied on a non-ferrous plate 3 in. x 4 in. size which shall be, as nearly as practicable, irremovably fastened to the boiler near the water-column connections. All other boilers may have the stampings so applied or they may be applied directly to the boiler structure.

Manufacturers, before using the A.S.M.E. symbol, shall be given a registration number by The American Society of Mechanical Engineers. This number shall be stamped directly on the boiler or placed on a non-ferrous plate. The registration number shall be placed not more than one-half inch above the symbol and centering on it. Inspection jurisdictions shall be furnished by the A.S.M.E. a list of registered manufacturers, with the corresponding registration numbers issued.

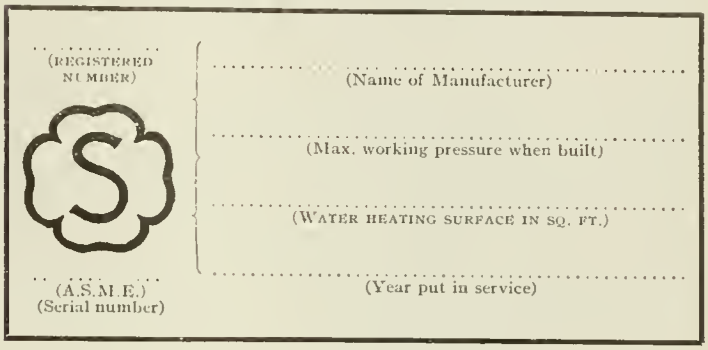

Fig. 24 Form of Stamping

Par. 429 Omit revision in form printed in December 1922 issue of Mechanical Engineering.

New Revisions of A.S.M.E. Boiler Code, 1923

Par. 22 Revised:

22 *Tubes for Fire-Tube Boilers.* The minimum thickness of tubes used in fire-tube boilers measured by Birmingham wire gage, for maximum allowable working pressures not exceeding 175 lb. per sq. in., shall be as follows:

	Gage—B. W. G.	
	Steel or Wrought Iron	Copper
Diameters 1 in. or over, but less than $2^1/_2$ in.	13	10
Diameter $2^1/_2$ in. or over, but less than $3^1/_4$ in.	12	8
Diameter $3^1/_4$ in. or over, but less than 4 in.	11	7
Diameter 4 in. or over, but less than 5 in.	10	6
Diameter 5 in.	9	5

For each increase of one gage in thickness above that shown in the table, the maximum allowable working pressure will be increased by 200 lb. divided by the diameter of the tube in inches.

Copper tubes shall not be used for pressures in excess of 250 lb. per sq. in.

Copper-tube specifications: Specifications for seamless copper boiler tubes will be included following those of the American Society for Testing Materials, serial designation b 13–18.

Par. 179 Revised:

179 *Maximum Allowable Working Pressure.* The maximum allowable working pressure is that (at which a boiler may be operated as) determined by employing the factors of safety, stresses, and dimensions designated in these Rules.

(Remainder of paragraph unchanged)

Par. 333*c* Revised:

c On traction, portable or stationary boilers of the locomotive type or Star water-tube boilers—on the furnace end, above the handhole. Or on traction boilers of the locomotive type—on the left wrapper sheet forward of the driving wheel.

(*Continued on page 273*)

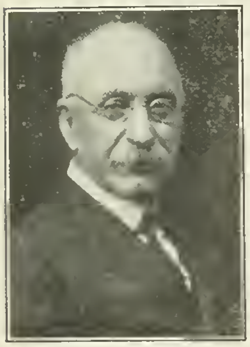
Plain Speaking



Dr. Ira N. Hollis

"BROTHERHOOD of all engineers and their united action in any service that will be for the good of our country." This motto, worthy and characteristic of Dr. Ira N. Hollis, the 1917 President of The American Society of Mechanical Engineers, appeared in the volume of Transactions for that year, during which he took his place as first chairman of the Engineering Council, an important first step toward the national coöperation of engineering societies. Dr. Hollis' life has been given to the ideal of service: he realizes the need for straightforward engineering thought in our modern civilization, and he has confidence in the ability of the engineering profession to perceive this need and adapt itself for it. However, he believes that facts must be faced, and in a recent communication he directs our attention to the purposes of The Federated American Engineering Societies. We are privileged to print below a portion of this letter. Read it carefully.

"The plain truth is that the engineers have not yet come to an understanding of themselves. In their own minds they have not yet passed out of that classification that the public has given them, namely, of being technical men called in to advise only on technical questions. A few of them have passed out of that category in the esteem of the public, but the rank and file are still laboring under the disadvantage of being simply hired men. One may well wonder how long this is to continue. We know perfectly well that we all ought to be good citizens and that we ought to have our share in the government of nation and city. That does not at all mean neglecting our professions, but it does mean giving some time and some money toward wielding our own proper influence.

"The Federated American Engineering Societies was organized as a kind of senate wherein would appear public questions. It sprang out of the old Engineering Council where the four oldest national societies got together on certain things that are common to all in order that they might not have to present a too great variety of opinions or decisions. The old Council was really the outcome of an effort to work together. This new society, which takes in local and national societies alike, holds out a prospect of bringing the engineer before the public as nothing else ever has. If it did absolutely nothing else than to teach the American people the value of the engineering profession and capacity of its members to assist in the decision of great national problems, it would justify itself. The main difficulty is found in its support. Few engineers are opposed to it in principle, but there are altogether too many who do not care to put in even the small amount of dues now required. Some societies find the total amount paid over by them a burden and fear to lose their own members by diverting any part of their income to this activity. It is unenlightened in men to demand immediate personal benefit from the payment of a small amount, \$1.00 or \$1.50 per year, for the support of this public institution. They might as well ask for some immediate personal benefit springing out of their taxes paid over to the state and Government. We all get a benefit from the taxes, but not all alike. The man who pays a thousand dollars gets only just what the man who pays ten dollars gets. We pay willingly because our taxes mean the maintenance of society. The case of the F.A.E.S. payment is the same as any public assessment. The engineer has been the hired man of the ages. He is found from time to time in the historic period. Upon him the Egyptians depended for the life of the population in the Nile Valley. The same is true in the valley of the Euphrates and the Tigris. Wherever he has been absent, the nation has gone steadily down hill, and yet he has, up to within a comparatively recent period, had little consideration from the general public simply because he has had a tendency to treat himself as purely a technical man. There is only one way to recover from that in our modern days, and that is by organization. We know it. There must be a thousand other associations or organizations in the United States for different purposes, and we cannot afford to become ineffective in that direction. The Federated Societies, or something like them, offer us the only means of making the profession well known in its larger possibilities."

Safe Engineering Versus Safety Engineering

Champlain Studios, N. Y.

Wm. J. Venning

EVER SINCE the earliest ages man has been forced to provide means for self-protection. Primitive man fashioned cudgels from stone which he used as weapons of defense as well as offense, and for aid in self-preservation lived in groups with his fellow-beings. As these groups grew in size and men were compelled to depend upon one another for protection of the group as a whole, it became necessary to make laws defining the conduct of the individual. Some of these laws the present-day safety engineer would call strictly "safety-first" laws. For instance, in the Bible, the eighth verse of the 22nd chapter of Deuteronomy specifically interprets a building law; then again King Hamurabi, whose death occurred in Babylon in the year of 2185 B.C., promulgated a building law as follows: "If a builder build a house for a man and do not make its construction firm, that builder shall be put to death." And so on down through the ages to our present safety codes.

The need for a safety code is usually determined by a study of accident causes, and since industrial development has been so rapid, what was considered a good code yesterday is obsolete today. Then again, the lack of uniformity and agreement between the various states has always been an insurmountable obstacle.

"Safe Engineering" takes into consideration not only safety factors in design and construction but should also provide for safe operation or use. "Safety Engineering" is applied where design and construction have failed to provide for safety operation or use. That it would be much cheaper to always incorporate safe engineering in construction and design cannot be gainsaid. Fifty machines of the same design, made by the same builder, sold to fifty different users, if not properly guarded during construction, will eventually be guarded fifty different ways by the purchasers with varying degrees of efficiency and cost strictly in accordance with the purchaser's state of mind. Where it has been the writer's task to initiate the uninformed industrial plant owner into the realm

of safety by offering certain recommendations for safeguards as a result of plant inspection, one of the first questions asked is, "Why doesn't the manufacturer properly guard the machine when he constructs it?"

There are three important points to be considered in the safeguarding of machinery:

1 Drive belts and pulleys or drive device
2 Moving and reciprocating parts
3 Point of operation.

The drive belts or device of any machine are easily guarded, the most efficient construction being of expanded metal, perforated metal, or woven wire, mounted on an angle-iron frame of the box type and securely fastened in place. Guards of this type will stand hard usage and repay for their cost in reduced insurance rates.

To guard the moving and reciprocating parts invariably requires a little more thought. Solid guards made of sheet iron are usually employed, although for quantity production on similar-type machines a cast guard made from a pattern is the least expensive. The installation of these guards must permit of easy machine adjustment and in no way interfere with efficient operation.

The point of operation of a machine is that part where the stock is fed in. Automatic feeds with the moving parts guarded and which remove the hazards inherent in hand feeding are most desirable. Where hand feeding is necessary, the guard should fully protect the operator and expedite the work. Although the machine designer and builder can easily guard the drive device and moving parts of any machine during initial construction and can do it much cheaper than the purchaser because the work is done on a production basis, he cannot always guard the point of operation because of the many and various kinds of work performed on the same machine; for instance, a gate guard that would be practical on a punch press for second-operation hand-fed work, would not do for blanking work from strip stock. Particularly in small shops with limited mechanical equipment does the safety engineer meet with this difficult problem. However, closer coöperation between the machine builder and the professional safety engineer should gradually solve this problem, and teaching safety engineering in the technical schools and engineering colleges should eventually make "Safe Engineering" the principal factor in design and construction.

In every instance sound engineering practice should be followed to obtain the best results.

An efficiently guarded machine will give the operator a greater sense of security, thereby removing the necessity of continual caution.

Guarding prevents property damage often caused by careless handling of stock around and near machinery in motion.

Well-guarded machines permit the piling of stock close up to the machine and conserve floor space.

A machine properly guarded makes it possible to use unskilled labor on many operations that would otherwise call for skilled labor, because part of the skill or training consists in being able to localize and avoid the hazard.

Efficient machine guarding reduces labor turnover by keeping the worker on the job uninjured, thereby increasing production through increased shop efficiency.

William J. Venning.[1]

Asiatic Markets for Industrial Machinery

FOR YEARS there has been a not unfounded complaint to the effect that the American exporter does not receive the same amount of support from his government as do his competitors from theirs. In particular, attention was called to the excellent information service maintained for the export trade before the war by the British and German governments.

That this situation is rapidly changing for the better is well indicated, for example, by a recent publication of the Bureau of Foreign and Domestic Commerce of the Department of Commerce, entitled Asiatic Markets for Industrial Machinery, by Walter H. Rastall, Mem. A.S.M.E.

This book is a veritable repository of information not only on the actual export statistics but on conditions surrounding the business of exporters of industrial machinery to Asiatic markets, their purchasing power and requirements. The investigation deals primarily with machinery used in and about factories and power plants, but also includes data on construction machinery, mining machinery and certain other types—not, however, such special machinery as cash registers, automobiles and sewing machines. In addition to the more obvious features of such an investigation, an effort has been made to examine into the advertising, financing, and selling methods employed by foreign competitors as well as by successful American exporters, and certain sections of the report have been prepared with the idea of furnishing detailed information needed by men who are starting in export work as well as those with more ample experience.

In the letter of submittal of the Director of the Bureau to Secretary of Commerce Hoover, it is pointed out that a notable movement toward industrialization is in progress in the more important Asiatic countries, and Mr. Rastall is decidedly optimistic with regard to the prospects for development. Considering that the total population of the countries covered by this report is probably well in excess of half a billion souls and that they have large natural resources still awaiting development, the subject of these markets for American machinery is one well worthy of serious attention.

[1] President, American Society of Safety Engineers.

Montreal Spring Meeting

THE coming Montreal Spring Meeting of The American Society of Mechanical Engineers is the first to be held outside of the borders of the country since 1894, when one was also held in Montreal. It is hoped that the coming convention, May 28–31, will afford an excellent opportunity for the development of the already amicable relations between the engineers of Canada and the United States. The members of the Engineering Institute of Canada have been invited to attend, and the Montreal Branch of the Canadian Institute is coöperating wholeheartedly in the plans for the meeting.

The technical program will of course stress Hydroelectric Development, and two sessions will be devoted to that subject. The other topics to be considered are Management Engineering, with special application to the Paper and Pulp Industry, Port Development, in which the harbor problems of Montreal will be treated; Textiles; Railroads; and Fuels. The Professional Divisions on Power, Management, Materials Handling, Textiles, Railroads, and Fuels are coöperating in these sessions and the Divisions on Aeronautics, Forest Products, and Machine Shop Practice are presenting papers for the miscellaneous sessions.

The meeting will be notable for its entertainment features which will comprise a smoking concert at which members of the A.S.M.E. will be the guests of the Montreal branch of the Engineering Institute of Canada, a dinner dance, and excursions to points of scenic and engineering interest in and around Montreal. The number of points to be visited make Montreal an exceptionally attractive convention city. Following the meeting a trip to Grandmere and Quebec is being planned.

Detailed information will be found in the current issues of *A.S.M.E. News* and the tentative program for the meeting will appear in the April 7 issue.

Bureau of Standards Report on Welded Vessels to Come Later

THE complete report on the Bureau of Standards investigations on welded pressure vessels which was promised in the March issue of Mechanical Engineering, page 210, has not as yet been received by the A.S.M.E. Boiler Code Committee and its presentation will necessarily be deferred to a later issue. It is hoped that it will be possible to present a comprehensive report on this most interesting and valuable series of tests.

Erratum

IN extracts from the U.E.S. treasurer's report for 1922, printed in the March issue of Mechanical Engineering, page 205, the cash on hand as of December 31, 1922 was inadvertently stated as amounting to $138,294.27. The figure should have been $32,754.89.

Dr. M. A. Hunter Presents Facts About High-Temperature Alloys at Newark Meeting

THE requirements of electric heaters, valves for internal-combustion engines, containers for high-temperature furnace work and parts of steam boilers for use with high superheats have made the subject of high-temperature alloys of great interest to mechanical engineers. The Metropolitan Section of the A.S.M.E. held a meeting on this subject in Newark on February 13 which was addressed by Dr. M. A. Hunter, professor of electrochemistry at Rensselaer Polytechnic Institute. Dr. Hunter presented many facts which are of importance to those engaged in work of the nature mentioned.

The line between high- and low-temperature alloys may be roughly drawn at around 1800 deg. fahr., although not all metals or alloys melting above this temperature can be used, either for technical or commercial reasons. Thus the metals of the platinum groups are too rare and costly, at least for large-scale applications, although used extensively for high-temperature chemical work and pyrometry. Metals like tungsten, tantalum, and molybdenum are chemically unstable when exposed to air, but can be used as in gas-filled electric lamps at extremely high temperature under proper conditions.

The most common metals available for high-temperature commercial work in air or active gases are iron, melting at 1520 deg. cent.; chromium, at 1550 deg.; cobalt, at 1590 deg.; nickel, at 1450 deg.; silicon, at 1420 deg.; manganese, at 1225 deg.; and copper, at 1084 deg. These are the chief constituents of high-temperature alloys, which, however, may contain other metals, such as tungsten, in small quantities.

In general, high-temperature alloys consist of two or three components united in what metallurgists call a "solid solution."

High-temperature alloys may be subjected to the action of high temperature alone or in combination with chemical actions—of which the most important are those of a corrosive nature—and mechanical stresses, and alloys good for one purpose may not be suitable for another. For temperatures below 700 deg. cent., particularly where chemical attack is to be feared (except in the case of nitric acid), copper-nickel mixtures form an important class. Of this the best known is monel metal, an alloy of about 30 per cent copper and 70 per cent nickel. Its melting point is said to be 2480 deg. fahr. Monel metal may be used in the form of castings, rolled sheets, and drawn wire. Its strength approaches that of mild steel in corresponding products. At temperatures above 700 deg. cent. it is apt to oxidize. Cast monel metal usually has a high silicon and low manganese content, as this helps the fluidity of the metal; rolled or drawn monel is low in silicon and high in manganese.

An alloy consisting of 40 per cent nickel and 60 per cent copper, known as "Advance wire," is of considerable value in temperature-measurement work as it has a zero temperature coefficient over a range of 300 deg.

Some of the valuable high-temperature alloys are characterized by the presence of chromium in considerable degree. The earliest of those developed commercially were the nickel-chrome alloys which have found extensive application as electrical resistance wire and heating elements for electric stoves and the like. The most used combination is 80 per cent nickel and 20 per cent chromium. This alloy is noteworthy chiefly for its ability to withstand oxidation at high temperatures. Alloys with practically any proportion of chromium can be formed by casting, but where the metal has to be worked the percentage of chromium should not exceed 20 per cent. The matter of carbon content has to be watched in this alloy with extreme care. The nickel-chromium wire patents are understood to have expired in February of the current year.

Alloys of nickel, iron, and chromium are used for applications where temperatures not exceeding 900 deg. cent. prevail. The alloy nichrome (containing 26 per cent iron, 12 per cent chromium, the remainder nickel and impurities) is used as rod, strip, or wire in electrical resistors. As a cast material it finds increasing applications in carbonizing boxes, retorts, lead and cyanide pots, etc. These alloys do not carburize at high temperatures, crack, warp, or scale, and except under high sulphur conditions in the fuel used, give very satisfactory service. One of their remarkable properties is the ability to retain a considerable proportion of their original strength at 1000 deg. cent., which is very different from the behavior of steel and similar alloys.

Nichrome exhibits great tensile strength at high temperatures. At 1000 deg. cent., material which at room temperature shows 67,000 lb. strength has 12,000 lb. strength, an elongation of 55 per cent, and a reduction in area of 15 per cent. This same metal at 850 deg. cent. has an ultimate strength of 20,000 lb., and at 600 deg. cent. 44,000 lb. It has been successfully used for internal-combustion-engine valves.

Other high-temperature alloys deserving consideration for commercial work are those of the chrome-iron group. These contain chromium in varying percentages from about 20 up to 35 or even 40 and are remarkable for their high resistance both to temperature and to chemical stresses. The physical properties of the chrome-iron alloys (which, of course, differ basically from cast nichrome in that they contain no nickel) are essentially determined by their carbon content, alloys with carbon content below 0.30 per cent machining practically as freely as cold-rolled steel; with carbon content between 0.30 to 1.5 the machining becomes increasingly difficult, and finally, when the 1.5 per cent carbon limit has been reached a material is obtained which casts very well but cannot be machined by ordinary means.

In the discussion which followed, the question was raised as to whether these high-temperature alloys would withstand the combination of temperatures up to 1200 deg. fahr. with pressures such as are encountered, for example, in oil-cracking stills (Burton and Rittman processes). In this connection, it might be mentioned that in France an alloy has been developed of practically the same composition as cast nichrome but with the addition of about 2 per cent tungsten, and that tubes cast of this material have been used in the Claude ammonia process where both high temperatures and high pressures are used simultaneously.

David A. Decrow Dies

DAVID A. DECROW, manager of the water-works department of the Worthington Pump & Machinery Corporation, New York City, died on February 15, 1923. Mr. Decrow was born in Bangor, Me., in 1858, where he received his early education. He was graduated from the University of Maine, College of Mechanic Arts, with the class of 1879.

In the early eighties he became associated with the Holly Manufacturing Co., Lockport, N. Y. His promotions with this company were rapid; in 1893 he was made designing engineer, in 1900 chief engineer, and in 1903 secretary of the firm.

Some years ago the Holly Manufacturing Co. was combined with the Snow Steam Works at Buffalo, N. Y., as part of the International Steam Pump Co., and at that time Mr. Decrow went to Buffalo to take charge of the pumping machinery manufactured by both companies. In April, 1916, the International Steam Pump Co. was succeeded by the Worthington Pump & Machinery Corporation. Soon after this Mr. Decrow was called to the New York office to become manager of the water-works department, the position he held until his death.

Mr. Decrow was active as a member and recently as chairman of the A.S.M.E. Committee on the Test Code for Reciprocating Displacement Pumps. He was a member of a number of clubs and organizations in Buffalo.

Engineering Division, National Research Council, Elects Officers

DR. F. B. JEWETT, vice-president of the Western Electric Company, New York N. Y., has been elected chairman of the Engineering Division of the National Research Council, to succeed Alfred D. Flinn, who resigned that office last year to become director of Engineering Foundation.

E. B. Craft, chief engineer of the Western Electric Company, was elected vice-chairman of the Division, and M. Holland, formerly of the U. S. Air Service, McCook Field, Dayton, Ohio, appointed director. G. H. Clevenger was reëlected a vice-chairman and W. Spraragen secretary.

Philadelphia Holds Successful Machine Meeting

Technical, Historical, and Economic Phases of Machine Tools and Machine-Shop Practice Discussed Before Large Gatherings. Dean Dexter S. Kimball, President John Lyle Harrington of A.S.M.E., and E. F. DuBrul among the Speakers

TECHNICAL, historical, and economic phases of the machine-tool industry and machine-shop practice were presented and discussed at the Conference on Machine Tools which was held in Philadelphia on February 27 under the auspices of the Engineers' Club of Philadelphia and the Philadelphia Sections of The American Society of Mechanical Engineers and the American Institute of Electrical Engineers, and with the coöperation of the Machine Shop Practice Division of The American Society of Mechanical Engineers.

Over three hundred attended the sessions and dinner, and the good papers, interesting discussion, and increased fellowship among the engineers in machine-shop practice which resulted from the meeting form an achievement of which the Philadelphia engineers may well be proud.

Two sessions were held, the afternoon session being given over to the presentation and discussion of technical papers, the first of which, on the Effect of Variations in Design of Milling Cutters on Power Requirements and Capacity, by Prof. James A. Hall, of Brown University, and Benjamin P. Graves, of the Brown & Sharpe Mfg. Co., appeared in the March issue of MECHANICAL ENGINEERING. The discussion is given later in this account of the meeting. The second paper, on the Design and Construction of Large Machine Tools, by George H. Benzon, Jr., of William Sellers & Co., appears as the leading article of this issue. Charles Penrose, chairman of the Philadelphia Section of the A.S.M.E., was introduced as presiding officer by Dr. Robert H. Fernald, president of the Engineers' Club of Philadelphia. Mr. Penrose called on Frank O. Hoagland, of Worcester, Mass., chairman of the Machine Shop Practice Division of the A.S.M.E., who told of the plans of his Division in meetings, research, and standardization.

Dinner was served at the Engineers' Club and was followed by a brief talk by President John Lyle Harrington of The American Society of Mechanical Engineers, who outlined the steps in the development of modern equipment for industry and transportation. Dean Dexter S. Kimball of Cornell University, past-president of the A.S.M.E., followed with a lantern-slide talk on the History of the Machine Tool and Its Effect on Present-Day Civilization. He elaborated somewhat on the paper which appeared in the March issue of MECHANICAL ENGINEERING and his picturesque portrayal of the romance of mechanical development held the interest of those who filled the seats of the auditorium and a large number who stood throughout his talk. He was followed by Ernest F. DuBrul, general manager of the National Machine Tool Builders' Association, who spoke on the Economic Features of the Machine-Tool Industry. Mr. DuBrul's paper appeared as the leading article in the March issue of MECHANICAL ENGINEERING. Ross B. Mateer, secretary of the Philadelphia Section of the A.I.E.E., presided at this evening session.

Discussion at Afternoon Session

Following the presentation of the paper on Effect of Variations in Design of Milling Cutters on Power Requirements and Capacity by Professor Hall and Mr. Graves, written discussion by Fred A. Parsons[1] was presented. Mr. Parsons took exception to the use of the terms "feed per tooth" or "maximum chip thickness" as bases for the comparison of cutting tools. He favored "average thickness of chip" as a satisfactory basis as it eliminated differences in depth of cut, diameter of cutter, and type of tool. He agreed with the conclusions of the authors in regard to the superiority of coarse-tooth cutters for general purposes.

W. A. Knight[2] stated as his opinion that spiral face milling for large flat-surface work should be obsolete as the cutting edge of a milling cutter must ride the surface every time a cut is taken and the cut is comparatively short.

[1] Kearney & Trecker Corp., Milwaukee, Wis. Mem. A.S.M.E.

[2] Acting-Director Industrial Arts Dept., Ohio State University. Mem. A.S.M.E.

R. Poliakoff[1] submitted a written discussion descriptive of a milling-machine dynamometer. He also pointed out that the end thrust found when using spiral cutters could be overcome by making the cutters with one-half having a right-hand spiral and the other half a left-hand spiral. He agreed with the authors that a 10-in. rake angle is desirable.

Carl G. Barth[2] agreed with the findings of the authors in the advantages of milling cutters with few teeth. He expressed the desire for further experimentation to discover the value of the exponent n in the formula P = constant $\times\, wf^n$ for the pressure on the lathe slicing or cutting-off tool taking a cut w with a feed f. Mr. Barth gave his derivation of an expression for horsepower consumption per cubic inch of metal removed with milling cutters as follows:

$$\mathrm{HP}_c = \text{constant}\ (N/F)^{1-n}\ (D/H)^{1/4}$$

in which N = number of teeth in cutter, F = feed per revolution, H = depth of cut and D = diameter of cutter, and which thus shows that HP_c increases with the number of teeth and decreases with feed per revolution, both raised to the power $(1-n)$; and increases with diameter of cutter and decreases with depth of cut, both raised to the power $^1/_4$; and that this is because the increased diameter reduces while increased depth of cut increases the chip thickness.

John Airey[3] presented a lengthy oral discussion in which he decried the fact that so little effort had been put into research work in machine-shop practice. He agreed with the authors on the subject of rake and lack of consistency of material. He disagreed in the manner of measuring the power consumption and in ascribing some parts of the power loss to the cutter. He gave some of the information previously presented in the paper on the Art of Milling, presented jointly with Carl J. Oxford at the 1921 Annual Meeting of the A.S.M.E., and reiterated the statement made in that paper that the sole criterion of the efficiency with which metal can be removed was the maximum chip thickness for any given material. The spacing of the teeth of the diameter of the cutter had nothing to do with this.

Carl J. Oxford[4] congratulated the authors on presenting scientific facts about an obscure subject. He expressed disappointment, however, because of the narrowness of scope of the research, and the authors' attempt to draw general conclusions from an unquestionably special case, mild steel, one size of milling cutter, and one type of cut only being used. While mild steel could be successfully milled at a speed in excess of 120 ft. per min., high-machineability alloy steels could seldom be milled at a speed higher than 50 ft. per min., although the chip thicknesses of from 0.006 in. to 0.010 in. per tooth might be the same as for mild steel. Productivity of a given size of milling cutter was in direct proportion to the number of teeth in that cutter and the limiting factors for numbers of teeth were:

1 Rigidity of the machine and holding devices

2 Depth or width of cut and the ability of the machine to deliver power to the cutter

3 Structural strength of the cutter.

In discussing Mr. Benzon's paper on the Design of Large Machine Tools, L. R. Meisenhelter[5] pointed out as three important factors in modern large-machine-tool design the importance of the quality and design of gears, the need for centralized control, and the development of proper lubrication.

Engineering and Industrial Standardization

New Plan for Financing Industrial Standardization Is Approved

A NEW plan for financing the industrial standardization work of the United States, which provides for membership dues on the basis of one cent per $1000 of gross receipts, has been formally approved by the Executive Committee of the American Engineering Standards Committee. Twenty of the most influential industrial executives of the country have accepted places on an Advisory Committee which will coöperate with the Ways and Means Committee in the refinancing of the American Engineering Standards Committee.

This report announces a new class of members in the A.E.S.C. to be known as "sustaining members," and provides for them a special service, including information bulletins on developments in standardization work in this country and in every other country where industrial standardization is in progress.

The newly created Advisory Committee of the A.E.S.C. consists of the following men:

W. H. Barr, President, National Founders' Association, Chicago, Ill.
A W. Berresford, General Manager, Cutler-Hammer Company, Milwaukee, Wis.
L. F. Butler, President, Travelers Insurance Company, Hartford, Conn.
Wm. Butterworth, President, Deere and Company, Moline, Ill.
John J. Carty, Vice-President, American Telephone and Telegraph Company, New York, N. Y.
W. W. Coleman, President, Bucyrus Company, South Milwaukee, Wis.
G. B. Cortelyou, President, Consolidated Gas Company, New York, N. Y.
J. K. Cullen, President, Niles-Bement-Pond Company, New York City
J. E. Edgerton, President, National Association of Manufacturers, New York, N. Y.
John R. Freeman, Consulting Engineer, Providence, R. I.
E. M. Herr, President, Westinghouse Electric and Manufacturing Co., East Pittsburgh, Pa.
Charles E. Hodges, President, American Mutual Liability Insurance Company, Boston, Mass.
Sidney J. Jennings, President, U. S. Smelting, Refining and Mining Company, New York, N. Y.
J. W. Lieb, Vice-President, New York Edison Company, New York. N. Y.
John B. Morton, President, National Board of Fire Underwriters, Philadelphia, Pa.
Dr. Chas. L. Reese, Chemical Director, E. I. du Pont de Nemours and Company, Wilmington, Del.
E. W. Rice, Jr., Honorary Chairman of the Board, General Electric Company, Schenectady, New York.
Henry D. Sharpe, Treasurer, Brown and Sharpe Manufacturing Company, Providence, R. I.
S. W. Stratton, President, Mass. Institute of Technology, Cambridge, Mass.
Ernest T. Trigg, President, John Lucas and Company, Inc., Philadelphia, Pa.

The American Engineering Standards Committee, which was organized in 1918, has heretofore been financed entirely by dues from the nine technical societies and seventeen national trade associations which with seven departments of the Federal Government constitute its present membership. Annual deficits have been cleared by contributions from individual corporations.

It is expected that the new plan of financing will provide an annual budget of $50,000 for the Standards Committee. As this sum is to be realized from sustaining-membership dues amounting to one-thousandth of one per cent of gross receipts, the total of $50,000 would be spread over industries with aggregate gross annual receipts of five billion dollars. For firms which for any reason prefer to subscribe on the basis of capital rather than gross annual receipts, the recommended basis is one and one-half cents per thousand dollars of aggregate market value of the corporate securities of the firm.

The plan calls for the appointment of an engineer-translator who will provide translations of standards developed in foreign countries for the information service to sustaining members. The new information service will be an elaboration of the work which the A.E.S.C. has been carrying on in a small way, in calling to the attention of coöperating bodies and the technical press the important developments in standardization work, foreign as well as American.

The Ways and Means Committee which drew up this plan of financing consisted of the following members:

Albert W. Whitney, Associate General Manager, National Bureau of Casualty and Surety Underwriters.
A. Cressy Morrison, Vice-President, Compressed Gas Manufacturers Association.
W. W. Nichols, Assistant to the President, Allis-Chalmers Manufacturing Company, and President, Electrical Manufacturers Club.
Frank W. Smith, Vice-President, The United Electric Light & Power Company, and President, National Electric Light Association.

Recent Progress of Some Sectional Committees

Standardization of Shafting. Though this Committee has held no meeting since that of December 5, 1922, it has been by no means inactive. The Sub-Committee headed by Prof. A. H. Beyer has held monthly meetings and is well along toward the completion of Part 2 of its report, namely, the Technique of Shafting Design.

Sub-Committee No. 1, of which Louis W. Williams is chairman, has drafted and circulated a questionnaire to approximately 260 dealers and manufacturers in an effort to ascertain which stock lengths of shafting are preferred. With this questionnaire the manufacturers received another prepared by the American Society for Testing Materials on the present methods employed in manufacturing steel shafting and the minimum values for elastic limit and tensile strength for the different sizes and kind of shafting produced by them. The real purpose of this inquiry was to secure data by which a minimum value of the unit stress for this material might be determined for the use of Professor Beyer's Sub-Committee. The response to these questionnaires has been very gratifying.

Standardization of Plain Limit Gages for General Engineering Work. A letter ballot on the first report to be completed by this Sectional Committee is now being taken. The report covers standard allowances and tolerances for fits in interchangeable manufacture, and is the part of the work assigned to the Sub-Committee of which George T. Trundle is chairman.

The Sub-Committee on Methods of Gaging Manufactured Material, headed by F. O. Hoagland, and the Sub-Committee on Gages and Their Limits, Manufacture and Use, presided over by Earle Buckingham, are both hard at work on their respective sections and promise reports in the near future.

Standardization of Pipe Flanges and Fittings. The all-day session which this Sectional Committee held in December produced many valuable suggestions which have been made good use of in preparing the revised drafts of the four flange standards which are now before the members of the Sectional Committee for approval. These standards are:

1 Cast-Iron Flange and Fittings Standards for 125 lb. Maximum (Saturated) Steam Working Pressure
2 Cast-Iron Flange and Fittings Standards for 250 lb. Maximum (Saturated) Steam Working Pressure
3 Cast-Steel Flange and Fittings Standards for 400 lb. Maximum Steam Working Pressure
   800 lb. Cold-Water Working Pressure—Hydrostatic (No Shock)
   500 lb. Cold-Water Working Pressure—Shock
   800 lb. Air or Gas Working Pressure—Temp. Not Exceeding 100 Deg. Fahr.
4 Cast-Steel Flange and Fittings Standards for 600 lb. Maximum Steam Working Pressure
   1200 lb. Cold-Water Working Pressure—Hydrostatic (No Shock)
   800 lb. Cold-Water Working Pressure—Shock
   1200 lb. Air or Gas Working Pressure—Temp. Not Exceeding 100 Deg. Fahr.

The Sub-Committee on Screwed Fittings is now at work on standard dimensions for cast-steel fittings and is preparing a supplementary report on the Malleable Fittings which will assign tolerances to certain of the dimensions.

Standardization of Bolt, Nut, and Rivet Proportions. At its December meeting this Committee elected as chairman, Arthur A. Norton, assistant professor of mechanical engineering, Harvard.

University. It also created an eighth Sub-Committee on Nomenclature which consists of the chairmen of the other seven Sub-Committees, the chairman and secretary of the Sectional Committee and is headed by George S. Case as chairman.

Tentative reports of four of the Sub-Committees are now being considered by the members of the entire Sectional Committee and are available for distribution to those who may desire to look them over. These reports cover:

1 Standards for Large and Small Rivets
2 Standards for Wrench-Head Bolts and Nuts
3 Standards for Slotted-Head Products
4 Standards for Carriage Bolts.

The Sub-Committee on Track Bolts, of which C. W. Squier is now chairman, held a meeting on March 9 and made a very careful survey of the large task assigned to it. A mass of data was laid before the Sub-Committee and this is being carefully studied as the first part of its program.

Safety Code for Mechanical Power-Transmission Apparatus. On February 8 this Sectional Committee held a meeting in New York at which were considered comments which had resulted from the circularization of galley proofs of this safety Code. The correspondence and the discussion at the meeting centered very largely around Rule No. 313 which covers the use of metal belt lacing on belts shifted by hand. A number of representatives of the manufacturers of this material were present and after considerable discussion this rule was revised to read as follows:

Rule 313—Belt Fasteners

Belts which of necessity must be shifted by hand and belts within six (6) feet of the floor or working platform which are not guarded in accordance with the intent of this code shall not be fastened with metal in any case nor with any other fastening which by construction or wear will constitute an accident hazard.

The final revision of the text of this Code are now finished and it is before the Sectional Committee for vote. Copies, therefore, will soon be ready for distribution.

Safety Code for Elevators. Sullivan W. Jones, a representative of the A.I.A. on the Sectional Committee and now New York State Architect, was elected chairman of this Committee at the meeting it held on February 19, 1923. At this meeting an Executive Committee was appointed consisting of S. W. Jones, Chairman, O. P. Cummings, Vice-Chairman, J. A. Dickinson, Secretary, M. B. McLauthlin, C. H. Weeks, and K. A. Colahan.

After the Committee had increased its personnel by electing Byron Cummings and D. L. Lindquist as members at large, it turned its attention to the report of its Plan and Scope Committee, of which Bassett Jones was chairman. As the result of the discussion which followed the presentation of this report, the chairman was directed to appoint two Sub-Committees and to develop with the assistance of the Executive Committee a strong Advisory Committee. The first of these Sub-Committees is to be charged with the interpretation and revision of the Code. It will maintain contact with the various regulatory and other interested bodies for the purpose of answering specific questions about the Code, to issue special interpretations and to recommend such changes to Sub-Committee No. 2 which have been suggested by these regulatory bodies or others.

The task assigned to Sub-Committee No. 2 is fourfold; (*a*) to indicate the sections of the present A.S.M.E. Code which apply to existing installations; (*b*) to revise the present Code wherever necessary to cover completely new installations; (*c*) to draft a set of rules for operation and inspection; and (*d*) to compare existing rules of various states and cities so that the Sectional Committee shall at all times be thoroughly informed.

The Federated American Engineering Societies

Labor-Saving Machinery

At a meeting of the Committee on Procedure of the American Engineering Council, held on February 16, 1923, the advisability of making an intensive study of labor-saving devices was brought up for consideration. Walter S. Moody, of the General Electric Company, Pittsfield, Mass., who, in a communication addressed to President Cooley, first suggested such an investigation as a means of overcoming the present labor shortage in the United States, stated that in his opinion a large amount of labor now performed by hand could be accomplished by power-driven devices, thereby releasing great numbers of men for other and higher-grade work. He advocated a general survey of industry for the purpose of selecting kinds of work now done manually where machinery might be employed, followed by the coöperation of industries and suitable engineering organizations in the development of the necessary devices.

The Committee believed the matter to be of very great importance and after discussion voted that it be referred to The American Society of Mechanical Engineers to ascertain, first, if the A.S.M.E. considers such an investigation opportune and practical; and second, if that society will undertake the study or, in case it does not desire to do so, if it advises that the work be undertaken by American Engineering Council, and in what form.

Reforestation

Reforestation, involving such agricultural and industrial problems as soil conservation, flood control, and power development, is one of the projects now being studied by a special F.A.E.S. committee, in coöperation with the Government. The chairman of this committee, which was appointed to assist in developing a comprehensive constructive plan of reforestation, is Charles H. McDowell of Chicago; other members are S. H. McCrory, chief of the Division of Agricultural Engineering, U. S. Department of Agriculture. W. H. Hoyt, of Duluth, Minn., and J. C. Ralston, of Spokane, Wash.

Chief McCrory, in an announcement of the project issued recently through Dean M. E. Cooley, president of the Federation, stated that in the past land development and utilization has depended largely upon local initiative but that consideration must soon be given to the probable needs of the United States for crop, pasture, and forest lands. America's supply of timber, which has been decades in growing, is rapidly being exhausted. If timber is to be grown to replenish the supply, a considerable acreage must be permanently devoted to this purpose. He pointed out that the easily developed tillable land has nearly all been brought into use, and emphasized the need for the most effective utilization of undeveloped lands, clearing, draining or irrigating for crop and pasture land, or reserving for timber growth.

The committee believes it essential that mountainous regions such as the Appalachian area be kept timbered in order to minimize erosion. The watersheds of rivers must not be divested of timber, otherwise erosion will be rapid and power development retarded. The committee is supporting legislation for the establishment of a national hydraulic laboratory to study flood control.

Eyesight Conservation Council

A continuation of one phase of the work of the Committee on the Elimination of Waste in Industry is being conducted by the Eye Sight Conservation Council of America, which is directing a campaign to eliminate economic and physical losses due to poor eyesight in schools and factories, and to conserve vision. The Waste Report showed that poor eyesight among workers causes heavy annual economic losses. A similar condition exists in schools.

L. W. Wallace, executive secretary of the F.A.E.S. was reëlected president of the Eye Sight Conservation Council at its annual meeting, held in New York, February 5, and Guy A. Henry, of New York, was reëlected general director. Others recently appointed to the governing bodies of the Council are Secretary Davis, of the U. S. Department of Labor, and Prof. F. C. Caldwell of the Department of Electrical Engineering, Ohio State University. Among those serving on the Board of Directors and the Board of

Councilors are Prof. J. W. Roe, New York University, president of the Society of Industrial Engineers; Dr. Morton G. Lloyd, chief of the Safety Section of the U. S. Bureau of Standards and vice-president of the American Society of Safety Engineers; and G. E. Sanford, of West Lynn, Mass., past-president of the American Society of Safety Engineers.

The personnel of those assisting in the movement includes also representatives of the U. S. Department of Education, the U. S. Public Health Service, and numerous other engineering and educational bodies.

Passage of Bill for Reclassification of Governmental Positions and Salaries

ONE OF THE closing acts of the sixty-seventh Congress was the passage of the Sterling-Lehlbach Bill for the Reclassification of Governmental Positions and Salaries, H. R. 8928. As a means of maintaining a high standard of scientific and technical service of the Government, this bill has received the active support of the F.A.E.S. through its committees on patents and on reclassification and compensation of engineers. A delegation of engineers headed by Col. J. H. Finney, a member of the Patents Committee, was instrumental in securing its passage before Congress adjourned.

Although the law will not go into effect until July 1, 1924, it undoubtedly has an immediate benefit. High-grade professional men already in Government employ, with the definite salary increase before them, will feel that they can "stay by the ship," and others of similar type will be drawn into Government service, filling many vacancies which low salaries have caused. Until the law goes into effect the present basic rates of pay, plus the $240 bonus that has been paid for the last six years, will continue.

The bill as finally passed by the House carries revisions made by the Senate. In the Patent Office, for instance, primary examiners will receive $5040 instead of $4600. The enactment of the Lambert Patent Office Bill, early in 1922, prevented the complete collapse of the Patent Office; the salaries under the Sterling-Lehlbach law will attract for new appointments a high grade of men. In the course of time the whole examining corps will be raised in quality. The law will equally benefit all other professional and scientific branches of the Government.

Engineering organizations have done much to secure the passage of these two important bills. Engineers may be justly proud of their part in completing the task set before them. Such success should make them realize that they do have a strong national influence and should go a long way toward bringing about whatever seems to them just and wise.

Reorganization of Government Departments

THE OUTLINE of the plan for the reorganization of the executive departments of the U. S. Government as recommended by the President and the Cabinet at the request of the Joint Committee on Reorganization was recently placed in the hands of that committee for consideration. The outstanding recommendations are as follows:

I The coördination of the Military and Naval Establishments under a single Cabinet officer, as the Department of National Defense.

II The transfer of all non-military functions from the War and Navy Departments to civilian departments—chiefly Interior and Commerce.

III The elimination of all nonfiscal functions from the Treasury Department.

IV The establishment of one new department—the Department of Education and Welfare.

V The change of the name of the Post Office Department to Department of Communications.

VI The attachment to the several departments of all independent establishments except those which perform quasi-judicial functions or act as service agencies for all departments.

The suggested changes of particular interest to engineers are found in the Department of the Interior and Commerce. The Interior Department is given two major functions: the administration of the public domain and the construction and maintenance of public works. The subdivisions of the department are grouped accordingly under two assistant secretaries. The Bureau of Mines and the Patent Office are transferred to the Department of Commerce, and the non-military engineering activities of the War Department, the Supervising Architect's Office of the Treasury Department, the Bureau of Public Roads of the Department of Agriculture, and the Federal Power Commission, an independent establishment, are all transferred to the Department of the Interior.

The three major functions given to the Department of Commerce are the promotion of industry, the promotion of trade, and the development, regulation, and protection of the merchant marine, each division under an assistant secretary. In addition to the transfer of the Bureau of Mines and the Patent Office from the Department of the Interior, the Department of Commerce is given the Lake Survey, the Inland and Coastwise Waterways Service, the supervision of New York Harbor, the Hydrographic Office and the Naval Observatory, and the Life Saving Service.

While this plan does not provide for the establishment of a National Department of Public Works, which has been advocated by engineering organizations, the proposed transfers have in view the same object, that of bringing together related activities. The outline has been studied in detail by the Federation's Committee on Government Reorganization as it Relates to Engineering Matters, of which J. Parke Channing, New York, is chairman, and was reported upon to the Executive Board, at its meeting in Cincinnati, March 23–24, 1923.

Discussion on Effect of Pulsations on Flow of Gases

(Continued from page 229)

perhaps nearly eliminated, by the use of the proper amount of throttling observing at the same time that equal spaces were provided at the manometer connections for varying quantities of flow. They concluded that it was an extremely doubtful and uncertain method, if not wholly dangerous, to rely too fully on such expedients for reducing the pulsating error.

The question raised in regard to the relative effect of the pulsation on the static pressure was answered, the authors believed, in the reply to Mr. Packard.

The authors agreed with Mr. Hodgson and Mr. Packard that the velocity of propagation of the pulsating wave approached that of sound in the flowing fluid plus the velocity of the flowing air. However, in their opinion, as based on their experiments they were not willing to concede that the pressure pulsation had a less effect than the velocity pulsation in meter installations where these pulsations acted on manometers with static connections at right angles and even with the inside of the pipe. From the "dead-end" flow experiments it would also seem evident that the pressure pulsation effect was many times greater than that due to the velocity pulsation.

The statement was made by Mr. Hodgson that the simplest way of reducing the pulsation by the use of a capacity combined with throttling was not mentioned by the authors. In conclusion they had stated that the "muffler" device, a combination of capacity, or volume, with throttling was probably "the most effective device for the mechanical elimination of pulsations." The capacity or "muffler" was always inserted between the disturbing element and the meter. It would not seem advisable in their opinion, to insert the throttling device in the line below the meter. It would seem better to eliminate the pulsations as far as possible before the meter was reached.

The authors regretted that Mr. Hodgson's paper containing his latest investigations involving the development of a formula for pulsating flow had not been available for examination and study until after their paper was written. Mr. Hodgson was to be congratulated in being able to reduce the results of his researches to a working formula which showed the factors involved in their proper relation. They were in full accord with his opinion that the only sure way to meter pulsating flow was to reduce the pulsations by means of suitable capacity and throttling, and they likewise believed that even the formula proposed, or any similar formula, while serving in a general way could not be too rigidly applied in practice. Each installation would present its own peculiar problem.

Meetings of Other Societies

American Institute of Mining and Metallurgical Engineers

The 127th meeting of the American Institute of Mining and Metallurgical Engineers was held in New York, February 19–22, 1923. So valuable was each of its sessions to the group of engineers interested in the particular problem with which it dealt, that no session can be called outstanding.

The opening technical session on Monday morning was on the subject of ground movement and subsidence, which has received comparatively little treatment during recent years. Much interest was evidenced in the papers presented and the session was continued in the afternoon.

A meeting for the organization of a Division on Petroleum and Gas was held on the morning of the first day of the convention and three entire sessions were devoted to symposiums on this subject. Twenty-three papers covered oil developments throughout the world during 1922, and six papers dealt with miscellaneous oil-development problems.

Based upon replies to questionnaires sent out to a large number of mining companies during 1922, a number of papers on mining methods were presented at four mining sessions, one of which was devoted entirely to coal.

Two iron and steel sessions were held. At the first the A.S.T.M. Tentative Specifications for Foundry Pig Iron were presented and the discussion led by Dr. Richard Moldenke, Watchung, N. J. Dr. Moldenke is chairman of the A.S.T.M. Committee on Cast Iron, at whose request the specifications were presented at the Institute meeting. The specifications were thought to be liberal in character and were favorably received.

At the same session Norman B. Pilling, Research Department, Westinghouse Elec. & Mfg. Co., gave an illustrated talk on Low-Temperature Brittleness in Silicon Steels. He stated that temporary ductility may be obtained by carrying on cutting or deformational operations at temperatures slightly above atmospheric, the temperature depending on the steel composition, and that brittleness is only slightly modified by heat treatment.

Speaking at the second session on iron and steel, W. R. Bean, Naugatuck, Conn., stated that the deterioration of malleable in the hot-dip galvanizing process is intimately connected with the phosphorus and silicon contents of the iron. In general, low-phosphorus (under 0.15 per cent), low-silicon (under 0.80 per cent) iron will withstand the process best and show practically no deterioration. High-phosphorus, high-silicon irons are practically certain to deteriorate and be embrittled by galvanizing. A second paper at this session, dealing with the influence of temperature, time, and rate of cooling on physical properties of carbon steel, gave the results of an investigation of the heat treatment of carbon steels carried out under the auspices of the Committee on this subject of the Engineering Division of the National Research Council.

There was also a joint session on iron and steel and coal and coke, at which blast-furnace cokes and coke ovens were considered.

Joint sessions were held with the Industrial Relations Committee and Mining Section of the National Safety Council, at which hoisting ropes and mine-fire prevention were the main subjects considered. An interesting paper on Non-Destructive Testing of Steel Hoisting Rope by Raymond L. Sanford, physicist of the National Bureau of Standards, was presented and discussed. It outlined work soon to be undertaken by that bureau to develop if possible suitable magnetic methods of testing steel hoisting ropes.

Technical education was discussed at a joint meeting with the Mining and Metallurgical Society of America. One of the papers was by E. P. Mathewson, consulting metallurgist of New York and incoming president of the Institute, who gave his opinions on training engineering students, based upon his contact during thirty-five years with graduates of engineering schools all over the world.

Mechanical engineers will be chiefly interested in the papers presented under the auspices of the Institute of Metals Division. Dr. Walter Rosenhain, head of the metallurgical department of the National Physical Laboratory at Teddington, England, delivered the second annual Institute of Metals lecture, on the subject of Solid Solutions, to a large audience on February 19. The high quality of Dr. Rosenhain's lectures has been appreciated by many in this country who have heard him during recent months at various technical and educational institutions. It was announced that Dr. Zay Jeffries will deliver the lecture next year.

The Nature of Solid Solutions was the title of a paper by Edgar C. Bain, of the General Electric Company, Cleveland, Ohio. E. H. Dix, Jr., described methods of polishing aluminum and its alloys for metallographic study as employed in the metallurgical laboratory of the Engineering Division of the U. S. Air Service, McCook Field, where he is chief of the Metals Branch. Junius D. Edwards, assistant director of research, Aluminum Company of America, spoke on the thermal properties of aluminum-silicon alloys, dealing with the accurate determination of densities of aluminum alloys containing variable amounts of silicon and presenting data on crystallization shrinkage, total solid shrinkage, and the tendency to form pipe.

Christopher H. Bierbaum, vice-president of the Lumen Bearing Company, Buffalo, N. Y., in an address on bearing metals, described an instrument developed for use in determining the relative hardness of individual crystals in the bearing metal and the journal.

Among the other papers was one on tests on high-tin bearing metals, including remarks on the chemical composition and microstructure of suitable alloys, directions for casting in bronze shells, and data on tests of commercial alloys for hardness, compressive strength, and coefficient of friction; a paper on the thermal conductivity of some industrial alloys; and one on the bright annealing of copper wire.

At the annual dinner of the Institute, at which Prince Gelasio Gaetani, the Italian ambassador, was guest of honor, the James Douglas medal was awarded to Frederick Laist, manager of the reduction plant of the Anaconda Copper Mining Co., Butte, Mont., for achievements in non-ferrous metallurgy.

E. P. Mathewson was elected president of the Institute to succeed Col. Arthur S. Dwight.

American Institute of Electrical Engineers

Out of the unusually large number of technical papers presented at the Eleventh Midwinter Convention of the American Institute of Electrical Engineers, held in New York, February 14–17, 1923, are several which are of interest to mechanical engineers. E. J. Blake, electrical engineer for Gould Coupler Co., Depew, N. Y., reviewed the circumstances which have made train control an acknowledged problem and stated the characteristics desired in automatic train-control devices. Automatic control, he believed, should act as a check on manual control, not as a substitute. It should conform to established safe signaling practices, should be designed for the severe conditions of railway operation, should not conflict with existing signals or otherwise introduce new hazards, should so far as possible conform to existing clearance lines and should not impede traffic. Methods of transmitting and indication of track conditions to the train which he described were (1) by intermittent mechanical and electric contact; (2) by intermittent induction through the use of permanent or electromagnets; and (3) by continuous induction from the rails. Relations between the type of controlling action and traffic capacity were also discussed by Mr. Blake.

Applications and Limitations of Thermocouples for Measuring Temperatures was the subject of an address by Irving B. Smith, Research Department, Leeds & Northrup Co., Philadelphia, Pa. He classified temperature measurements under the heads of feed-water, boiler water, economizer, flue gas, superheated steam, bearings, generator windings, transformer windings, and cables. The sources of error that may arise in making temperature measurements with the thermocouple were outlined as residing in thermocouple calibration, instrument calibration, thermocouple circuit, radiation losses, conduction losses, parasitic e.m.f., temperature lag, cold-junction temperature, measured temperature variable, and measured temperature not representative. Mr. Smith considered these classifications and sources of error in detail.

At the same session J. W. Legg, consulting engineer for Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa., presented a paper

on the Expansion of Oscillography by Portable Instrument, describing fully the oscillograph in its redesigned form and discussing its possibilities. The new instrument has been constructed along the same general principles as the early portable oscillograph, but has been reduced in bulk about fifty per cent and considerably improved. It is complete in one unit and is designed to operate from any standard 6-volt storage battery.

A feature of the meeting which aroused great interest was the joint session with Chicago on the evening of February 14, made possible by two-way loud-speaking telephone installations. The proceedings of the meeting were also broadcast. Speakers on the use of public-address systems with telephone lines discussed the various applications of this novel combination, stated requirements for the lines, showed the circuit arrangements used, and described some of the important operating features. The application of the public-address-system apparatus and methods to radio broadcasting were also briefly discussed.

Inspection trips to the McGraw-Hill Company, the Pennsylvania Exchange of the New York Telephone Company, the Bell System Research Laboratories, and the A.T. & T. Broadcasting Station were made during the convention.

American Society of Heating and Ventilating Engineers

Following a business session in New York on January 23, the American Society of Heating and Ventilating Engineers held the first technical session of its twenty-ninth annual meeting at the Bureau of Standards in Washington, January 24. The morning was devoted to Bureau of Standards papers on subjects of great importance to heating and ventilating engineers, which were based on current research in the laboratories of the Bureau; the afternoon was given over to an inspection of the laboratories and an explanation of the methods of investigation. The papers presented were Heat Transmission of Building Structures, by M. S. Van Dusen; The Testing of Anemometers, by O. J. Hodge; and Tests of Radiator Return Line Valves, by W. F. Stutz. S. H. Ingberg gave a talk on Fire Tests of Structural Materials.

On January 25 a research session was held at the Bureau of Standards at which F. Paul Anderson spoke on The Research Laboratory, and papers on the physiological reactions of humans to high temperatures and high humidities, equal-comfort lines for still-air conditions, the capacities of steam-heating risers as affected by critical velocities of steam and condensate mixtures, and the Anderson and Armspach dust determinator were presented. The latter paper included information on results obtained in a series of tests upon the dust determinator, as well as a description of the apparatus.

The other sessions of the meeting were held at the Hotel Washington on January 24 and 26. At the first, M. S. Cooley of the Bureau of Yards and Docks, told how the new gun shop at the U. S. Navy Yard is heated, describing in detail the hot-blast system which is provided with fans and heaters in roof spaces and distributing ducts alongside of columns. C. R. Denmark, engineer at the Smithsonian Institution, gave details of the forced hot-water circulation and air-exhaust systems in the Natural History Building, of the U. S. National Museum. Nelson S. Thompson, chief mechanical and electrical engineer, Office of Supervising Architect, U. S. Treasury Department, pointed out the simplicity of the heating and ventilating systems installed at the Bureau of Engraving and Printing.

Heating and ventilating sessions were held on the closing day of the convention, at which a number of interesting papers and reports were heard. F. B. Rowley, professor of mechanical engineering at the University of Minnesota, gave a report of tests of five distinct types of roof ventilators and described the method and apparatus used in making the tests. Dr. George T. Palmer, of the Michigan Department of Health, outlined ventilation practice since 1850 and indicated what developments may be expected in the near future. H. L. Dryden discussed wind-tunnel tests of roof ventilators.

The program included various sight-seeing and inspection trips to the many beautiful institutions which are to be found both in and around Washington.

LIBRARY NOTES AND BOOK REVIEWS

Analytic Geometry. By Clyde E. Love. Macmillan Co., New York, 1923. Cloth, 5 × 8 in., 306 pp., $2.25.

A textbook for beginners, covering the elements of plane and solid analytic geometry. The emphasis is placed on geometry rather than on analysis to a greater extent than usual, and the course is intended to give the student, first, a knowledge of simple fundamental methods, and then to extend, adapt, and generalize these as need arises.

Comparison of British and American Foundry Practice. By P. G. H. Boswell. University Press of Liverpool, Liverpool; Hodder & Stoughton, London, 1922. Paper, 6 × 9 in., 106 pp., illus., diagrams, tables, 4s. 6d.

The author of this work was sent to the United States in 1918 by the British Ministry of Munitions of War, to investigate American foundry practice, particularly as regards the use of sands for steel molding. For this purpose he visited the principal iron, steel, and brass foundries, the quarries and other sources of refractories, and research laboratories. His report discusses the casting of metals, desiderata in molding sands, the molding-sands used in America, bonding of molding sands and silica sands for furnace hearths. British and American methods are compared. Tables give chemical and mechanical analyses and the mineralogical composition of a number of American and European sands.

Construction and Exploitation des Grandes Réseaux de Transport D'Energie Électrique a Trés Haute Tension. Proceedings of the International Conference held in Paris November 21–26, 1921. L'Union des Syndicate de L'Electricite, Paris, 1922. Cloth, 7 × 10 in., 1176 pp., illus., diagrams, 100 fr.

The reports of this conference are now available in a well-printed volume of nearly twelve hundred pages containing a review of its organization and purpose, a general report of its activities, and the text of the sixty-eight reports presented before it. These reports include summaries of the legislation pertaining to high-tension transmission in various countries, descriptions of existing systems and projects, papers upon various topics connected with current production and transformation, the construction of high-tension lines, and the exploitation, protection, and safeguarding of transmission systems. The conference was attended by delegates from twelve countries. The papers and discussions give a wide survey of the present status of high-tension transmission.

Descriptive Geometry. By Lawrence E. Cutter. First edition. McGraw-Hill Book Co., London and New York, 1923. Cloth, 6 × 9 in., 244 pp., diagrams, $2.50.

In descriptive geometry there are two general methods of applying its fundamental principles: one, the method of rotation; the other, the method of choosing new projection planes. The present book is the first, the author states, prepared on the latter plan, which he considers superior in utility to the first plan, and equally good in point of mental discipline.

In it theory has been reduced to four simple principles, covering one page of the text. The use of these is illustrated through the detailed solution of problems from the fields of civil, mechanical, and mining engineering, and of architecture. Original exercises for solution are given.

Diesel Engine. By A. Orton. Isaac Pitman & Sons, London and New York, 1923. (Pitman's Technical Primers.) Cloth, 4 × 6 in., 111 pp., diagrams, tables, $0.85.

The aim of this book is to act as an introduction for those intending to study the subject thoroughly, and also to serve as a broad but fairly complete treatment for those who seek just sufficient

knowledge to understand and apprehend the principles of working, construction, and operation. The author has endeavored to treat the subject in the simplest possible manner, without omitting anything of vital importance. A bibliography, confined to British publications, is included.

Optical Methods in Control and Research Laboratories. By J. N. Goldsmith and others. Vol. 1, Second edition. Adam Hilger, London, 1923. Limp cloth, 6 × 10 in., 56 pp. illus., 1s 6d.

The optical methods here dealt with are those employing spectroscopes, spectrophotometers, refractometers and polarimeters. The book is intended to provide the works chemist with a guide to the selection of these instruments, an introduction to their use in metallurgy and analytical chemistry and an index to sources of further information concerning their use in research and control laboratories. The book is confined to these indications of the usefulness of these instruments, and does not include detailed descriptions of their design or their techniques; for information on these points, references are given to other publications.

Principles and Practice of Toothed Gear Wheel Cutting. By George W. Burley. Scott, Greenwood & Son, London; D. Van Nostrand Co., New York, 1922. Cloth, 6 × 9 in., 460 pp., illus., diagrams, tables, $8.

This book deals with the fundamental principles of all the several descriptions of toothed-wheel gearing now in use; the measurement of toothed-wheel gears, generating and non-generating methods for forming gear-wheel teeth mechanically, and the machines and tools that apply these methods. An attempt is made to treat both the theoretical and practical side of the subject.

The book is intended for students of engineering, apprentices, and machinists. The subject is not dealt with from the viewpoint of the designer.

Scientific Management. By Horace Bookwalter Drury. Third edition. Columbia University, New York, 1922. (Studies in history, economics and public law). Cloth, 6 × 9 in., 271 pp., $2.75.

Dr. Drury's account of the development of scientific management appeared originally in 1915. In 1918 a revised edition appeared which corrected the errors of the original edition and extended the account down to the latter date. The present edition is substantially a reprint of the 1918 edition, with a long introduction in which later tendencies and the present situation are described.

The volume is divided into two sections, historical and critical. The historical section gives an account of the genesis of scientific management, of the leaders in its development and of the trades and plants that adopted it. The critical section discusses its effect on productivity, on the labor problem and on the worker.

Steam Power. By C. F. Hirshfeld and T. C. Ulbricht. Second edition. John Wiley & Sons, New York; Chapman & Hall, London, 1922. Cloth, 5 × 8 in., 474 pp., illus., diagrams, $3.25.

In preparing this textbook the authors have attempted to collect in a comparatively small book such parts of the field of steam power as should be familiar to engineers whose work does not require that they be conversant with the more complicated thermodynamic principles considered in advanced treatises. They have therefore eliminated mathematical treatment as far as possible, and confined themselves to giving a correct viewpoint with regard to the use of heat in the power plant, to supplying what is required to solve common power-plant problems and to describing the more common types of apparatus.

Treatise on the Theory of Bessel Functions. By G. N. Watson. University Press, Cambridge, 1922. Cloth, 7 × 11 in., 804 pp., tables, $16.

The author states that this book has been designed with two objects in view. The first is the development of applications of the fundamental processes of the theory of functions of complex variables, for which purpose Bessel functions are admirably adapted. The second is the compilation of a collection of results which would be of value to the increasing number of mathematicians and physicists who encounter Bessel functions in the course of their researches. Such a collection seems to be demanded by the greater abstruseness of properties of Bessel functions which have been required in recent years in various problems of mathematical physics.

While the endeavor has been made to give an account of the theory of Bessel functions which a pure mathematician would regard as fairly complete, the author consequently has also endeavored to include all formulas which, although without theoretical interest, are likely to be required in practical applications. A very full bibliography is included.

Twelve-Hour Shift in Industry. By Federated American Engineering Societies. Committee on Work-Periods in Continuous Industry. E. P. Dutton & Co., New York, 1922. Cloth, 6 × 8 in., 302 pp., tables, $3.50.

The investigations reported upon in this volume were undertaken by the Federated American Engineering Societies in 1921. The objects were to ascertain the extent of two-shift work in continuous-process industries other than the manufacture of iron and steel, the experience of manufacturers who had changed from two-shift operation to some other system, and to study the technical aspects of changing from the two-shift to the three-shift system in the iron and steel industry.

This volume includes a report on the first two points prepared by Dr. Horace B. Drury and one on the third point by Mr. Bradley Stoughton, as well as a brief general summary of the conclusion to be drawn from their studies. These are favorable to the two-shift system.

Vector Calculus, with Applications to Physics. By James Byrnie Shaw. D. Van Nostrand Co., New York. Cloth, 5 × 8 in., 314 pp. $3.50.

Embodies the author's lectures to graduate students. The attempt has been to give a text to the mathematical student on the one hand, in which every physical term beyond mere elementary terms is carefully defined. On the other hand, for the physical student there is a large collection of examples and exercises which will show him the utility of the mathematical methods. The system adopted is algebraic.

New Revisions of A.S.M.E. Boiler Code, 1923

(Continued from page 263)

Part II

The following action was taken on this section:

Voted: That Part II, on Existing Installations, be placed in the Appendix as suggested rules for the old boilers.

Revisions on Locomotive Boiler Code

L-53 Revised:

L-53 All holes in braces, lugs and sheets for rivets or staybolts shall be drilled, or they may be punched, at least 1/8 in. less than full diameter for material not more than 5/16 in. thick, and at least 1/4 in. less than full diameter for material more than 5/16 in. thick.

Such holes shall not be punched in material more than 5/8 in. thick.

For finishing the rivet holes, the plates, butt straps, braces, heads and lugs shall be firmly bolted in position by tack bolts, for final drilling or reaming to full diameter.

The finished holes must be true, clean and concentric.

L-62 Revised:

L-62 Each safety valve shall be plainly marked by the manufacturer in such a way that the markings will not be obliterated in service. The markings may be stamped on the casing [body], cast on the casing [body], or stamped or cast on a plate or plates permanently secured to the casing (body), and shall contain the following:

a The name or identifying trademark of the manufacturer

b The nominal diameter

c The steam pressure at which it is set to blow

[*d* Blow down, or difference between the opening and closing pressures]

d [*e*] The weight of steam discharged in pounds per hour at a pressure 3 per cent higher than that for which the valve is set to blow

e [*f*] A.S.M.E. Std.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 111-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AIRPLANES

Bristol. The Bristol 3-Seater Airplane. Aerial Age, vol. 16, no. 3, Mar. 1923, pp. 140–141, 2 figs. Taxiplane designed to compete economically with road transport. See also Aviation, vol. 14, no. 10, Mar. 5, 1923, p. 273, 2 figs.

Sailplanes. The Development of the Hannover Sailplane, Georg H. Madelung. Soc. Automotive Engrs.—Jl., vol. 12, no. 1, Jan. 1923, pp. 77–85, 15 figs. Difference between airplane-racer and sailplane problems; features of early gliders; analysis of rate of descent; section and best-chord determination; why it was not advisable to build biplane; form and arrangement of body; model test; constructional details; torque; static tests and safety factor.

ALLOY STEELS

Heat Treatment. The Heat Treatment of Alloy Steels, R. R. Moore and E. V. Schaal. Forging & Heat Treating, vol. 9, no. 2, Feb. 1923, pp. 113–121, 40 figs. Effect of heat treatment upon metallographic and physical characteristics of chrome-nickel, chrome-vanadium and chrome-molybdenum steels; results obtained at various drawing temperatures.

AVIATION

Experimental Work, Bureau of Standards. Aviation Work of the Bureau of Standards, Fay C. Brown. Aerial Age, vol. 16, no. 3, Mar. 1923, pp. 115–119, 5 figs. Work is for most part in coöperation with Army & Navy Air Service and Nat. Advisory Committee for Aeronautics; deals with aircraft structure and instruments, power plants and radiators; the aeronautical safety code.

BEARINGS, ROLLER

Spherical. Advantages of the Spherical Type Roller Bearing, H. E. Brunner. Ry. Age, vol. 74, no. 9, Mar. 3, 1923, pp. 517–519, 3 figs. New design which combines self-alignment, low frictional resistance and high capacity.

BOILER FEEDWATER

De-Aeration, Closed-Feed. A New Closed Feed System. Engineer, vol. 135, no. 3502, Feb. 9, 1923, pp. 155–156, 5 figs. System developed by Hick, Hargreaves & Co., consists of feed piping and auxiliaries which are arranged so that only de-aerated water is supplied to economizers and boilers.

BOILER FURNACES

Design for Drying Fuel. Furnace Design for Effective Drying, Zuce Kogan. Power Plant Eng., vol. 27, no. 5, Mar. 1, 1923, pp. 265–268, 8 figs. Special arrangements of grates and arches are essential for drying fuel with high-moisture content in boiler furnace.

BOILERS

Atmos. Superpressure. Swedish Boiler Operates at Pressure of 1500 Pounds, Edvin Lundgren. Power, vol. 57, no. 7, Feb. 13, 1923, pp. 238–241, 5 figs. Among features of Atmos. boiler, designed by J. V. Blomquist, are steam generation from centrifugally formed shells of water in rotating tubes of 12 in. diam. and evaporation of 60 lb. of water per hr. per sq. ft. of steam-making surface.

DIE CASTINGS

Metals for. Metals Used for Die-castings, A. G. Carman. Machy. (N. Y.), vol. 29, no. 7, Mar. 1923, pp. 516–518, 1 fig. Babbitts, zinc-base metals and aluminum alloys for die castings; specifications giving limits of weight and accuracy for die castings made from different metals.

DIES

Built-up. Advantages of Built-up Die Construction, C. E. Stevens. Machy. (N. Y.), vol. 29, no. 7, Mar. 1923, pp. 528–530, 5 figs. Points to be considered in designing dies, which have been incorporated in set of dies for producing rheostat base herein described.

EVAPORATION

Compression, Method of. Evaporation by Compression, Wilhelm Gensecke. Chem. & Met. Eng., vol. 28, no. 10, Mar. 7, 1923, pp. 448–456, 15 figs. Process now in operation in several important industrial plants in Europe, where it has proved a valuable factor in heat economy; also close study of heat consumption usually calculated in sugar industry.

FLOW OF FLUIDS

Thin Slits. Leakage Through Thin Clearance Spaces, Edgar Buckingham. Engineering, vol. 115, no. 2982, Feb. 23, 1923, pp. 225–227, 1 fig. Results of experiments on slits of rectangular section by Frank F. Fergusson; notes on stream-line flow; change to turbulent flow; comparison of rectangular with annular slits; equations for computing resistance of thin, smooth, annular channels. Published by permission of U. S. Bur. of Standards.

FORGING

Flow of Metal During. The Flow of Metal During Forging, Harold F. Massey. Forging & Heat Treating, vol. 9, nos. 1 and 2, Jan. and Feb. 1923, pp. 25–30 and 122–127, 33 figs. Discussion of flow of metal when forged in hot state; special emphasis given to relation existing between action of forging by press and hammer. Paper read before Manchester Assn. Engrs.

GRINDING

Centerless. The Production of Small Parts by Centerless Grinding, Howard Campbell. Am. Mach., vol. 58, no. 10, Mar. 8, 1923, pp. 357–359, 10 figs. Examples of centerless grinding, together with figures on production; methods of handling odd work; grinding tungsten bars.

INDUSTRIAL MANAGEMENT

Engineering Department. The Successful Operation of an Engineering Department, W. E. Irish. Indus. Management (N. Y.), vol. 65, no. 3, Mar. 1923, pp. 136–141. Discussion of actual operation of department organized on principle described in previous articles.

Production Planning. How Production Planning Cuts Costs, H. S. Owen. Indus. Management (N. Y.), vol. 65, no. 3, Mar. 1923, pp. 182–187, 13 figs. Describes system of planning which, in actual operation, has produced very profitable results.

INTERNAL-COMBUSTION ENGINES

Explosion Tests. Internal Combustion Heat Losses and Specific Heat of Working Fluid, Wm. J. Walker. Engineer, vol. 135, no. 3504, Feb. 23, 1923, pp. 191–192, 1 fig. Discusses extent of transparency of combustion products of normal mixture to its own radiated heat; test determinations of values of specific heats at constant pressure and volume.

IRON CASTINGS

Annealing. Effect of Annealing Gray Iron, J. F. Harper and P. S. MacPherran. Foundry, vol. 51, no. 5, Mar. 1, 1923, pp. 176–180, 11 figs. Test bars heated at different temperatures for various lengths of time show changes in strength and hardness caused by annealing; results charted and micrographs shown. Paper before Am. Foundrymen's Assn.

Softening Gray Iron by Annealing, E. Piwowarsky. Forging & Heat Treating, vol. 9, no. 2, Feb. 1923, pp. 127–129, 1 fig. Object and theory of annealing of cast iron; experiments to soften by annealing; most certain method to accomplish this end. Translated from Stahl u. Eisen, Sept. 28, 1922.

LABORATORIES

Hydraulic Testing. A Well-Designed Hydraulic Testing Laboratory, John S. Carpenter. Power, vol. 57, no. 9, Feb. 27, 1923, pp. 331–332, 5 figs. Describes public testing flume built by Holyoke Water Power Co. at Holyoke, Mass.; laboratory equipment.

LOCOMOTIVES

Mikado. Most Powerful Mikados on the Lackawanna Railroad. Ry. Rev., vol 72, no. 7, Feb. 17, 1923, pp. 279–285, 10 figs. partly on supp. plate. Latest Mikado-type locomotives develop 79,200 lb. tractive effort. See also Ry. Age, vol. 74, no. 9, Mar. 3, 1923, pp. 510–513, 2 figs.

Pacific and Mikado. Locomotives for Brazilian Centennial Exhibition. Ry. Age, vol 74, no. 8, Feb. 24, 1923, pp. 467–468, 3 figs. Two Pacifics and a Mikado displayed by Am. Locomotive Co.

Superheater. Southern Railway—Three-Cylinder Simple Superheater Locomotive. Engineer, vol. 135, no. 3504, Feb. 23, 1923, pp. 200–201, 3 figs. 2-6-0-type engines, built at Ashford works to design of R. E. L. Maunsell. See also Ry. Gaz., vol. 38, no. 8, Feb. 23, 1923, pp. 282–283, 3 figs.

MEASURING INSTRUMENTS

Small Motions. Precision Measuring Instrument for Small Motions of Solid Bodies, H. A. Thomas. Engineer, vol. 135, no. 3502, Feb. 9, 1923, pp. 138–140, 12 figs. Apparatus consists essentially of high-frequency electrical oscillator in which amplitude of oscillation is varied by motion of body under observation.

MOTOR TRUCKS

American Specifications. American Trucks Approach Standard Design in Major Features. Automotive Industries, vol. 48, no. 8, Feb. 22, 1923, pp. 402–419, 6 figs. Specifications indicate only slight changes over last two years. Specifications for gasoline trucks and motor buses.

Axle, Triple Reduction. Triple Reduction Features New 5-Ton L M Truck Axle. Automotive Industries, vol. 48, no. 9, Mar. 1, 1923, pp. 518–519, 2 figs. Said to be more compact than one of double-reduction type with same ratio; differential placed on highest-speed shaft where stresses are lowest; first and third reductions by spur gears, second by bevels.

OIL ENGINES

Heavy Oil Engines, Evolution of. The Evolution of the Heavy Oil Engine, R. E. Mathot. Engineer, vol. 135, no. 3502, Feb. 9, 1923, pp. 137–138. Comparison of four-stroke explosion motors with Diesel engines operating on same cycle. Points out advantages of moderate pressures applied to engines without use of compressed air for fuel pulverization.

OPEN-HEARTH FURNACES

Krupp Plant. Krupps Build New Open Hearths. Iron Trade Rev., vol. 72, no. 9, Mar. 1, 1923, pp. 661–663, 4 figs. Plant started during war and recently remodeled one of most complete in Europe; cold-metal process used now, but provisions are made for molten-metal process in future.

PUMPS, CENTRIFUGAL

Extraction. A New Condenser Extraction Pump. Engineer, vol. 135, no. 3502, Feb. 9, 1923, p. 152, 2 figs. New type of high-vacuum centrifugal extraction pump placed on market by Mirrlees Watson Co., which will form one of integral units of Mirrlees closed-feed system; chief feature is elimination of all air leakage. Acceptance for mailing at special rate of postage provided for in section 1103, Act of October 3, 1917, authorized on January 17, 1921.

Contributors and Contributions

The Cross-Flow Impulse Turbine

Forrest Nagler

The advancement of civilization has followed closely on the perfection of prime movers. The first prime mover was a water wheel of the impulse type. Forrest Nagler's paper in this issue describes a new type of water wheel for high heads which departs radically in principle from present practice. Mr. Nagler received his B.S. in mechanical engineering from the University of Michigan in 1906 and since his graduation has been with the Allis-Chalmers Manufacturing Co. In his work on axial-flow hydraulic-turbine runners he has developed a suction type of high-speed, low-head runner which holds several world records for capacity. Life Membership in the A.S.M.E. was awarded him in 1919 for his paper describing this work.

Lignite Char

O. P. Hood, chief mechanical engineer of the U. S. Bureau of Mines and in charge of the Bureau's fuel investigations, discusses the handicaps and possibilities of lignite char as fuel. Before assuming his present position in 1911 Mr. Hood spent twelve years in the engineering department at Kansas State Agricultural College, and from 1898 to 1911 he was professor of mechanical and electrical engineering at the Michigan College of Mines. He holds degrees from Rose Polytechnic Institute.

Aluminum Bronze as an Engineering Material

W. M. Corse, chairman of the Division of Research Extension of the National Research Council, was graduated from the Massachusetts Institute of Technology with the degree of B.S. in 1899. He went to work immediately as a chemist and has specialized in the manufacture of non-ferrous alloys, principally brass and bronze. He has worked for the Detroit White Lead Works, the Detroit Lubricator Co., Titanium Bronze Co., the Ohio Brass Co., and the Monel Metals Products Company. At present he is consulting engineer for the International Nickel Co. and the Buffalo Bronze Die Case Corporation.

High-Temperature and High-Pressure Steam Lines

A paper giving available data and formulas on radiation and friction losses in pipe lines is presented by B. N. Broido, consulting engineer with the Superheater Co. Mr. Broido was born in Russia and educated in Germany. His early work on superheaters was done in Germany with the Seiffert Co. and the Egestorf Machine Manufacturing Co. In 1914 he came to this country where he took post-graduate work in New York City. Before assuming his present position Mr. Broido did designing work for the Roessler & Hasslacher Chemical Co. and the Philadelphia and Reading Railway Co. He has filed over forty patent applications.

Refinery and Rolling Mill for Monel Metal

Economic problems involved in selecting a site for a mill for rolling monel metal and facts leading to their solution are given by W. L. Wotherspoon in a paper describing such a mill at Huntington, West Va. Mr. Wotherspoon is of English birth and received his training at large engineering works in England and South Africa, where he was a member of the consulting staff of the Central Mining and Investment Corporation of Johannesburg. In 1912 he came to New York where he has been executive engineer in charge of engineering and construction work for the International Nickel Co.

Management Engineering in Paper Industry

R. B. Wolf is president of The R. B. Wolf Co., of New York City, an organization specializing in the design, construction, and operation of pulp and paper mills. He was graduated from Delaware College in 1896 as an electrical engineer, but two months after his graduation he determined to enter the paper business. Beginning as a "workman" he has worked in practically every department of a paper mill. He resigned his position as manager of the Spanish River Pulp and Paper Mills during the war to become staff assistant to vice-president Piez of the Emergency Fleet Corporation.

The Oil Venturi Meter

The measurement of the flow of viscous fluids is discussed in this issue by E. S. Smith, Jr., of the California National Supply Co. of Los Angeles. Mr. Smith, who is a graduate of the University of California, class of 1919, has done special research work at the University, and for two years was an engineer testing venturi and orifice meters at the Standard Oil Company's refinery at Richmond.

Boiler-Furnace Design

Edwin B. Ricketts, assistant to the chief operating engineer of the New York Edison Co., contributes a paper on boiler-furnace design to this issue. Mr. Ricketts received the degree of B.S. from Millsaps College in Mississippi in 1901. He has been employed by various iron and steel works throughout the country, and previous to his last connection with the N. Y. Edison Company he designed and built a glass-manufacturing plant for the United States Glass Co. of Pittsburgh.

A.S.M.E. Spring Meeting

Montreal, May 28-31

The interesting technical program and many points of excursion interest bid fair to make the coming Spring Meeting the most popular of any recent Spring Meetings of the Society.

There will be sessions on Hydroelectric Power, Management, Port Development, Railroads, Textiles, Fuels and Machine-Shop Practice.

Complete particulars of the final program are given in the April 22 issue of the A.S.M.E. News.

MECHANICAL ENGINEERING

The Cross-Flow Impulse Turbine

Particulars Regarding a New Type of Water Wheel Designed for Use with High Heads

By FORREST NAGLER,[1] MILWAUKEE, WIS.

THE ORIGIN of the first prime mover is lost in antiquity, but we are able to state with practical certainty that it was an impulse-type water wheel; more specifically, that it was of the impact type, a current wheel with flat paddles, but an impulse wheel nevertheless. Written descriptions of these wheels date back nearly 2000 years, and current wheels, modified possibly to a slight extent in the direction of breast wheels, are probably several times that old.

It is with the history of this type of prime mover, its modification to date, its present state of development and possible improvement that this paper is to deal.

The term "impulse" is commonly used with those wheels in which water is applied to the rotating element in a free jet with all its energy in the form of velocity. It will be so used here although the term is somewhat of a misnomer as modern impulse wheels develop power as much by reaction as they do by impulse or impact. The term "impulse" or perhaps better, "impact" might have been accurately used to designate the original current wheels and some of the pioneer forms, such as the hurdy-gurdy wheel, where the water was received on flat surfaces and no attempt was made to utilize the reaction of the water leaving the wheel. The modern wheel, however, receives the water without shock, completely avoiding what might be termed impact, and turns it by a smooth path into a relative direction substantially contrary to that of the motion of the wheel. The essential distinction between the hydraulics of the so-called impulse wheel and the reaction type is found in the fact that in the former the entire energy of the water received by the wheel is in the form of velocity.

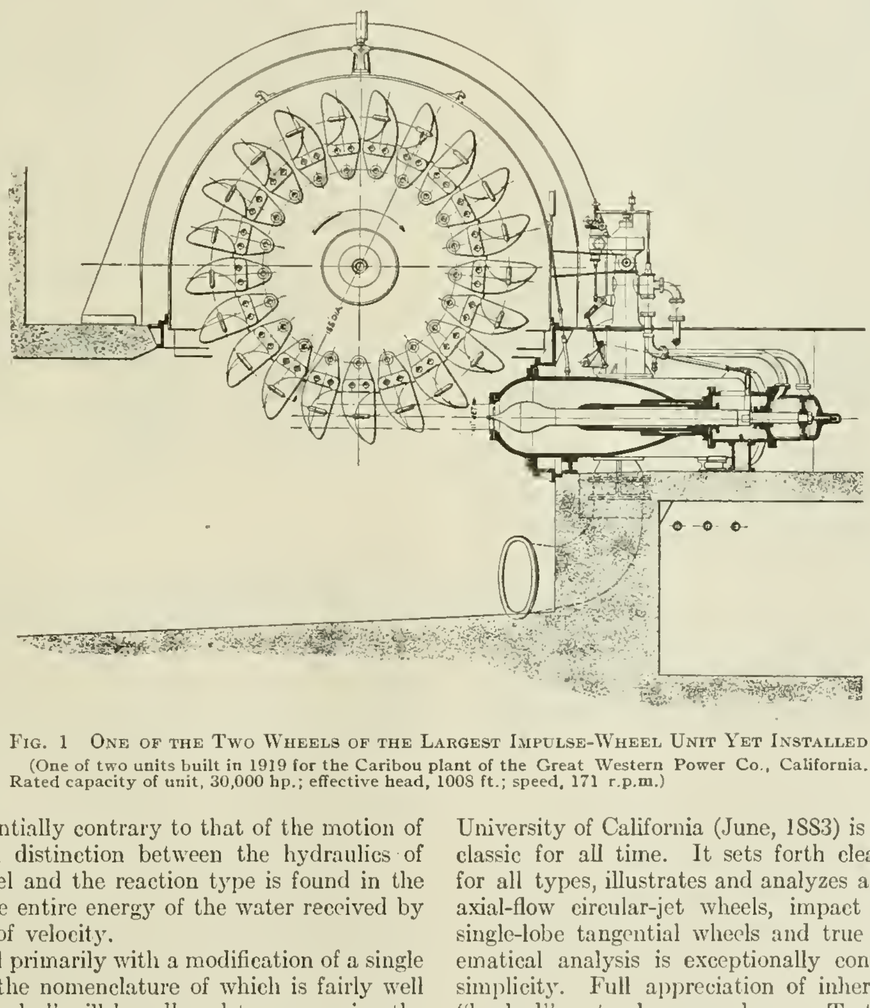

Fig. 1 One of the Two Wheels of the Largest Impulse-Wheel Unit Yet Installed
(One of two units built in 1919 for the Caribou plant of the Great Western Power Co., California. Rated capacity of unit, 30,000 hp.; effective head, 1008 ft.; speed, 171 r.p.m.)

As this paper has to deal primarily with a modification of a single type of wheel or turbine the nomenclature of which is fairly well established, the term "impulse" will be adhered to as covering the general and specialized forms known variously as Pelton, tangential, Girard, Schwankrug, pressureless, and impulse or action types as contrasted to Francis, Jonval, Fourneyron, pressure, and reaction. It is with this thought of conforming to accepted practice that the term "impulse" is employed.

Historical

Prior to recorded history we may infer that mankind required a matter of centuries to produce the flat-blade impulse wheel. We know that this type persisted with little or no change, up to about the sixteenth century A.D., that is, about two thousand years.

It required three hundred years more to definitely get beyond the flat-blade stage, realization of its disadvantages (only 50 per cent maximum theoretical efficiency) not materially affecting practice up to about 1850, although the faults of the flat blade were recognized 100 years previously. Some samples of the impact type of wheel survived in our own country up to the latter part of the nineteenth century, these being represented typically by the hurdy-gurdy wheel of the California mining days. Actual installations of this crude wooden wheel with its flat impact surfaces were made as late as 1880, but it gave way to the impulse wheel in approximately its present form, Fig. 6 (*a*), during the period of 1870 to 1880.

As late as 1883 and again in 1890–1891 comprehensive tests made on impulse wheels included tests on designs of flat-vane wheels. Bulletin No. 1 of the University of California (June, 1883) is probably the impulse-wheel classic for all time. It sets forth clearly the reaction principle for all types, illustrates and analyzes arrangements of radial- and axial-flow circular-jet wheels, impact wheels with flat surfaces, single-lobe tangential wheels and true splitter types. The mathematical analysis is exceptionally comprehensive without losing simplicity. Full appreciation of inherent disadvantages such as "backed" water loss was shown. Tests on impact wheels (40 per cent best efficiency) and Pelton wheels (82 per cent best efficiency) are given. Incidentally, this latter efficiency has not since been materially improved upon, considering the small jet size ($^3/_8$ in.) and low head (50 ft.).

Tests at the University of Michigan by Profs. M. E. Cooley, C. E. DePuy and L. J. Hill in 1890–91 similarly included tests on both impact and impulse wheels of commercial forms and with

[1] Hydraulic Engineer, Allis-Chalmers Mfg. Company, Mem. A.S.M.E.
Presented at a meeting of the Milwaukee Section, Feb. 20, 1923. Also presented at the Pacific Coast Regional Meeting of The American Society of Mechanical Engineers, Los Angeles, Cal., April 16 to 18, 1923. Abridged.

modifications to improve the efficiencies of both. A maximum of 37 per cent with flat blades and 82.75 per cent efficiency with Pelton buckets were obtained, the nozzle being $^3/_8$ in. in diameter and the head 92.4 ft. Analyzing the separate losses the authors concluded that the bucket efficiency approximated 90 per cent, that the nozzle efficiency could be brought to 99 per cent, but that windage and friction losses could hardly be reduced below $3^1/_2$ per cent.

In the United States occasional patent references are available back to 1850, but in none of them is there a clear setting forth of

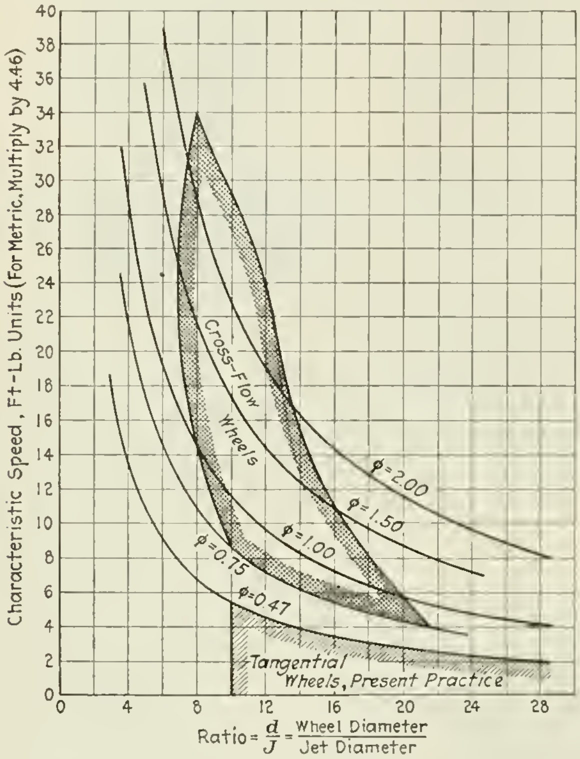

Fig. 2 Curves Showing Relation Between Characteristic Speeds of Impulse Wheels and Their Proportions as Evidenced by the Ratio d/J

(The plottings for the various peripheral coefficients indicate the increases possible with larger coefficients than are used at present. The lower shaded area indicates the approximate limits of proportions and characteristic speeds of tangential impulse wheels, and the upper area roughly the field available for development by the cross-flow wheel. The increase in characteristic speeds that is possible is quite strikingly shown.)

the reaction principle as applied to impulse wheels nor a construction suitable for applying the principles until subsequent to that date. The earliest written account is that of Atkins, who applied for patents in 1853, although issue was delayed until 1875. Apparently Atkins fully appreciated the hydraulic principles involved.

It remained, however, for the mining industry of California to produce the predecessors of the type accepted universally at present. This was perhaps inevitable as they, to probably to a greater extent than any other group of men in the world, were in daily contact with large-sized jets of water under high pressure. The first application of these jets was for the purpose of hydraulic mining, but the developing of power followed immediately. The wheels first used were known generally as the hurdy-gurdy wheels and they dominated the period from 1850 to 1870.

The development work of the period 1870–1880 is dominated by the names of Knight, Moore, Hesse, and Pelton. The origin of the present type of tangential wheel, characterized by its cup-shaped bucket for securing full reaction and by its splitter for avoiding impact losses, lies with some or all of this group of men, but Pelton undoubtedly did most to develop and commercialize this form and to him belongs the credit for first increasing the efficiency to approximately where it stands today. Later modifications were made to improve the efficiency, to avoid erosion or secure some better mechanical standard, but the inherent characteristics have so far remained unchanged.

A most interesting historical account[1] and analysis of Pelton's work is contained in the report of a Committee appointed by the Franklin Institute. This covered the various works, both European and American, leading up to Pelton's, disposed of contending claims and finally made unqualified award on the basis of simplicity, economy of maintenance, adaptability to high heads, transportability, newness, correctness of principle, and commercial importance, but above all from the standpoint of efficiency. An appended test made at the U.S. Naval Academy in 1895 by Lieutenant F. J. Haeseler, U.S.N., and Ensign W. H. G. Bullard, U.S.N., shows a maximum efficiency of 86.56 per cent with a $^3/_4$-in. jet developing only 7.756 hp., volumetric measurement of water being used. This is the type that has remained unchanged to date.

European practice starting along a divergent line during the incubation period (1850–1880) of the American designs developed the Girard axial-flow and Schwankrug radial-flow impulse wheels for high head.

Any working mechanism exposed to fluid in motion should desirably have the smallest possible hydraulic radius, that is, the least surface in contact with the water, to minimize losses and variations in velocity. For any given area the circle is the most advantageous shape as no figure has a greater area for a given periphery.

The accident of circular jets used in our western mining work was responsible for a feature of design that was very instrumental in causing the American design of impulse wheel to supersede all others. This circular-jet nozzle, later of the needle type developed by Mr. Doble, obviated pitting trouble and low nozzle efficiency (frequently as low as 85 per cent) encountered in the various forms of partial annular nozzles, square nozzles and tongue nozzles that characterized European design and were features of practically all Girard and Schwankrug wheels. Other than circular jets may work out advantageously, but so far all types of impulse wheels using them under high heads have failed or have been superseded commercially.

All impulse wheels have gradually resolved themselves into the specialized type known variously as the Pelton wheel, the tangential wheel, or more generally the impulse wheel. These have been

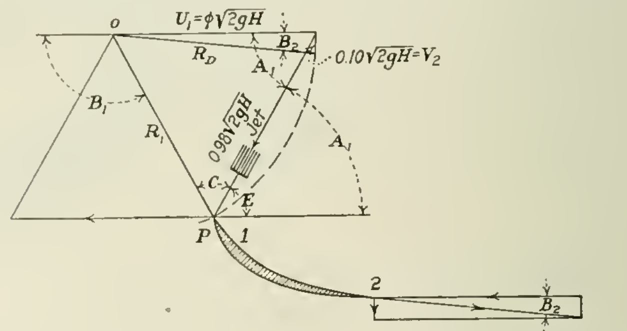

Fig. 3 Fundamental Diagram of the Impulse Wheel

(Diagram is laid out for the axial cross-flow type of wheel, but represents an average of all types, whether of radial-inward, radial-outward, conical, or axial arrangement.)

highly improved, are very simple, efficient, and reliable, and gradually all other forms of pressureless wheels have given way to them. The last to go was the Girard impulse wheel or Girard turbine as it is variously known. On account of its relatively large nozzle area it had a high characteristic speed and filled a gap not covered by either Pelton or Francis wheels except disadvantageously by the multiple-jet types of the former.

Characteristics of the Impulse Wheel

Practically all writers of hydraulic textbooks agree in their treatment of the impulse wheel that it is known by the following characteristics, the first three applying to impulse wheels in general, and the fourth identifying the present dominant type.

1 A free jet operating under the full spouting velocity due to the operating head
2 Substantially tangential application of the jet to the wheel, that is, with the major component of jet velocity along a tangent
3 A bucket velocity practically 50 per cent of the jet velocity
4 Splitter-type buckets concave on the working surfaces.

According to definition, characteristic No. 1 is inherent with

[1] *Journal of the Franklin Institute*, September, 1895.

all impulse wheels. Nos. 2, 3, and 4 dominate the impulse-wheel field at present and have done so with almost no interference for thirty years, within which period practically all the development of modern water-power machinery has taken place. During the first half of this period these characteristics covered commercial requirements which demanded the slowest-speed wheel that could be made under high heads. While certain conditions, notably high heads, still demand tangential wheels for about 15 or 20 years, the requirements of commercial practice have frequently exceeded limitations imposed by characteristics Nos. 2, 3, and 4, and to meet these new conditions the new form of wheel proposed by the author has departed from these three characteristics in a decided and radical manner.

Contrary to the general impression, the modern impulse wheel is the slowest-speed type of turbine known, although it utilizes the highest water velocities. This low-speed type has found an extensive field of usefulness by reason of its mechanical simplicity and the relatively small surface exposed to high water velocities. Its mechanical simplicity permitted the original development of this type without going beyond the capacity of carpenter's and blacksmith's tools. Its low speed was essential in connection with the small capacities and high heads to which it was adapted, as it permitted revolutions per minute sufficiently low to readily permit of direct connection with alternators of reasonable speed. Its arrangement permits elimination of clearances and packing, which involve careful design and fine machine work and are a continual source of trouble under high heads. The small

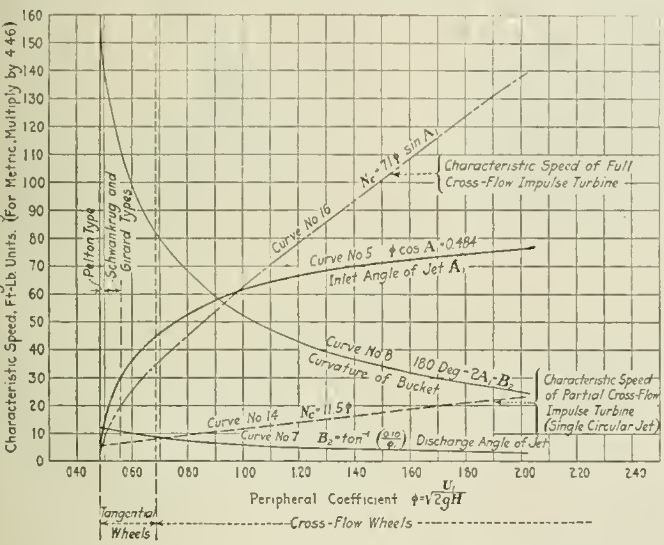

Fig. 4 Diagram of the Entire Field of Impulse Wheels, Showing the General Characteristics of Modern Tangential Impulse Wheels of the Superseded Historical Types and of the Proposed New Cross-Flow Type

(Assumptions: Discharge loss = 0.10 $\sqrt{2gH}$; jet velocity = 0.98 $\sqrt{2gH}$; overall efficiency = 80 per cent; d/J = 10.)

amount of surface exposed to water flow and the ease with which such surfaces may be inspected and renewed overcame one of the greatest problems in high-head turbine design.

It is probable that the intimate association of the low peripheral coefficient of 50 per cent with impulse-wheel design results from the fact that practically without exception authors of hydraulic treatises and writers of textbooks on the subject of hydraulic-turbine design confine themselves almost solely to this basis.

It is to this that the author takes exception, particularly since this 50 per cent basis is usually presented as a very fundamental consideration of all impulse-wheel design, whereas it really should be presented as an extreme used to permit of securing the lowest possible bucket speed. A single glance at the complicated forms of the most noteworthy impulse-wheel installation of the last few years should be all that is needed to indicate to the unbiased engineer whose ideas have not already been prematurely and positively fixed along a certain line, that the desirability of low speed in the buckets of these units has long since passed. The unit of Fig. 1 illustrates this point, as do also all of the record capacity units above 5000 hp. or since 1904.

So far as water velocity is concerned, the impulse type of wheel should have the highest speed of any type of turbine, except those which may be classed within the so-called "suction" field. The water velocity in the usual reaction wheel (Francis) seldom exceeds 50 to 75 per cent of the spouting velocity, or the same percentage of that which holds in all impulse practice. The main reason for the low characteristic speed of impulse wheels is found in the fact that the whole periphery of the Francis is utilized for developing powers, whereas the usual impulse wheel comes under the classi-

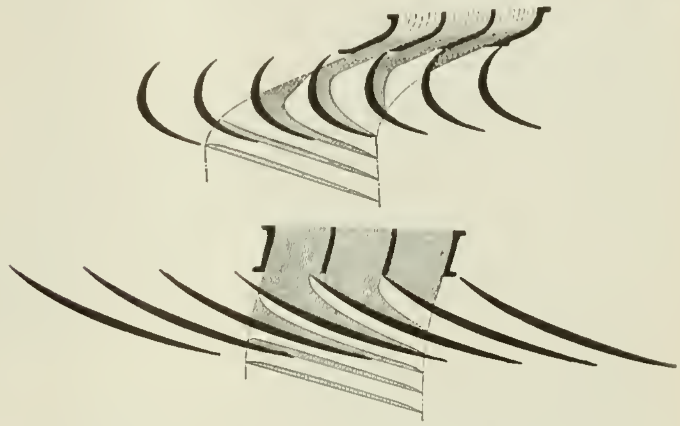

Fig. 5 Diagrams Illustrating the Relatively Smaller Portion of the Periphery of a Wheel Utilized by a Given Jet of the Cross-Flow Type as Contrasted With That of the More Nearly Tangential Flow. The Possibility of Utilizing a Larger Number of Jets Without Interference is Evidenced

fication of partial turbine. The result is that in comparing on the basis of a certain hp. the diameter of the impulse type becomes so large that its r.p.m. is unduly reduced. This is further emphasized by the fact that the reaction wheel usually runs with a coefficient of rim velocity in the neighborhood of 60 to 90 per cent as contrasted to the 50 per cent for the present impulse type.

Speeds of tangential impulse wheels cannot be increased by reducing their diameter beyond a certain limit illustrated in the lower curve of Fig. 2, because the bucket turns so abruptly out of the working path of the jet. The relationship between the characteristic speed of the tangential impulse wheel and its ratio of wheel to jet diameter illustrate the approximate limitations of commercial practice. Exceeding the ratios indicated simply means that there will be what is called "racing water," with its inherent loss of efficiency.

Unit capacities have so grown that for a considerable period, possibly for the last 15 or 20 years, strenuous efforts have been made to increase specific speeds of impulse units. As is usual in such cases, human inertia has been such that the new need was not recognized, the result being that the art of impulse-wheel design went through the same evolution as did that of reaction-type turbines, i.e., multiplicity of runners, nozzles, etc., without attacking the fundamental element of relative bucket velocity or direction of jets on the wheel to avoid interference. The orthodox 50 per cent velocity of bucket and tangential application of jet with its large consumption of wheel periphery were and still are the dominant factors of the impulse units of even recent manufacture and of all engineering textbooks on the subject.

Experimental Work of the Author

During the years 1913 to 1918 the author was experimenting almost continually with flat-angle runners of the axial-flow type. This work resulted in the development of the high-speed suction type of propeller runner since applied extensively to low heads and led to an appreciation of the characteristics necessary to high speed in any vane moving in a fluid. In his paper describing this work before the A.S.M.E. in December, 1919, the following statement was made as covering any water wheel, the ice boat illustration incidentally coming under the classification "impulse" as defined herein.

Neglecting friction and possibly blade thickness, there are no mathematical or hydraulic laws that will prevent doubling or quadrupling any particular characteristic speed by simply flattening the blade angles.

A direct analogy to this is the well-known illustration of relative velocities evidences in the sail of an ice boat.

Continuing this work on high-speed runners with impulse wheels, the author in company with J. F. Roberts experimented with small-angle single-lobe types of buckets with the jet making small angles with the tangent. The purpose was to secure an arrangement whereby more jets might be used on a single wheel without interference and to eliminate the splash losses resulting from water discharged upward and falling back on the wheel in vertical shaft arrangement. The result was difficulty from the "backed" water indicated at B in Fig. 6, which was one of the causes of the low efficiency and pitting that contributed largely to the commercial failure of Girard wheels and other single-flow impulse turbines. In playing jets from an ordinary garden hose on small models of these wheels that were running at a high rate of speed (10,000 to 20,000 r.p.m.) a decided change in their tune was noticed with various positions of the jet. On account of ease in construction one of the wheels happened to have been cast without back curvature of buckets, similar to the propeller-type suction runner. With this wheel the highest pitch or note was developed with the jet directed almost perpendicular to the plane of the wheel. This was so contrary to fundamental impulse practice as indicated by all commercial installations built in recent years and covered in any treatise on hydraulics that it attracted instant attention. Analysis of the condition resulted in a series of diagrams such as Fig. 3, and these worked naturally into the following algebraic analysis.

Let—

$$\text{Jet velocity } V_1 = 0.98\sqrt{2gH}$$

From the right triangle on base OE

$$R_D = \sqrt{U_1^2 + V_2^2}$$

and from the law of cosines

$$R_I = \sqrt{V_1^2 + U_1^2 - 2V_1U_1 \cos A_1}$$

But $R_D = R_I$,

$$\therefore U_1^2 + V_2^2 = V_1^2 + U_1^2 - 2V_1U_1 \cos A_1$$

whence

$$\phi^2(2gH) + 0.01(2gH) = 0.96(2gH) + \phi^2(2gH) - 2\,\phi \times 0.98(2gH) \cos A_1$$

and (see curve 5, Fig. 4)

$$\phi \cos A_1 = 0.484 \qquad [1]$$

Note that varying the assumption of $0.10\sqrt{2gH}$ discharge loss has very little effect on the inlet angle.

For the average impulse wheel the bucket inlet angle is practically twice the jet angle, that is (see curve 6, Fig. 4),

$$B_1 = 2A_1$$

Proof:

$R_D = R_I$ since relative velocities are practically constant in an impulse wheel (exactly so in axial flow).

$R_D = OE$ (Fig. 3) very closely since B_2 is always very small. Exact equality could be attained by allowing a slight forward component.

$OE = OP$

$\therefore$ Angle C = Angle A_1

But $A_1 = E$ by construction and $C + E = 2A_1$

$\therefore B_1 = 2A_1$

$$B_2 = \tan^{-1}\left(\frac{0.10\sqrt{2gH}}{\phi\sqrt{2gH}}\right) \text{ from right triangle}$$

$$= \tan^{-1}\left(\frac{0.10}{\phi}\right) \qquad [2]$$

$$\text{Bucket curvature} = 180° - B_1 - B_2 = 180° - 2A_1 - B_2$$

$$= 180° - 2\cos^{-1}\left(\frac{0.484}{\phi}\right) - \tan^{-1}\left(\frac{0.10}{\phi}\right) \qquad [3]$$

(See curve 8, Fig. 4.)

With impulse wheels simple relationships may be deduced for comparative purposes as follows, letting J = jet diameter or thickness and d = wheel diameter, both in feet.

The equation for the characteristic speed of the wheel is—

$$N_c = \frac{\text{r.p.m.} \times \sqrt{\text{hp.}}}{H^{5/4}} \qquad [4]$$

and the speed is

$$\text{r.p.m.} = \frac{60\,\phi\sqrt{2gH}}{\pi d} \qquad [5]$$

Assuming 80 per cent efficiency and one circular jet per wheel,

$$\text{hp.} = \frac{\pi J^2}{4} \times \frac{0.98\sqrt{2gH} \times H \times 62.4 \times 0.80}{550} = \frac{J^2H^{3/2}}{1.78}$$

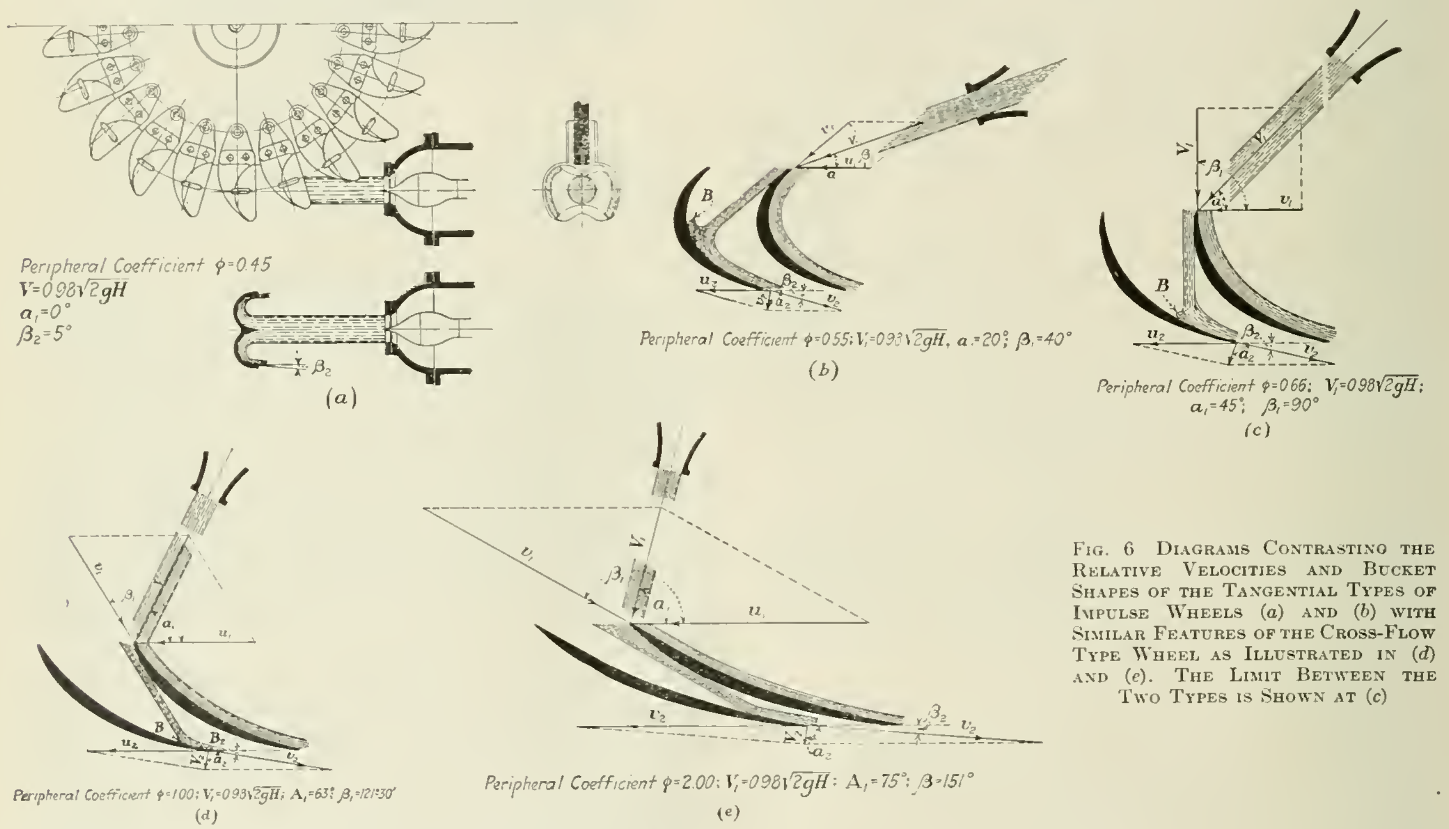

Fig. 6 Diagrams Contrasting the Relative Velocities and Bucket Shapes of the Tangential Types of Impulse Wheels (a) and (b) with Similar Features of the Cross-Flow Type Wheel as Illustrated in (d) and (e). The Limit Between the Two Types is Shown at (c)

and

$$\sqrt{\text{hp.}} = \frac{JH^{3/4}}{1.335} \quad \ldots\ldots\ldots [6]$$

Substituting [5] and [6] in [4] gives

$$N_c = \frac{115\ J\phi}{d} \quad \ldots\ldots\ldots [7]$$

Most engineers dealing with the subject are familiar with Equation [7] expressed for tangential wheels as

$$N_c = 55\frac{J}{d} \quad \ldots\ldots\ldots\ldots [8]$$

ϕ being taken as equal to 0.48.

Modern tangential impulse wheels preferably have a ratio of wheel diameter to jet diameter of 12 to 14, with 10 as a desirable minimum. Using the latter value for comparative purposes,

$$N_c = 11.5\ \phi \quad \ldots\ldots\ldots [9]$$

for impulse wheels with single circular jets (see curve 14, Fig. 4).

With multiple jets the limit of characteristic speed is reached with a solid annular jet of width J or when the nozzle area is πdJ. In this case, assuming 80 per cent efficiency,

$$\sqrt{\text{hp.}} = \frac{2H^{3/4}\sqrt{dJ}}{1.335}$$

which, substituted with [5] in [4] gives

$$N_c = 225\ \phi\ \sqrt{J/d}$$

neglecting for the moment the jet angle; and for the d/J ratio of 10 assumed above,

$$N_c = 71\ \phi \ldots\ldots\ldots\ldots [10]$$

Since the full annular area of the nozzle is not effective on account of the inlet angle of the jet expressed in [1], Equation [10] must be altered to read

$$N_c = 71\ \phi\ \sqrt{\sin A_1}$$

(see curve 16, Fig. 4), since the quantity and consequently the hp. vary as the axial or radial component and N_c varies as $\sqrt{\text{hp.}}$

The significant relationship between wheel speed and jet angle is shown perfectly in Equation [1], the graphical showing being curve No. 5 of Fig. 4.

Considering the fact that this relationship is based on the fundamental requirements of an impulse wheel, i.e., low exit loss and constant relative velocity (resulting from no change in pressure) in the bucket itself, the curve may be used for some very broad conclusions. The main one is this:

Speed in impulse-wheel work is a function of the angle the jet makes with a tangent.

If the jet angle is zero as in accepted present practice, the speed, which is a function of ϕ, is the lowest that can be obtained without preventable loss. As the angle of the jet increases to 45 deg. the relative wheel velocity increases from 50 per cent to only 69 per cent of the jet velocity. From this point, however, the most radical increase is effected. For example, from a 69 per cent coefficient at 45 deg. the speed increases to 100 per cent at 61 deg. This feature combined with the obvious departure from the tangential flow of present practice led to the following designation of two classes of impulse wheels accordingly as the major component of the jet velocity is along or normal to the tangent:

Tangential Impulse Wheels—Jets making angle less than 45 deg. with tangent.
Buckets decidedly concave, curvature greater than 90 deg.
Bucket inlet inclined backward.

Cross-Flow Impulse Wheels—Jets making angle greater than 45 deg. with tangent.
Buckets flattened, curvature less than 90 deg.
Bucket inlet inclined forward.

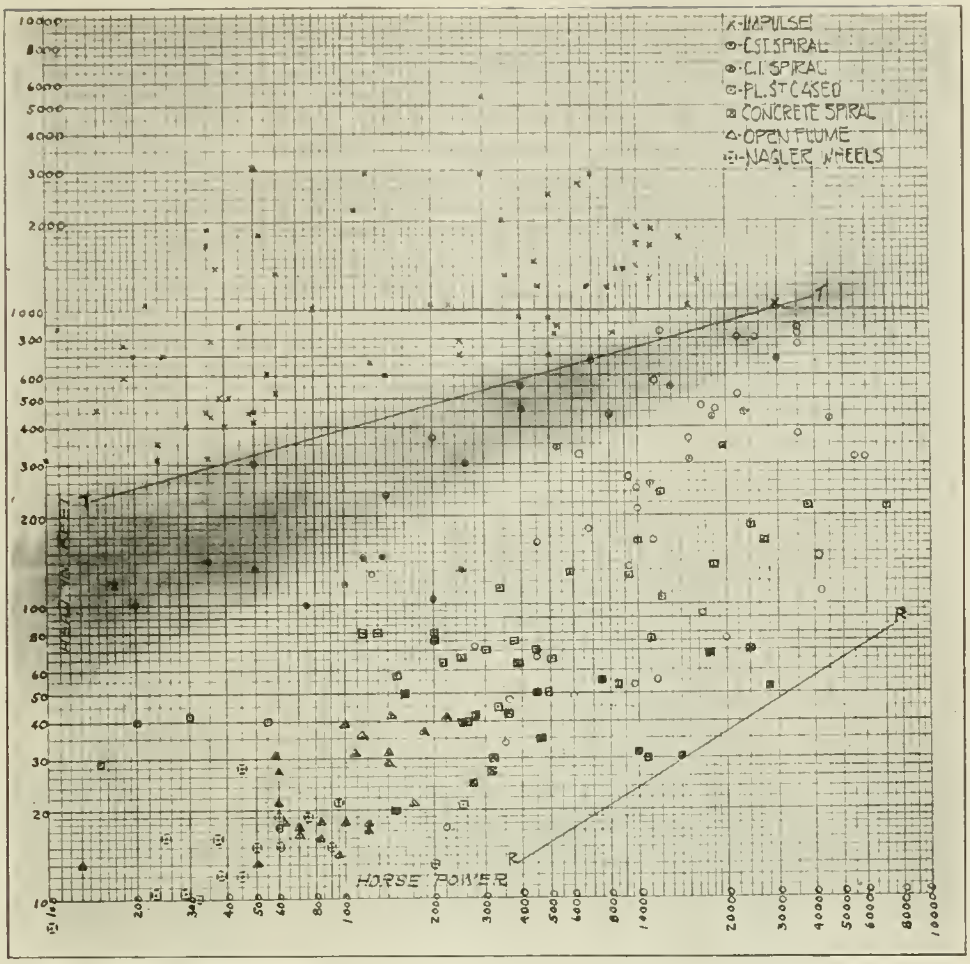

Fig. 7 A Plotting of the Entire Hydraulic-Turbine Field, Embodying Practically All of the Noteworthy Plants Ever Built

(Points above line T-T represent impulse units, practically all of them being of the tangential type. Line R-R represents approximately the limit of reaction units. The shaded portion adjacent to line T-T represents a field lying between the tangential impulse and high-head reaction fields and at present disadvantageously developed by them. This is the field to which the proposed cross-flow type of wheel is particularly adapted. Impulse-wheel horsepowers are plotted for one jet.)

The name "Cross-Flow" was selected after considering such terms as "vortex impulse" or "annular impulse" (on account of the ease with which so many jets may be used as to form a continuous whirling jet); and "axial impulse," "radial impulse," "mixed-flow impulse," etc., for reasons connected with the noticeable feature of various mechanical arrangements. "Cross-flow" seemed especially appropriate not only because it so aptly describes the direction of flow across the wheel but because it so distinctly defines the direction of flow as contrasted to that in the present wheels which are universally known as the tangential type.

Advantages of the Cross-Flow Type of Impulse Wheel

The cross-flow wheel, aside from its advantage in speed, automatically corrects one of the defects that contributed greatly to the failure of single-flow impulse turbines such as the Girard and other partial wheels. The "backing" of water in the wheel resulting in its being dragged around with the wheel and ultimately discharged at wheel velocity at about half its original velocity, results from impact due to the large angle between the relative water path and the surface of the bucket at the point of impact [point B, Fig. 6 (b)]. The slower the speed of the bucket, the greater the curvature and consequently the greater the impact and "backing" loss.

With higher speeds the bucket becomes flatter and the "backing" loss with its poorer efficiency and greater tendency to pit is more and more reduced [see B, Fig. 6 (d)] without resorting to the undesirable expedient of increasing the number of buckets. Inspection of the successive diagrams of Fig. 6 indicates how the angle of impact between the jet and bucket is successively reduced as the speed is increased and the bucket correspondingly flattened. The author believes that this principle can be utilized to eliminate

or at least reduce the efficiency losses and pitting troubles experienced with the Girard types, and with it there will be a rapid return to radial and axial and even conical or mixed-flow impulse wheels. In combination with nozzles designed to deliver circular jets with their higher efficiencies and more uniform distribution of velocities cross-flow wheels can be applied to a considerable portion of the field for which there is at present no design except the disadvantageous multiple-runner or multiple-nozzle types. For low heads and small powers or where efficiency may not be of the greatest importance the circular jet may be dispensed with and rectangular jets arranged to partly cover the wheel periphery (partial turbines), or even solid annular jets (full turbines) may be utilized.

The cross-flow wheel does have an inherent disadvantage from an efficiency standpoint. The relative velocity between jet and bucket is the lowest (50 per cent of spouting velocity) in a tangential wheel and higher in the cross-flow types; for example, for a 100 per cent coefficient the relative velocity is practically twice what it is in a tangential wheel. This, of course, involves a greater friction loss, but in actual practice this may be offset by reduction of windage and splash losses and particularly by the possibility of developing more power in a given working volume of space swept by the buckets than it is possible to do with the tangential type (see Fig. 5).

Vertical impulse wheels have certain mechanical advantages when large capacities are considered, these being similar to those which underlie the popularity and economies of the vertical reaction units and in addition incorporate the possibility of feasible mechanical arrangement of more jets than possible with horizontal types. Engineers experienced with impulse work, however, are familiar with the tremendous disturbances that exist even in horizontal wheels having but a single jet and can appreciate the condition that must exist when several jets are played on one wheel. When it is further considered that all the upwardly discharged water that falls or is spattered back into the path of the buckets must again leave the wheel at practically wheel velocity or half its own initial velocity, and that this represents a total loss, the desirability of getting the water positively and clearly away from the wheel is apparent. The cross-flow design, embodying as it does the feature of single direction of flow through the wheel without "backed" water losses, lends itself admirably to this arrangement. This is particularly so as in extreme cases multiple or annular jets may be used without injurious interference, as each elemental jet uses such a relatively small portion (see Fig. 5) of the periphery as contrasted to the tangential type where each jet needs for its working space a chord subtending a relatively larger angle.

Fig. 7 presents the entire field of hydraulic-turbine practice. On this diagram are plotted the heads and horsepowers of practically every water wheel of note ever built, particularly those that extended the developed field in any direction, regardless of type or nationality. The upper field above the line *T-T* (points marked ×) are of the impulse type. Those below the line *T-T* are of the reaction (Francis or suction) types. Portions below, to the right, or above the limits of the field of plotted points are as yet undeveloped.

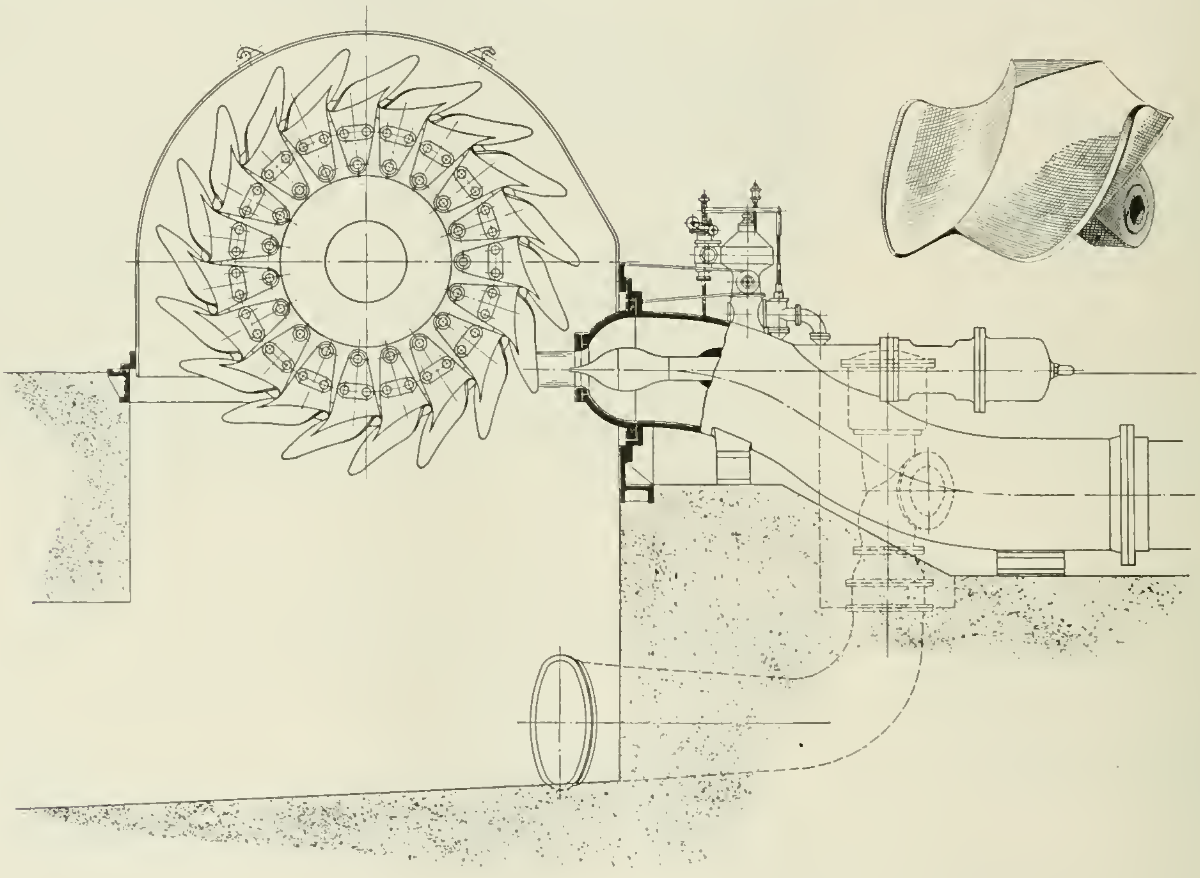

Fig. 8 Suggested Application of the Cross-Flow Principle to an Impulse-Wheel Unit of Conventional Arrangement

(The large angle of incidence shown is obtained by simply raising the jet above a tangential line so that it flows in a more nearly radial direction. The sketch at the upper right of the figure shows a bucket for use with a cross-flow wheel and designed to illustrate dividing the discharge and equalizing the thrust by a splitter.)

Undesirably low generator speeds have so far restricted further development below and to the right of the line *R-R*. Size of parts and transportation limitations retard although do not prohibit extension to the right above the line *R-R*. The infrequency of points at the top of the sheet arises from the difficulties arising from extremely high pressures (above 3000 ft. for example), the difficulties in securing suitable material for withstanding high stresses, and the comparative infrequency with which such high-head conditions are encountered. Undoubtedly the next few years will see units of 100,000 hp. capacity, and possibly more heads in the neighborhood of 3000 ft. 70,000-hp. impulse units for 2150 ft. head are even now being worked out in detail.

The significance of Fig. 7 so far as this paper is concerned lies in the comparatively undeveloped gap existing between the impulse and reaction types. This gap exists by reason of the difference between the highest impulse characteristic speed (about 5 ft-lb. units) and the lowest reaction characteristic speed (about 10). Even the multiplication of jets and nozzles incorporated in

most of the larger-capacity impulse units has failed to bring the two fields together.

The field of head and capacity now covered by impulse wheels of the tangential type needs extending only a limited amount. This extension is indicated roughly by the shaded section of Fig. 7, this section lying along and below the line *T-T*, between the fields to which tangential impulse and reaction wheels are well adapted. Going beyond this neutral ground in a lower direction, involves competition with the reaction-type runners that give economical generator speeds with lower water velocities and better efficiencies. It is to this intermediate field that the cross-flow impulse design is peculiarly adapted, as with it characteristic speeds of 5 to 20 are readily obtainable with single jets as shown in the upper shaded area of Fig. 2 and curve 14 of Fig. 4. With multiple or annular jets even higher speeds are possible, theoretically up to over 100 from curve 16, Fig. 4. There will probably be no commercial demand for such extreme speeds using the cross-flow principle as the reaction type covers this field satisfactorily and with more desirable water velocities. The greater simplicity of the impulse type may, however, make those high-speed types work out advantageously with small or auxiliary units.

As in all simple developments, a detailed search of prior art shows numerous designs that might be construed to anticipate the cross-flow principle. These comprise various designs from the earliest forms of flutter wheel where water from a trough falls on a paddle wheel, up to and including various forms of Jonval wheels, which may have been set above tail water, and through the various designs of Girard and Schwankrug wheels. All of these installations with which the author has been familiar have a flow other than tangential, not by reason of its advantage but because of certain desired mechanical arrangements and in spite of the acknowledged disadvantage of departing from the tangential arrangement. This fact is indicated by the numerous details of design which indicate the extreme measures which were used to secure flow as nearly as possible tangential. Exhaustive search has indicated no single instance where free circular jets, adjustable in size, have been purposely directed against the buckets at angles greater than 45 deg. with a tangent.

That the problem of securing higher specific speed in the impulse field is one of real commercial significance is indicated by the fact that such variety of expedients have recently been used to raise speeds. These efforts parallel with surprising exactness the multiple-runner craze that dominated the reaction field during the years 1900 to 1910, resulting from the attempts of water-wheel builders to keep pace with electrical designers in speeds of units. The reaction program was confined at first to using multiple runners, as the entire periphery was used at the start. Later the reaction development followed lines of widening the inlet to the runner, increasing the velocity of the water, and finally in increasing the relative wheel velocity.

The impulse-wheel designer started with the limit of water velocity, has gone through the stages of multiple jets, then multiple wheels, and is now at the point of facing the use of larger percentages of wheel periphery (larger inlet area) and higher wheel speeds.

The analogy to the history of reaction-wheel development is perfect, even to the point where for a large field of head and capacity the electrical designer is ahead of the wheel designer in speed. With the development of high-speed impulse wheels there should be experienced a return to the single wheel and possibly to the vertical shaft setting, the two features that so completely dominated the tremendous advances experienced in the reaction field in the past decade.

This does not mean that the tangential wheel is to be displaced, rather that it should be supplemented. For a certain range of head and capacity—a very wide range at that—it affords a perfect solution, one that harmonizes with desirable generator speeds with excellent efficiency and the utmost simplicity and durability.

It is for lower heads and larger capacities that new designs are needed. While the elements of the machines themselves are not subjected to mechanical complication or hydraulic losses as serious as those which caused the multiple-runner reaction turbine to be superseded by the single vertical arrangement, the general complications of water passages and governing mechanisms and possibilities of flow interference are certainly such as to be expensive and undesirable. If the history of the progress in reaction wheels is any guide, future developments in the impulse field will return to single runners of higher characteristic speeds just as the multiple-runner reaction wheels yielded first to higher-speed mixed-flow wheels and later to the still higher-speed axial-flow or suction wheels.

Fig. 8 is shown as an example of proportions and possible details of a unit based on the cross-flow principle for conditions of reduced head and increased capacity comparable with those which incur multiple jets or wheels. This is shown as indicating a possible trend in impulse design based on investigation of modern commercial needs and analysis of the hydraulic and mechanical features involved. It is not suggested that initial installations should be made for such large capacities and heads without first obtaining more operating data than are now available on the new type proposed. It is believed, however, that the low-head extension of the field of impulse wheels, particularly for small and moderate capacities, is warranted immediately.

The main purpose of this paper is not to present a complete solution of problems confronting the designer of impulse wheels, nor is it intended even to present the new type as being completely worked out. It is intended to draw attention forcibly to the possibility of departing from the orthodox tangential flow and 50 per cent coefficient, departing even from the specter of practice, precedent, usage, and textbooks without violating perfectly sound hydraulics. If the only too common tendency to get in a rut and stay there is lessened, the author will be more than satisfied.

Power from Tides

THOSE interested in power generation from tides might do well to read Hydro-Electric Engineering, vol. 2, edited by A. H. Gibson (compare review in *Engineering*, Feb. 16, 1923, p. 193).

In the simplest manner the author states the principles on which alone a scheme can prove a commercial success, and he is under no misapprehension as to the difficulties that any proposal will have to face and overcome. He submits the loose and somewhat optimistic views of irresponsible guides to the stern arbitrament of actual statistics drawn from the published balance sheets of Canadian companies, who have had the advantage of acquiring land at prairie value, and little to fear in the way of active competition. It is idle to point out that the nation is allowing a valuable asset to run to waste by neglecting tidal movement while the coal fields are being extravagantly depleted, unless it is explained how that force is to be utilized. At present there is no market for such power; only new undertakings can utilize the energy, and there are but few signs of these forthcoming.

Apart from the commercial success there are, however, many interesting problems that arise in considering the novel scheme of harnessing the tides. Some of these, more particularly concerned with hydraulics, were discussed in the earlier volume. Dr. Gibson now carries the inquiry a stage further. Matured reflection has convinced him that multiple-basin systems must be excluded as outside the limits of practicability, and that the only schemes likely to lead to a successful issue must be based on the use of a single basin developing power on both rising and falling tides, or on the outflowing tide only. Assuming that the tidal basin has an area of 1 sq. mile, that the water surface is sensibly level at all stages of the tide, that the range at spring tides is 42 ft., that 5 hr. are occupied in rising and 7.5 in falling, that at neap tides the range is 16 ft., and that the time consumed in rising equals that in falling, it is possible to form a very definite idea of the power that would become available. Three cases may be considered: First, working on a falling tide only—the least favorable case—and making the usual allowance for loss in storage supply, the output may amount to 7680 b.hp. continuous 24 hr. working. In the second case, operating on rising and falling tides under natural head, the output rises to 12,400 b.hp. Finally, if the scheme be arranged to work with rising and falling tides with constant rates of rise and fall in basin, a maximum output of 13,150 b.hp. is attained if all the energy is absorbed. In these estimates it is assumed that the primary turbines have a mean efficiency of 75 per cent, but this value may be too high, for under the extreme variations of head the efficiency of any constant-speed turbine falls off rapidly.

Lignite Char: Its Production and Possibilities

By O. P. Hood,[1] Washington, D. C.

Lignite char is lignite which has been dried and distilled in an oven especially designed for the purpose. About two and one-half tons of raw lignite reduce to one ton of char, the heating value of which is about 12,000 B.t.u. per lb. While raw lignite can be used satisfactorily in large steam-raising operations the author believes that the search for a means to improve the fuel must continue. American lignites do not briquet well without the addition of a binder, and the Bureau of Mines has therefore been led to investigate the possibilities of an inexpensive carbonizing process and the use of the resulting lignite char direct without briquetting. This process is briefly described in the paper.

The greatest difficulty with our lignite is the fact that in nearly every district where it should be the natural fuel it is put in competition with high-grade fuel. We are all spoiled by having been blessed with an abundance of the best, so that we are impatient with the limitations of lower-grade fuels. If we had been obliged to go down 2000 ft. or more and win good coal from thin seams in scattered districts as they do in Europe, we would have long ago worked out a successful technique for utilizing our lignites. Canadian and North Dakota lignite must compete with anthracite and with Pittsburgh and Illinois bituminous coal; our Texas lignite must compete with gas, oil, and Oklahoma bituminous coal. It is evident, however, that there must be a price at which the lower-grade fuel will begin to be attractive. In round numbers the ratio is somewhere in the neighborhood of half the price of good coal. With the rising price of bituminous coal we are fast approaching the time when this ratio will be common.

The handicaps of lignite are well known, but not always properly valued. The heating values of high-moisture fuels are somewhat misleading. The heat carried by the moisture is recovered and measured in the calorimeter, but is not fully utilized in a boiler furnace. The B.t.u. ratios, therefore, do not give the relative possible steaming values of the fuels if comparison is made between a high-moisture lignite and a low-moisture bituminous coal. Although the ash percentage may be low, there is usually a larger total amount of ash to handle in a plant using lignite. The fusing temperature of the ash is usually low, making high rates of combustion difficult and requiring larger grate areas and furnace volumes than with higher-grade coal. Notwithstanding these handicaps, with present technique, raw lignite can be used in large operations, and good efficiencies and reasonable capacities can be obtained. The problem is largely an economic one. When raw lignite is cheap enough in comparison with better coals it will be used in large steam-raising operations.

Improvement of Raw Lignite for Fuel Purposes

The search for a means to improve the fuel, however, must continue. A fuel classed as lignite in northern Bohemia, and weathering much as does our lignite, is as carefully prepared for market as is our anthracite. Seven prepared sizes are offered to the market. Raw lignite can probably be somewhat improved for steam raising by sizing the product more closely than is common practice. It is probable, however, that an improved lignite product must first cater to a special trade that will pay a special price. This is illustrated by the vision that has been so frequently held of improving the lignite by some process involving briquetting. Unlike the German "Braunkohle," our lignites do not make a stable and satisfactory briquet simply by drying the lignite and briquetting by heat and pressure. They lack sufficient inherent binder to consolidate and waterproof the mass. The necessary added binder increases the cost and hardly improves the quality. A quite satisfactory fuel can, however, be made by briquetting lignite char, and it is probable that some day such a fuel will be in common use.

There have been hopes that through the recovery of by-products sufficient credits might be obtained to materially lessen the cost of briquets. Profit can be shown on paper, but such a process is essentially a large-scale operation requiring a large investment and very substantial financial backing by those familiar with technical enterprise. It is difficult, therefore, to start such an industry, for there is no opportunity to begin small and grow up, returning profits into an improved plant. Capital familiar with technical enterprise finds less hazardous ventures, and capital unfamiliar with such enterprise is apt to be misled and lost.

Lignite Char and Its Possibilities

With these facts in mind, the United States Bureau of Mines is investigating the possibilities of a somewhat different program which has for its main features an inexpensive carbonizing device and the use of the lignite char direct, without briquetting. If a market for the char can be developed, and the small mine can produce char, there would be provided means for a natural evolution of an industry that in time might realize the larger vision of briquetting and recovery of by-products. Lignite char can best be described in a few words as a fuel rather near in analysis to anthracite coal, but softer, with a little more volatile matter, and thus kindling easier. In size it grades from pea coal to smaller sizes, and is a stable product. Whether a market can be developed for such a fuel at prices around five dollars a ton at the mine, remains to be shown, but it is at least encouraging to know that Germany used last year 400,000 tons of similar material for domestic heating and cooking. This fuel burns well with natural draft where a thin fuel bed, about $1^1/_2$ in. in thickness can be maintained. Base burners, cook stoves, and other heaters can be adapted to use the fuel satisfactorily. The Germans have developed a special stove, burning the fuel on a bed of ash in an enclosed drawer. There is no loss of fuel in the ash and our lignite char used in such a stove heats an oven sufficiently for baking operations and will boil water. It makes a very clean fire, is smokeless, and the char is clean to handle. It is, however, slow in getting under way as compared to a gas range.

Production of Lignite Char

To produce the char a very simple oven has been devised that greatly reduces the investment from that needed for ovens heretofore proposed. If lignite be passed through a combustion zone, moisture is first driven off; then combustible gases are distilled, and finally the solid carbon is burned. There is a considerable shrinkage in volume and a complete absence of caking quality. These steps are fairly distinct one from the other, so that the flow of lignite through the combustion zone may be so regulated that but little of the fixed carbon is burned. The combustion zone can be maintained by burning some of the distilled gases within the moving mass of lignite, and such direct heating is more efficient than where heat must be transmitted through refractory walls. The hot gases of combustion also pass through the mass, driving off the moisture and departing fairly cool. It is something like an open-top lime kiln. The process has proved simple and efficient. Of the gas driven off, much of it is used in the combustion zone, and in addition, less than 5 per cent of the weight of the original lignite is burned. That is to say, the fixed-carbon loss in the process for drying and distilling is lower than is usually found for drying alone where separate driers are used. Passing the combustion zone the lignite enters a lower section protected from the air, where it cools and is then removed. The char obtained by such a process may, of course, be briquetted.

An oven of this sort was operated at Grand Forks, North Dakota, during the past summer, and about 400 tons of various North Dakota lignites passed through. In February about 100 tons of Saskatchewan lignite was tried to discover whether this presented any special problems.

About two and a half tons of raw lignite reduce to one tone of char, and the heating value is about 12,000 B.t.u. per lb. The moisture is very low, and the char can be stored without danger of fire or degradation in size. Where the freight charge is heavy it would be an advantage to ship char instead of raw lignite.

Aluminum Bronze as an Engineering Material

By W. M. Corse,[1] Washington, D. C.

By aluminum bronze is meant, not the gray-white metallic coating used on radiators, but rather a strong, reliable metal resembling 0.35 per cent carbon Swedish bessemer steel to a remarkable degree. The color, of course, is different, but the mechanical properties are much the same. It resists alternations of stress unusually well and is superior to nearly all of the non-ferrous alloys except monel metal in this respect. Aluminum bronze is essentially 90 to 92 parts of copper and 8 to 10 parts of aluminum, while monel metal is approximately two parts of nickel to one part of copper. Naturally, the two metals behave differently with respect to corrosion, but they are much alike in strength and hardness. Both hold their strength much better than other alloys when exposed to elevated temperatures, a fact of importance to the steam engineer.

Properties

Aluminum bronze is about the color of 10-carat gold, has a tensile strength of 70,000 lb. per sq. in., and an elongation of 15 per cent. Its Brinell hardness number is 100–110. These properties place it in the class of strong bronzes suitable for the most exacting service. Particular mention should be made of its resistance to alternating stress or fatigue. "In the Landgraf-Turner endurance-testing machine the aluminum bronzes resisted 4500 blows before fracture, while the manganese bronze resisted about 500."[2]

"The results show clearly that aluminum bronze, in spite of its comparatively low yield point and proportional limit as shown in a tension test, is far superior to manganese bronze in endurance of alternating stresses or resistance to fatigue, and therefore its life would be longer in practical use."[3]

Similar comments were made by the authors of the Eighth Report to the Alloys Research Committee of the British Institution of Mechanical Engineers. Many practical tests have confirmed all of the above statements, so that an engineer in search of a metal to withstand fatigue should consider aluminum bronze. Such parts as those for air hammers and foundation bolts for drop hammers are good examples.

The other strong bronze, manganese bronze, has many admirable properties, but it is not adapted for bearing surfaces. Aluminum bronze has proved its worth in this field in such parts as worm-wheel gears. Every day's output of 1000 Ford trucks carries 12,000 lb. of this metal in gears. Extensive tests of aluminum-bronze gears against phosphor bronze in one-man tanks during the war proved the superiority of the former for this most difficult service.

Almost constant trouble was experienced with large spur gears on the locomotives on the Mt. Washington Railway until aluminum bronze was tried. Its service there has proved eminently satisfactory.

Pickle-crate equipment made of aluminum bronze has been found to withstand the action of sulphuric acid well. This fact, combined with its strength, fits it for this purpose. The property of resisting abrasion is useful for gears, but aluminum-bronze trolley wheels have been found to give remarkable service for the same reason. The toughness of the alloy is useful here as well, because the effect of a severe blow can be readily corrected under the hammer without breakage.

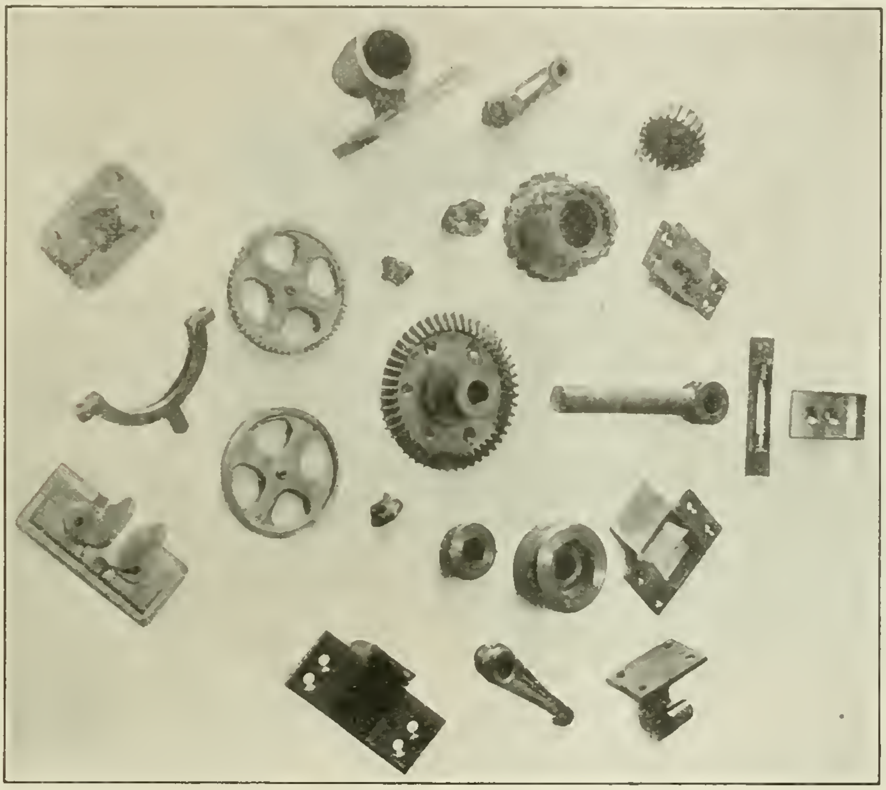

Fig. 1 Intricate Die Castings Made from Aluminum Bronze

Adaptability

Aluminum bronze is tough when cold, but is more so when redhot. This property makes forgings possible and also helps materially in the manufacture of die castings from this metal. A number of intricate die castings are shown in Fig. 1. These are not samples but are taken from regular production runs of lots of 10,000 or more. The process is a commercial one, for the dies are made so that they will withstand at least 10,000 openings in most shapes. The solving of the die problem is of equal importance with the metal problem, for one can not proceed without the other. The property of toughness is useful also in Jordan bars for beating engines. With its freedom from corrosion, the tough aluminum-bronze Jordan bar has been an increasing success in the paper industry.

Machinability

Many excellent properties of aluminum bronze have been mentioned, but it has its drawbacks. First, at least at present, is the difficulty of machining, compared with other bronzes or brasses. This does not mean that it cannot be machined readily under proper conditions, but that, compared to ordinary brass or bronze, its toughness makes it more difficult to handle in the machine shop. Sharp tools, kept so, of the proper angle are essential to success. Ample lubrication is necessary. With these precautions a most excellent job can be done as is evidenced every day at the Ford factory in Detroit. Aluminum bronze most nearly resembles mild steel in its machinability.

When one sees the stacks of golden-bronze worm wheels in the gear department of the Ford Company and examines the polished surface of the gear teeth left after the machining operation, there can be no doubt that aluminum bronze as an engineering material has arrived and that its excellent properties have been made available to the engineer because scientific research solved the problems of its manufacture in the foundry.

(Percentage composition: Copper, 92.46; iron 0 20; aluminum 7.29.)

The second objection to aluminum bronze might be its cost, which is about 25 per cent more than that of brass or bronze. But when compared to special bronzes with somewhat similar properties the difference in cost disappears.

Like all high-grade metals it must be manufactured under careful supervision, and more than usual care must be used in the casting shop and foundry.

Manufacture

Charles Vickers, in his book, Metals and Their Alloys, just published, devotes a chapter to aluminum bronze and goes into the manufacture and properties of the alloy thoroughly. Vickers devised the flux or degasifier that made the casting of aluminum bronze a commercial success in the sand foundry, and to him we owe much because of his untiring efforts in investigating the complicated problems connected with its manufacture. Vickers patented an alloy of copper, aluminum, and iron which shows markedly improved properties over the alloys without iron. Previously iron was considered detrimental in the manufacture of aluminum bronze, but as a result of Vickers' work many combinations of copper, aluminum, and iron are possible and enable us to make a series of alloys with widely varying properties.

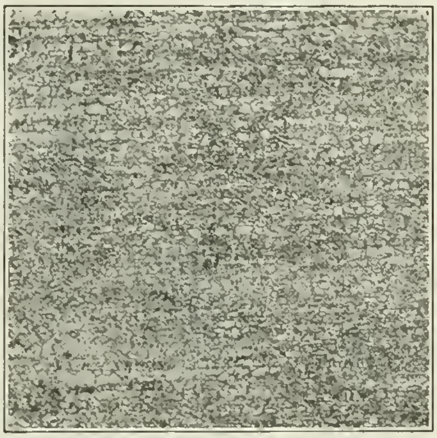

Fig. 5 Structure of Hard 8 Per Cent Aluminum-Bronze Rod. Magnification, 75 Diameters

George F. Comstock has investigated these alloys metallographically and published numerous articles of value on the subject. The author has had the privilege of being associated with the work of both Vickers and Comstock from the beginning, and has assisted in the commercial development of aluminum bronze since 1914. He heartily agrees with the following quotation from Erwin S. Sperry,[1] which, when written in 1905, was a prophecy, but has since become an accomplished fact.

> When a good casting of aluminum bronze is made, it is superior in every way to manganese bronze. I do not say this because I am prejudiced in any way, for I have had fully as much to do with one of these alloys as another; but for the reason that I firmly believe aluminum bronze has met with defeat, not because of its lack of strength, not from its unsuitability for all the work which manganese bronze will do, not on account of its excessive cost, but for the reason that no one has yet mastered its casting so that successful castings may be continuously turned out. When this has been done, and at some future time it will be accomplished, aluminum bronze will replace manganese bronze as it has been replaced itself.

The addition of manganese to the copper-aluminum alloys was investigated by W. Rosenhain and C. A. H. Lantsberry at the National Physical Laboratory, Teddington, England, and described by them in the Ninth Report to the Alloys Research Committee of the Institution of Mechanical Engineers of Great Britain. In general, the addition raises the yield point and tensile strength without diminishing the ductility.

Wrought Aluminum Bronze

Most of the remarks thus far have referred to cast aluminum bronzes, but as rolled or wrought alloys are commercial products and are manufactured in large quantities the author quotes below from W. H. Bassett, whose experience with these alloys gives authority to his statements.

> Aluminum bronze has a high resistance to corrosion, and is used principally when this property coupled with a high tensile strength and hardness is required.
>
> Copper-aluminum alloys can be made in wrought form in any proportions up to an aluminum content of approximately 10 per cent. Three alloys, however, are used principally. These contain 5, 8, and 10 per cent aluminum, respectively. All three alloys hot-roll easily, and these same remarks would apply to the cold rolling of the 5 and 8 per cent. The 10 per cent aluminum bronze does not cold-roll readily, in fact would not be considered a cold working alloy.
>
> The 5 per cent aluminum bronze is furnished principally in the form of sheets. It has when cold-rolled, a tensile strength as high as 100,000 lb. per sq. in., depending upon the degree of hardness or cold rolling, and an elongation in 2 in. of 10 per cent. When annealed this alloy has a tensile strength of 55,000 lb. per sq. in. with an elongation of 75 per cent in 2 in. This high elongation for annealed 5 per cent aluminum bronze is characteristic of the material, and it is rarely equaled in the other non-ferrous alloys.
>
> The 8 per cent aluminum bronze is manufactured extensively in both rod and sheet form, and is supplied when resistance to wear is also required in connection with the other general physical properties given for aluminum bronze.
>
> This alloy is in more general use than any of the other wrought aluminum bronzes. In the form of sheets when cold rolled the tensile strength may be as high as 130,000 lb. per sq. in., with 4 per cent elongation. When annealed this same material has a tensile strength of 60,000 lb. per sq. in. and an elongation of 60 per cent. The generally high tensile strength makes this material very valuable for many engineering purposes.
>
> Micrographs 1, 2 and 3 [Figs. 2, 3 and 4] show, respectively, the structure of 8 per cent aluminum bronze sheets hard or cold-rolled, light annealed, and soft annealed. These particular samples had the following physical properties:

Sample No.	Temper	Tensile strength, lb. per sq. in.	Elongation in 2 in., per cent
1	Cold rolled	102,000	7
2	Light annealed	77,000	36
3	Soft annealed	61,000	62

> Rods in 8 per cent aluminum bronze can also be supplied with approximately the same physical properties as sheet metal. However, it is customary to furnish them in a medium temper with a tensile strength of about 85,000 lb. per sq. in. and an elongation of 30 per cent. Micrograph No. 4 [Fig. 5] shows the structure of a rod of this nature.
>
> The 10 per cent aluminum bronze has, of course, the highest tensile strength and lowest elongation of this series. Owing to the fact that it can be only very slightly cold worked, it does not have the range in physical properties as shown by the other alloys. Its tensile strength may be taken as 75,000 lb. per sq. in. and elongation as 25 per cent. There is not a great demand for this class of material, but when supplied it is usually furnished in the form of hot-rolled sheets, hot-rolled or extruded rods, and extruded

Refinery and Rolling Mill for Monel Metal, Huntington, W. Va.

By W. L. WOTHERSPOON,[1] NEW YORK, N. Y.

This paper describes the steps taken in selecting the site for the location of a mill for rolling monel metal. The economic problems involved are stated and the facts leading to their solution are given. The remainder of the paper deals with the layout of the plant, emphasizing certain features of design that are of particular interest.

MONEL metal consists of 67 per cent nickel, 28 per cent copper and 5 per cent other elements, and is a natural alloy. In appearance it resembles nickel and in tensile strength it is comparable with steel, while its resistance to corrosion is very high. Its resistance to acids together with its physical and working qualities (for it can be cut, rolled, welded, machined, and forged) make a combination of properties which are not to be found in other common metals.

Monel metal is produced at the refinery in shot, pig, and ingot from monel-metal bessemer matte consisting of approximately 56 per cent nickel, 24 per cent copper, and 20 per cent sulphur, the iron content being about 0.4 per cent. The mill product consists of forgings, merchant and sheet bars, wire rod in coils, and sheets.

The International Nickel Company, in order to provide facilities for the increased requirements of monel metal, has recently completed a refinery and rolling mill at Huntington, W. Va. The project may be considered as new industry; active development of markets for monel metal having only been undertaken during the last few years, during which requirements have been met by arrangements with various steel mills for production of the above-mentioned products from ingots supplied from the Bayonne, N. J., refinery of The International Nickel Company.

The purpose of this paper is to describe the investigation leading to the location of these works, together with certain features of their design and construction, and to give information on the products manufactured, all of which is believed to be of general interest to engineers and manufacturers.

Investigation Regarding Location for Works

A general survey of requirements in order to prepare preliminary plans, and estimate the costs and acreage necessary, was first made, as a result of which the following conclusions were reached:

a That existing and prospective business for monel metal justified the estimated capital expenditure of approximately $3,000,000 for a rolling mill to produce rods and sheets

b That the potential markets for monel metal and other alloys were such that the plant should be laid out with provision for considerable expansion

c That natural gas, being practically free from sulphur, was the ideal fuel for heating purposes. Should it be necessary to utilize producer gas, the estimated capital expenditure for plant and equipment would be increased approximately by $200,000

d That the particular disposition and service of the merchant and sheet mills was such that individual electric drive, with gear reduction where necessary, would be best

e That purchased electric power was preferable, and if not available capital expenditure would be increased by approximately $750,000

f That at least twenty, and preferably up to fifty, acres were advisable for a site.

With the survey of requirements and the conclusions available, the following districts were given particular study: Bayonne, N. J., Buffalo, N. Y., Baltimore, Md., Pittsburgh, Pa., and Huntington, W. Va.

Although the ores and bessemer matte from which monel metal is produced come from The International Nickel Company's mines and smelter in the Sudbury district of Ontario, Canada, and there had within a few years been constructed by the company a refinery for nickel products at Port Colborne, Ontario, economic factors such as tariff, fuel, markets for finished products, etc., were such as to confine the detailed study of locations for these new works to the eastern half of the United States.

Bayonne, N. J., was considered, as The International Nickel Company's largest refinery had been established there many years and it was thought the rolling mill might be an addition to the existing works. The investigation resulted, however, in the Bayonne refinery being discontinued, the plant dismantled, and one of the most valuable sites on New York Harbor made available for some other industry for which the economic conditions are excellent, but which are unfavorable for the refinery and rolling

Fig. 1 General View of Plant from C. & O. R. R., June, 1922

mill. Important changes and extensions have therefore been made at the Port Colborne refinery so that nickel in all forms can be refined in Canada, and the refinery with rolling mill has been constructed at Huntington, W. Va., for the production of monel metal, malleable nickel, and other specialties.

The following is a list of the economic factors investigated, together with the comparative ratings given them:

Labor	250	Climate	50
Fuels	330	Supplies	60
Power	100	Taxes and laws	20
Living conditions	100	Site (cost and quality)	10
Transportation	50	Construction cost	20
Water supply	10		

The following general conditions apply to the district of Huntington, W. Va., which are considered especially suitable for the industry described:

Labor. Labor is made up of 95 per cent English-speaking Americans, both common and skilled, with good records in the territory in diversified industries; the turnover is light and a majority of the workers own their homes.

Fuels. A plentiful supply of natural gas for manufacturing and domestic purposes, from public-utility companies, is available at a cost of from 18 to 19 cents per 1000 cu. ft. (1100 B.t.u. per cu. ft.). Investigation of developed and undeveloped gas fields indicates supply of gas for 15 to 20 years. A good supply of high-grade oil of low sulphur content is available from the local oil refinery at a present price of 5 to 6 cents per gallon delivered at plant. There is an excellent supply of high-grade bituminous steam and gas coals from local coal fields costing $2.50 to $3.00 per ton, delivered at the plant.

[1] Consulting engineer, International Nickel Co. Mem. A.S.M.E.

Presented at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

Power. Two modern central stations supply power at a cost to large industries of 11 to 12 mills per kw-hr.

Transportation. Thirteen important railroads make connections within 175 miles. The Ohio River is navigable all the year, traffic between Pittsburgh, Huntington, and Cincinnati being on regular schedule.

Water. Both river and borehole water of good quality are available, the latter at an average depth of 60 ft.

Construction was commenced in 1921 and the plant was placed in operation in June, 1922. Fig. 1 is a general view of works as of June, 1922, and Fig. 2 a plan showing their general arrangement.

Crushing, Grinding, and Calcining Departments

The matte, which is received from the company's smelter in Canada in irregular pieces weighing about 50 lb., is unloaded from box cars and put through a 24-in. by 16-in. jaw crusher, being reduced to about $1^1/_2$-in. product, and is then fed to a No. 8 Krupp-type ball mill to be further reduced by dry grinding to pass a 16-mesh. The crusher and mill capacity is about 45 tons in eight hours, so that with the installation of a large storage bin with seven days' capacity for ground matte, this equipment can be operated intermittently to suit the convenience and arrival of cars of raw material. The crusher, ball mill, and elevators connecting them with each other and with the bin are belt-driven through a line-shaft by a 125-hp. 900-r.p.m. 3-phase high-torque squirrel-cage motor.

The ground matte is then introduced by mechanical feeders to roasting furnaces, of which there are three, the material being handled between the bins and the furnaces by 2-ton-capacity electric traveling monorail trolley hoists.

The roasting furnaces are horizontal, 80 ft. long by 17 ft. wide, and are of a modified Edwards type, the material being moved along the hearth by 32 rabbles operated by mechanical chain and gear transmission and mounted directly over each furnace. These rabbles are of cast iron with monel-metal shoes, and are hollow, being designed especially for efficient water cooling. Natural gas is used as fuel for these furnaces, the capacity of each being about 25,000 lb. per 24 hr., the sulphur in the material being reduced from 20 per cent to 0.005 per cent. The mechanism for each furnace is operated by a 5-hp. 220-volt 900-r.p.m. back-geared motor. The temperature under which roasting is accomplished varies from 2000 deg. fahr. to 500 deg. fahr. The roasted matte is discharged from the furnace by gravity into large buckets, ground charcoal being mixed with the hot material as it is discharged so that its reduction takes place from the time it leaves the roasting furnace.

Large flues with numerous baffles, facilitating the recovery of valuable dust, were given special attention in these furnaces, these connecting with a chimney 200 ft. high and 8 ft. in internal diameter at the top.

Large quantities of charcoal are used, so in this department there is provided as an extension a brick building for the storage of charcoal. Charcoal is procured locally in irregular sticks and, after passing over a conveyor provided with a magnetic pulley to extract any stray metallic substances, is delivered to a gyratory crusher, driven by a 10-hp. 220-volt 900-r.p.m. motor, to be pulverized to about $^1/_2$-in. size. A bin for the storage of crushed charcoal is provided, but the capacity is not large as it is inadvisable, due to the possibility of spontaneous combustion, to store this material in large quantities in ground form.

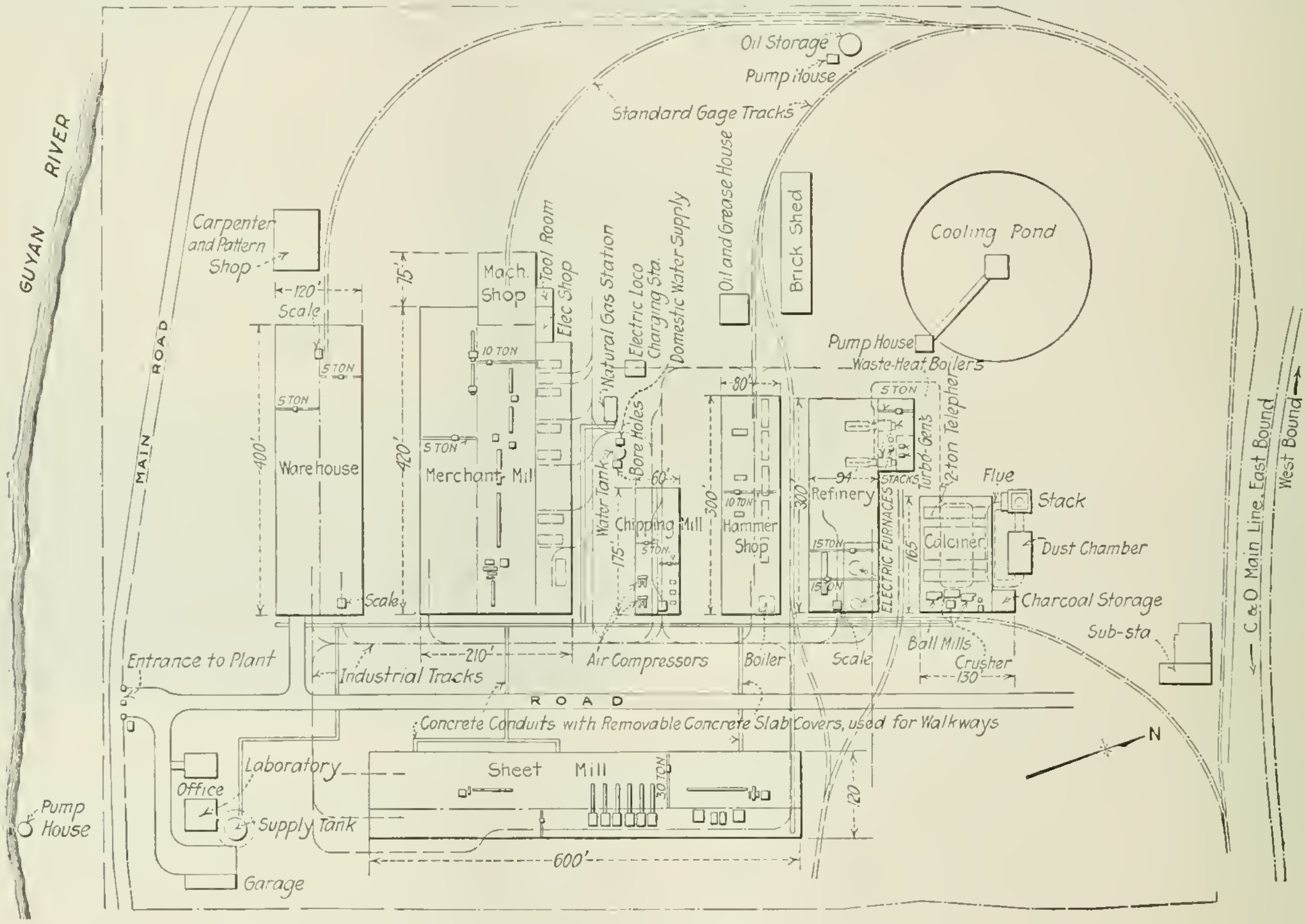

Fig. 2 Plan of Works, Showing General Arrangement

The cooling of the furnace rabbles takes about 100 gal. of water per min., the temperature being raised to 160 deg. fahr., which heat is utilized by pumping the water to the boiler-feedwater storage system of the auxiliary power plant.

The Refinery

The refinery department contains two open-hearth furnaces arranged for firing by either natural gas or oil. The capacity of each furnace approximately 35,000 lb. per day.

The electric traveling monorail-trolley hoist system already referred to operates between the calciner and the refinery departments, delivering the roasted monel-metal oxide from the calciner

furnaces directly to large feed hoppers mounted over the open-hearth furnaces. The telpher also delivers to the same feed hoppers ground charcoal from the crushing and grinding department and amounting to approximately 25 per cent of the furnace charge by weight. The heat utilized in furnaces of this type does not exceed 15 per cent of the value of the fuel, and a 600-hp. boiler of the waste-heat type, with superheater, is connected as close as practicable to each furnace, Fig. 3. The steam generated is used by the steam hammers and in the auxiliary power house.

There are at the side of each open-hearth furnace specially designed tanks used when making monel metal in shot form. This is accomplished by using a movable tapping spout and directing the stream of metal into water. There are also two electric furnaces, one known as the Moore, having a normal capacity of three tons per heat, and the other a Heroult, with a normal capacity of seven tons per heat. The charge floor is 100 ft. by 35 ft., of reinforced-concrete construction. The surface, where subject to rough usage, has an additional reinforcement of Irving grating.

The refinery department is equipped to produce monel-metal ingots directly from the open-hearth furnaces or from the electric furnaces. In the latter practice the furnace charge consists of pig metal produced in the open-hearth furnaces, together with selected scrap. In the work thus far done the power consumption has varied from 642 to 714 kw-hr. per ton of melted monel metal.

The Chipping Department

In order to insure a uniform hammered or rolled product of first-class quality, the outer skin of the monel-metal ingots must first be completely removed. Previous practice has been to remove this outer skin entirely by chipping with pneumatic hammers, a costly and laborious operation.

Experiments on a small scale demonstrated the economic possibilities of milling the surface of the ingots, and three high-powered milling machines belt-driven from a 20-hp. motor were installed in the chipping department. Approximately 250 lb. of metal is milled from the large ingot in an actual cutting time of 2 hr. 40 min. The total time to finish the ingot, including resetting of tools, turning and reclamping of ingots is 4 hr., thirteen operations being required. Eight-inch mills are used of special design with extra heavy steel bodies, case-hardened chip breakers, and ten inserted $1\frac{1}{4}$-in. by $\frac{3}{4}$-in. high-speed-steel blades. The blades are set in the body so that the rake angle which the face of blade makes with a radial line is 15 deg. Cutters of special design are used to mill the corners of the ingots. The face mill is run at 16 r.p.m., taking $\frac{1}{4}$-in. depth of cut with feeds of $4\frac{1}{4}$ in. and $4\frac{5}{8}$ in. per min. Angular cutters are run at 38 r.p.m. with $5\frac{5}{8}$ in. feed per min.

A skilled chipper cannot consistently chip out more than 1200 to 1500 sq. in. per eight-hour shift, or approximately two sides of a two-ton monel-metal ingot, whereas one milling machine finishes an ingot every four hours. This time will be considerably lessened on new machines with improved devices that have been ordered.

After the ingots have been milled they are taken to the chipping benches and carefully inspected. Any small defects that are not entirely eliminated by milling are chipped out by pneumatic chipping hammers. Compressed air for chipping and miscellaneous work is supplied from two direct-connected electrically driven horizontal air compressors located in a corner of the chipping building where most of the air is used. Each compressor will deliver 1030 cu. ft. per min. at 100 lb. gage pressure, and is driven by a 210-b.hp. synchronous motor running at 257 r.p.m.

The Hammer Shop

This department receives the ingots from the chipping shop. The ingots vary in size, depending upon their ultimate use, the major portion being about 13 in. by 13 in. and weighing up to 4 tons. The equipment consists of one 10-ton crane and four steam hammers of 16,000 lb., 10,000 lb., 3500 lb. and 1500 lb. capacity, respectively, together with the necessary handling equipment. There are five heating furnaces of the Stevens regenerative type, four with hearths 7 ft. by 20 ft. and one with a hearth 7 ft. by 14 ft., equipped with manual control and automatic air- and gas-regulating equipment.

Owing to the weight and toughness of monel metal the hammers are of a special design and possess some novel features. The 16,000-lb. and 10,000-lb. hammers are used for cogging or breaking down. These hammers are of a special double-frame type and are built of steel throughout. The main cylinders are bushed and valves of a new design assuring economy of steam and at the same time allowing for full control by the operator, have been embodied in their construction. The weight of one frame of the 16,000-lb. hammer is 44,000 lb., and the total weight, including the anvil, is 370,000 lb. The frames are held together at the bottom by a massive cast-steel base plate, giving a rigid construction. The ratio of the anvil weight to the falling weight is 15 to 1. Cushioned

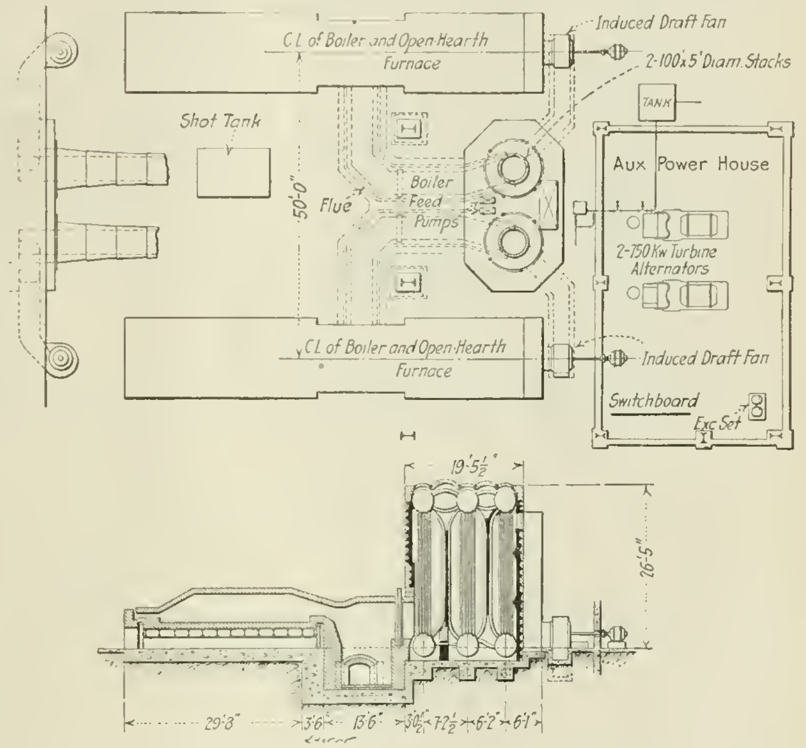

Fig. 3 Plan and Elevation Showing Arrangement of Open-Hearth Furnaces with Waste-Heat Boilers and Auxiliary Power Plant

safety cylinder covers are used with these hammers, also special guides and shoes.

The two smaller hammers follow the same general lines except they are of the two-leg type and in some parts cast iron replaces steel. Special shapes are forged on these hammers, in addition to the usual forged work.

The Rolling Mills

The mills consist of two departments:

a Merchant and wire-rod mills for the production of sheet bars, billets, rods of various sizes and shapes, and wire rod in coils

b A sheet mill for the production of hot- and cold-rolled sheets.

On account of the extremely tough character of monel metal and the tendency it has of cooling rapidly, it is necessary to have mills of great strength and rigidity. The type of material rolled is similar to alloy tool steel and it is very necessary to have mills with machine work and general finish the best of its kind and that are equipped with fittings that require a minimum of adjustment.

The hammered ingot or bloom after being overhauled to remove any scale or surface imperfections is delivered to the 24-in. sheet-bar mill, located in the merchant-mill building, Fig. 4. This mill consists of two stands, the first stand three-high and the bull head, or finishing stand, two-high.

The handling of blooms to the heating furnaces and thence to the standard mill tables is by means of a Brosius charger. The tilt-

ing tables, 25 ft. long, the transfer, and other table operations are controlled from the same pulpit. After being rolled the bar is carried to an exceptionally heavy shear with a capacity to cut $3\frac{1}{2}$-in. by 12-in. billets.

The Sheet Mills

The general arrangement of the sheet mills is shown in Fig. 5. The mills themselves are exceptionally heavy, the roll diameters

by a motor drive, a 40-hp. motor being used which is carried on the top of the pinion housing. The main motor to drive this mill is a 1200-hp. motor, which is geared with a double-reduction gear giving a total reduction of 13 to 1 and a mill speed of 26 r.p.m. Two 10-ton flywheels are used, running at the motor speed approximately 10,000 ft. per min.

The furnaces are of the wide-door type, being double sheet furnaces and four-door pair furnaces. The air at 16 oz. is furnished

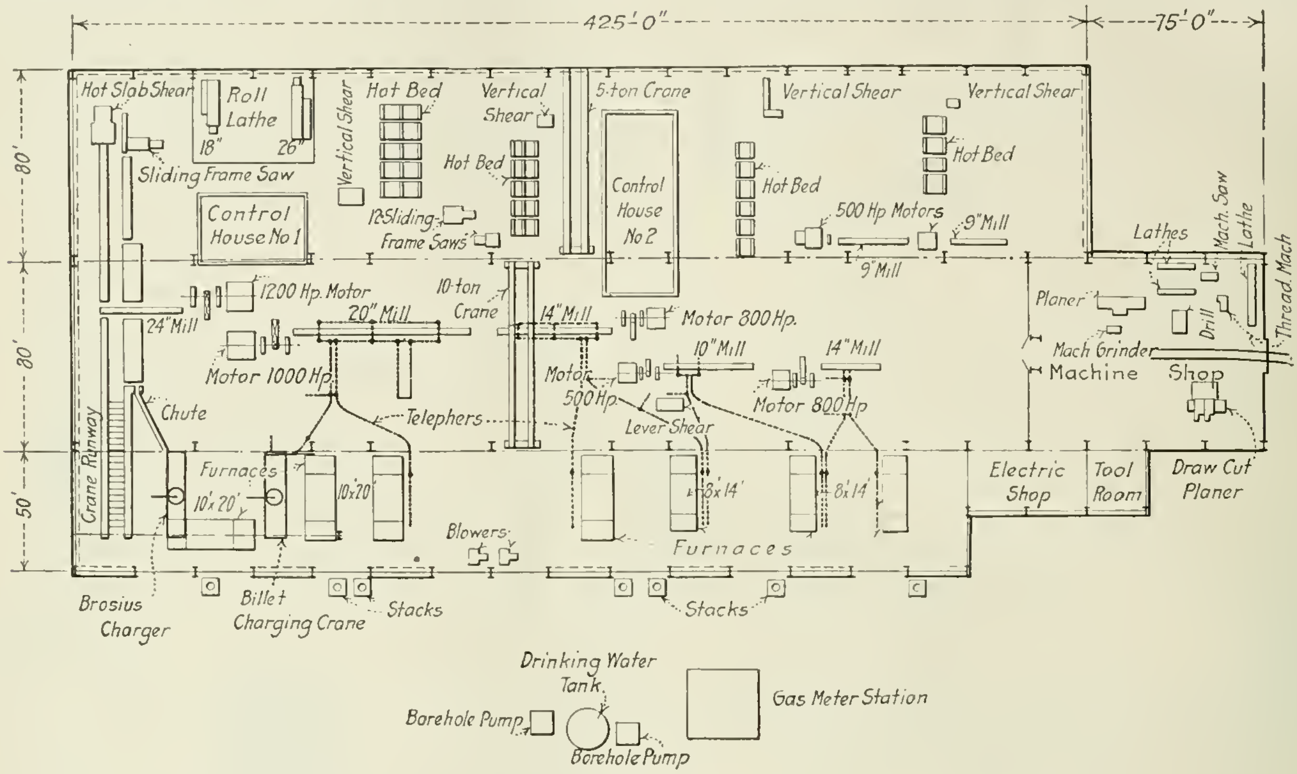

Fig. 4 General Plan of Merchant Mill

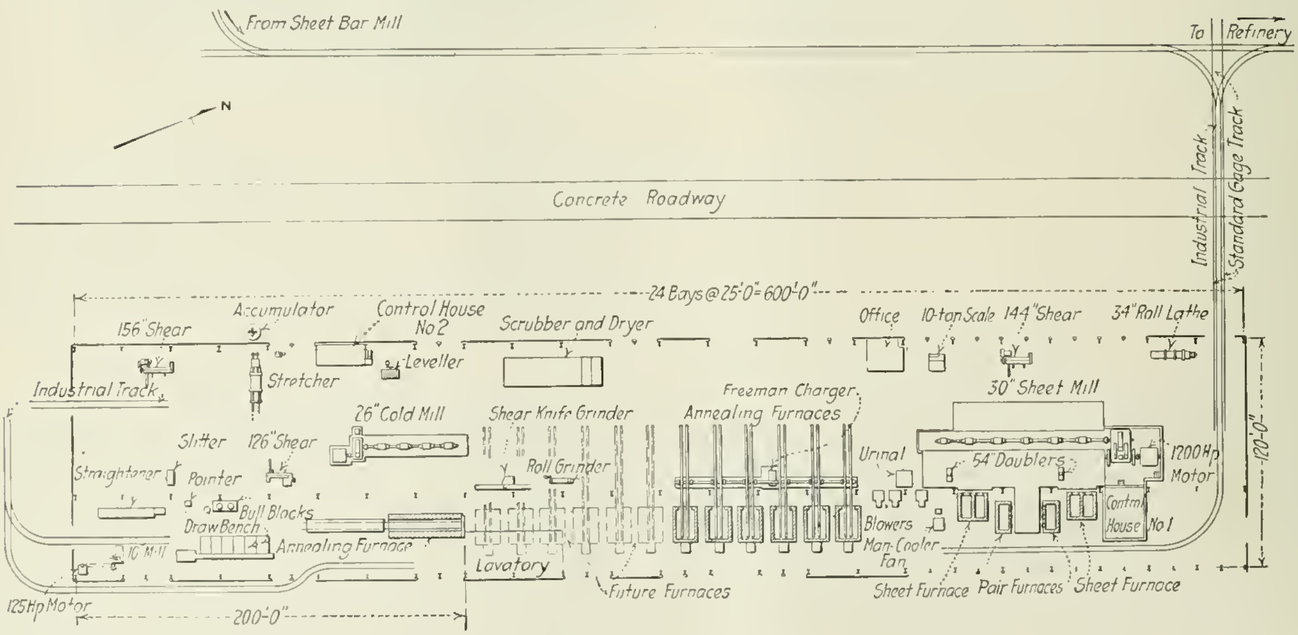

Fig. 5 General Plan of Sheet Mill

being 30 in. and the maximum sheet width 48 in. The present complement consists of two finishing mills and two roughing mills, each finishing mill having a roughing mill of its own. The roughing rolls are balanced and are driven by fully enclosed cut gears, a rather new development in sheet-mill practice, giving a very smooth movement and reducing the tendency of the pinion teeth to mark the sheet. A specially designed drag, known as the "Conklin" drag, is furnished. The roughing rolls are screwed up and down

by three blowers, of 4000 cu. ft. per min. capacity, which also furnish the air for the six annealing furnaces. Natural gas is used in all furnaces. The annealing furnaces are equipped with Freeman-type charging machines. The crane capacity over this mill is 30 tons with a 25 per cent overload and a 10-ton auxiliary.

The 26-in. cold-roll mill at the south end of the building consists of four stands of cold rolls driven by a 300-hp. motor. Construction

High-Temperature and High-Pressure Steam Lines

By B. N. Broido,[1] New York, N. Y.

The pronounced tendency of modern power-plant designers to use high superheat and high pressure, as well as the recent extensive use of highly superheated steam in process work, lead the author to make a review of the available data and formulas on radiation and friction losses in pipe lines. All tests to determine the radiation losses of pipe lines carrying high-temperature steam made in this country have been practically exclusively with electrically heated pipes. This paper gives results and an analysis of tests made with superheated steam flowing through a pipe line. The heat-transmission coefficients of bare and covered pipes at various steam velocities, superheats, and pressures are given. Suggestions are made regarding the steam velocities to be selected in order to transmit steam more economically.

The formulas available at present for figuring the friction losses of steam in pipe lines are limited to the range for which they were established, or for comparatively low pressures. Corrections of these formulas are shown in this paper, based on observations of a pipe line carrying high-pressure steam, which corrections may be used by designers of high-pressure power plants in dimensioning their pipe mains.

The paper further treats of pipe lines carrying superheated steam for other purposes than power. Recommendations as to the velocities or pipe sizes to be chosen are given, as well as a few examples from practice to show how the velocities selected were advantageously applied.

The use of superheated steam in power plants, as well as for various kinds of process work, has become so extensive during recent years that it is hardly necessary to enlarge on its advantages. The fuel saving effected by the use of superheated steam, the lower maintenance cost of turbines using it, and the numerous advantages it has in various kinds of process work are some of the factors which have helped to assign to it the important position it now occupies in the opinion of technical men.

One of the phases in which engineers, power-plant operators, and managers are naturally interested in this connection is that of conducting superheated steam through pipe lines. Very little, however, has been published in this country on the subject.

The recent tendency in designing power plants, particularly those of large size, is toward high pressures. The high temperatures and high pressures involve new problems, among others being that of proportioning the pipe lines. A study of the losses of heat and pressure in pipe lines carrying highly superheated and high-pressure steam at the present opportune time will aid the designer in dimensioning the steam lines.

The field is very large, and this paper will therefore be confined to the discussion of—

a Radiation losses in pipe lines carrying superheated steam
b Resistance to the flow or pressure drop of superheated steam in pipe lines
c The most advantageous steam velocity, particularly for high-pressure lines; and
d Other features to be taken in consideration in designing pipe lines for transmission of superheated steam of either low or high pressures.

Radiation Losses in Pipe Lines Carrying Superheated Steam

Up to the present the usual method of determining radiation losses has consisted in supplying saturated steam to a pipe either naked or covered with a definite thickness of lagging, and weighing the amount of steam condensed. Such experiments, however, are mostly inaccurate, due to the fact that no separator completely removes the moisture from the steam, and also because of the difficulties in completely draining the tested pipe. So far as the author is aware, no experiments with superheated steam in pipe lines have been made in this country.

The author has had the opportunity to study this subject and to examine the results of tests conducted in Europe in which both saturated and superheated steam were used, particularly the tests made by Dr. Bernard and Herr Eberle of Magdeburg and Munich, respectively.[1] Table 1 shows the results of tests with saturated steam in bare pipes of approximately 3 in. and 6 in. internal diameter. The surfaces given in the table include the surface of the flanges. It is of interest to note that while the temperature of the pipe wall was very near to that of the steam, the temperature of the flanges was slightly lower. The difference in some cases is as high as 30 deg. fahr.

The tests were also conducted with different types of insulation, the results, however, being similar to those obtained in like tests in this country.

Tests to determine the heat loss by transmission of superheated steam can be carried out only with steam that is flowing. The heat content of steam, both at the inlet and outlet of the pipe, must be determined, and the difference multiplied by the amount of steam flowing through the pipe gives the heat loss. Superheated steam flowing through a pipe may change its heat content—

a By decreasing its temperature
b By pressure drop
c By partial condensation.

The accurate measurement of any condensed water would be impossible, due to the fact already mentioned that separators are not reliable. To be accurate, tests with superheated steam must therefore be conducted with sufficiently high temperatures so that the temperature of the pipe wall at the outlet does not descend below that of saturated steam at the same pressure.

TABLE 1 HEAT LOSS FROM 3-IN. AND 6-IN. BARE PIPES—SATURATED STEAM

Knowledge of the wall temperature was considered important, not only to determine the minimum superheat required to eliminate condensation, but also to determine the coefficient of heat transfer from superheated steam to a pipe wall.

In view of the fact that the velocity of superheated steam doubtless has an influence upon the heat transmission, tests were conducted with different velocities. The results of tests conducted with bare pipes were highly impressive. At a velocity of about 100 ft. per sec. and steam temperatures of 291 to 390 deg. cent. (556 to 734 deg. fahr., corresponding to 221 and 399 deg. super-

heat), the temperature difference between the steam and pipe wall was 34 deg. cent., while α_1 the heat-transmission coefficient was 35. With steam velocities of 33 ft. per sec. the difference between the steam and the pipe-wall temperatures was greater. At the lower steam temperatures of 220 to 267 deg. cent. (428 to 513 deg. fahr.) the temperature difference was 45 to 65 deg. cent. (86 to 122 deg. fahr.) and the heat-transmission coefficient α_1 was 16. By decreasing the velocity of the steam one-third, the coefficient of heat transmission between superheated steam and the pipe wall was decreased to one-half of the first value. This indicates clearly that the behavior of superheated steam is different from that of saturated steam as far as imparting heat to a metallic wall is concerned, which is due to the fact that saturated steam, in transferring heat to the pipe wall, partly condenses or gives up some of its latent heat, which heat is not as closely combined with the steam as the sensible heat of a liquid or the heat of superheat. This fact often is not understood, even by technical men.

While the results of the tests with bare pipe—particularly the variation of the heat-transmission coefficient at different temperatures and velocities—are not important in connection with pipe lines which invariably are insulated, they are of considerable interest as far as the use of superheated steam for heating and drying purposes is concerned.

The experiments demonstrate that the heat-transmission coefficient increases considerably with the increased velocity, and also that the wall temperature depends not only upon the steam temperature but also upon its velocity.

Table 3 gives the results obtained with superheated steam in covered pipes. The same covering was used as for the test with saturated steam. A comparison of the values of Tables 2 and 3 for saturated and superheated steam in covered pipes brings out the fact that for the steam-temperature range from 100 to 200 deg. cent. (212 to 392 deg. fahr.), with either saturated or superheated steam, the heat-transmission coefficient K remains practically the same. With increased temperatures this coefficient shows a tendency to rise considerably. For temperatures from 100 to 200 deg. cent. (212 to 392 deg. fahr.), K for lines with pipes and flanges covered is about 0.47. It increases, however, with the steam temperature, up to 0.69 at 400 deg. cent. (752 deg. fahr.).

While from the tests one would conclude that the direct radiation losses for superheated steam are not appreciably lower than those of saturated steam of the same temperature, there are, however, a few other points to be considered in estimating the relative advantages of the two so far as their transmission through pipe lines is concerned. With saturated steam any heat radiated causes a part of the steam to be condensed, and the condensate, particularly for long pipe lines, is not returned to the boiler but is discharged through traps and wasted, so that in addition to the direct heat lost by radiation there is a further loss of the liquid heat of the condensate, which in some cases, particularly for high-pressure steam, may amount to 25 per cent of the radiated heat. With superheated steam the heat lost only decreases the temperature and no condensation occurs as long as the steam remains superheated so that no additional heat besides that radiated is wasted.

Another important fact to be considered in connection with superheated steam is that a considerably higher velocity in the pipe lines is permissible. The velocity of the steam in a pipe, or the size of the pipe, is usually determined by the maximum friction loss or pressure drop which can be allowed.

Due to the low pressure drop and high velocity possible with superheated steam a greater amount of steam can be transmitted with the same pipe, so that the radiation losses per unit weight are less. Therefore, in order to make a fair comparison between the radiation losses in carrying superheated and saturated steam, not the direct heat should be considered, but the total heat losses in percentage of the heat conveyed in the steam through the pipe. Table 4 gives the heat losses in pipe lines from 4 to 12 in. in diameter for saturated steam and for steam superheated 100, 150, and 200 deg., at gage pressures of 100, 150, and 200 lb. The values are calculated using the heat-transmission coefficients as given in Tables 2 and 3, and the values for saturated steam include the liquid heat of the condensed steam.

Pressure Drop of Superheated Steam in Pipe Lines

The question of friction loss in pipe lines carrying gases or vapors has been studied by many authorities, and a number of formulas have been established which differ considerably. The author has had the opportunity of making observations on the friction loss in long pipes with both superheated and saturated steam, and after a considerable study of the subject, has come to the conclusion that, particularly for long pipe lines and moderate pressures, the formula—

$$P = \frac{CW^2L\left(1 + \frac{3.6}{d}\right)}{Vd^5}$$

which varies with the diameter of the pipe—using the coefficient 0.0001321 suggested by Babcock—is approximately correct for smaller pipe lines up to 4 in. in diameter; while for larger pipes, especially with wet steam, the formula $P = CW^2L/Vd^5$, with the coefficient suggested by Martin, Hawksley or Gutermuth, varying from 0.0003135 to 0.0003557 and depending upon the wetness of the steam and the surface of the pipe, is more likely to be correct.

For superheated steam with low temperatures and low velocities so that the wall temperature is lower than that of saturated steam and the walls are therefore covered inside with a film of water, the pressure drop is approximately the same as that of dry saturated

steam. With higher temperatures, higher velocities and correspondingly higher wall temperatures so that the pipe remains dry inside, the coefficient C for superheated steam varies not only with the diameter of the pipe but also with the velocity, the pressure, the absolute temperature, and the density; and the friction loss agrees closely with that observed by Fritsche,[1] so that his suggested

formula for the coefficient C which follows can be considered reliable and used safely in calculating the pressure drop for long pipe lines carrying superheated steam and moderate pressures:

$$C = 0.0000022\ (R/144)^{0.148}\ (T/pw)^{0.148} d^{-0.269}$$

In order to facilitate the use of this formula a table was calculated giving for air (R = 53.34) the values of 1,000,000 C corresponding to values of the ratio T/pw for pipe diameters ranging from 1 in. to 48 in. This table is given in Marks' Mechanical Engineers' Handbook. When used for steam its values must be increased by 7 per cent on account of the different value of R used.

[1] Mitteilungen über Forschungsarbeiten, V. D. I. (Berlin), Heft 60.

As far as the author knows, all formulas for determining pressure drop, particularly for steam, are based on tests where the pressures in no case exceeded 300 lb. per sq. in. For higher pressures they should be used with caution. In his extensive study of this subject and search for a formula which would cover all conditions, Biel[1] found that the pressure drop caused by the resistance to flow of any fluid, for the same diameter of pipe, the same length, the same temperature, and the same constant R, can be expressed by the equation $P_d = CW^n p^m$, in which the values of the exponents are $n = 1.852$, $m = 0.852$. Approximately the same values were found by Brabbée,[2] who made extensive tests, particularly to determine the resistance, in pipe lines, for high- and low-pressure steam and hot-air heating. He found, however, that the exponents vary with the roughness of the pipe. For steel pipe his exponent is 0.853.

The question arises as to how far the known formulas for the resistance of flow are applicable to high-pressure and high-temperature steam. It is the opinion of the author that the pressure drop in *straight lines* carrying superheated steam of 300 to 600 lb. pressure is from 10 per cent to 25 per cent less than that calculated by the use of the existing formulas for moderate pressures.

A comparison of the results of tests made at pressures between 250 and 440 lb. with those obtained by using the Fritsche formula bears out this statement. The pressure drop in fittings and bends was carefully determined by mercury U-tubes, and the resistance to the flow, which is usually expressed in lengths of straight pipe, was considerably higher than formerly supposed. As compared with the formula of Conrad Meier, given in the paper of D. E. Foster,[3] the values obtained were from 20 per cent to 35 per cent higher.

The foregoing would tend to show that most of the pressure drop in pipe lines takes place in the bends, fittings, and valves, especially the latter, rather than in the straight pipes. In particular, sudden restriction of area and change in direction of flow affect the pressure of the steam. This has been verified by careful tests even with moderate pressures.

Best Velocity of Steam Flow for Use in High-Pressure Lines

It is therefore apparent that in pipe lines carrying high-pressure steam, provided they consist of long, straight pipe sections, high velocities are permissible, and for high pressures—say, from 300 to 500 lb.—10,000 to 12,000 ft. per min. seems to be the most advisable for lines over 5 in. in diameter and with a continuous steam flow, as, for instance, when the steam is used in turbines. With reciprocating engines, naturally, lower velocities are to be chosen, depending upon the length of the line, the percentage of cut-off, and the number of revolutions of the engine. For high-pressure reciprocating engines located at a considerable distance from the steam generator it was found advisable to make that portion of the steam line near the engine of a larger diameter in order to minimize the fluctuation of the steam flow due to the intermittent steam demands of the engine, and to allow higher velocities by means of a correspondingly smaller pipe diameter, near the boiler.

If a line carrying high-pressure steam contains a number of bends, fittings, and valves, lower velocities than those mentioned in the preceding paragraph should be employed if excessive pressure drop is to be avoided.

The higher cost of the larger sizes necessitated by lower velocities, and the strength of the material required for higher pressures, are factors to be taken in consideration in determining the size of the line.

The table previously mentioned giving values of 1,000,000 C is intended only for low pressures. Table 5 has therefore been devised to give values of the same quantity for pressures up to 600 lb. and any superheat. Table 6 gives the pressure drop and radiation losses for pipes from 8 to 12 in. in diameter and for 300 to 400 lb. pressure.

Pipe Lines Carrying Superheated Steam for Other Purposes Than Power Generation

The question of friction losses or pressure drop in a pipe line, particularly with superheated steam, is of importance only when the steam is used for generation of power. If it is used for heating, drying, or process work, only its temperature need be considered, the pressure being of no consequence. Higher velocities can therefore be chosen. Very often the pressure has to be reduced before the steam be used, and a pressure drop in the pipe line is even desirable. With saturated steam, however, it is necessary to limit the velocity. The usual velocities with saturated steam in commercial pipe lines are about 3000 to 6000 ft. per min. Any considerably higher velocity increases the danger of water hammer, particularly in long lines with a number of bends, fittings, and changes in diameter, and when the line cannot be completely and continuously drained. In such lines high velocities with saturated steam cause considerable vibration, especially when *much* moisture is carried with the steam, due to the effect at higher velocities of the greater weight of water at any change in direction of the flow.

With superheated steam, particularly at sufficiently high temperatures, practically no moisture is present in the line, and nothing prevents the use of the highest speeds desired. Velocities of

[3] Effect of Fittings on Flow of Fluids through Pipe Lines, Trans. A.S.M.E., vol. 42, p. 647.

12,000 to 15,000 (and more) ft. per min. can be and have been applied in larger pipe lines without any undesirable effects. In figuring the total radiation losses in Table 4, velocities of 3000 to 5000 ft. per min. were assumed for saturated steam, and 6000 to 10,000 ft. for superheated steam, which are conservative values that enable a fair comparison to be made.

Table 4 shows that the greatest saving, as far as radiation losses are concerned, is obtained with 150 deg. superheat, so that when the steam is superheated only for the purpose of elimination of condensation or reduction of radiation, a moderate superheat of 100 to 150 deg., depending upon the length of the line, is sufficient. It does not mean, however, that moderate superheat is in general more desirable. If the steam is used for power purposes, the advantages of high superheat in the prime mover will more than overbalance the slightly higher radiation losses.

A remarkable feature is the very slight increase of pressure drop, which throughout the whole range of the table, with one exception, does not exceed 1 lb. for 100 ft. of pipe length, in spite of the fact that the velocity was doubled. The lower density of superheated steam, the absence of mositure, the dry pipe walls, and the reduced amount of foreign matter—the greatest part of which is usually left in the superheater—account for the low pressure drop.

It is commonly believed that even with superheated steam the pipe walls are covered on the inside with a film of moisture. This is true for low superheat with low steam velocities. At higher superheat and high velocities, however, the wall attains a temperature higher than that of saturated steam, and remains dry.

Examples Showing Advantages of Using Higher Velocities with Superheated Steam

The three following examples from actual practice demonstrate how the possibility of applying higher velocities with superheated steam may be advantageously utilized in reducing the radiation losses and the cost of the piping and covering.

The management of a large textile concern, realizing that it was necessary to lower their power cost, decided as one means to this end to avail themselves of the advantages of superheated steam. Each of the five boilers in the plant was accordingly equipped with superheaters for 200 deg. superheat.

The steam was for use in two engines, one triple-expansion and one compound. The compound engine was located about 950 ft. from the boiler house. The piping between boiler and engine was entirely changed, the old 8-in. piping, being replaced by a new 6-in. line. With the old piping and saturated steam the average pressure drop in the line between boiler and engine was 6 lb. With the new line and superheated steam it was 7.5 lb. The comparatively low pressure drop in the new line was mainly due to the appreciably decreased steam consumption of the engine. The radiation loss of the 8-in. line would naturally be 33 per cent higher than that of the 6-in. line for the same steam temperature.

A chemical company manufacturing aniline dyes had an 8-in. pipe line, 1400 ft. long, in their plant, conveying steam from their boiler room to the process house. An increase in production required the approximate doubling of the steam consumption in the power house, and a second pipe line accordingly was planned. At the same time the use of higher temperatures was found advisable, since the boiler pressure could not be increased appreciably. Superheaters were installed in the boilers, and approximately double the amount of steam superheated was sent through the pipe. Pressure drop was of no consequence, while the radiation loss per pound of steam conveyed was decreased 36 per cent.

A heating plant had two mains 10 in. and 8 in. in diameter and 2300 ft. long. The 10-in. line was used in the cold winter months, while the smaller one was utilized during the remainder of the year. With saturated steam the larger steam demand in the winter months could not be supplied with the small pipe alone, due to the danger of water hammer and excessive vibration, and the larger pipe had to be used. In order to have dry steam at the end of the line, and avoid the losses in liquid heat of the steam condensed in the line, superheaters were installed, and it was found that the greater amount of steam could be conveyed through the smaller pipe without any difficulty. The radiation loss as compared with the 10-in. line was 20 per cent less.

Discussion[1]

Geo. A. Orrok[2] said that the author had once more emphasized that if the outside surface was kept low, and arranged so that it radiated but little, the pipe-line losses would be small. He had covered the velocity of steam in pipes up to 10,000 ft. per min. This was a very ordinary velocity for power plants; in most cases the velocities were greater. It should always be borne in mind that losses were proportional to the surface and not to the amount of steam in the pipe.

J. A. Barnes[3] wrote calling attention to a power plant at Conneaut, Ohio, operating with saturated steam through a pipe line between 400 and 600 ft. long. At this distance it was impossible to operate the engine at anything like its full capacity. Superheaters were installed and about 100 deg. of superheat was obtained at the engine, and the capacity was materially increased. At the Bellman-Brook Co., a finishing company in Fairview, N. J., superheaters were installed which gave from 100 to 150 deg. of superheat, and the output of the plant was increased approximately 35 per cent due entirely to the elimination of radiation losses.

W. H. Armacost[4] said that he had plotted some comparative curves, taking the data from papers presented before the Society by Messrs. McMillan, Bagley, Heilman, and the author. The curve plotted from the data of Mr. Broido's Table 3 bore out his statement that there was less radiation by using superheated steam in pipe lines than with saturated steam, due to the fact that saturated steam, in transferring heat to the pipe wall, partly condensed or gave up some of its latent heat, which heat was not as closely combined with the steam as the sensible heat of a liquid or the heat of superheated steam.

J. H. Lawrence[5] stated that in designing the Hell Gate station, probably the largest in the country, the losses in the steam line had been compared with the losses estimated by various formulas, and while there should have been a very excessive drop in the lines, the loss was only about half that given by any formula in the handbooks, and so small that it was almost negligible.

He did not believe in low velocities. The author mentioned 10,000 ft., but he considered this too low for most steam pipes in a large station. His concern used as a maximum 15,000, and in certain cases, where the lines would only be used in case of an emergency, they did not hesitate to go to 20,000 ft. per min. In most handbooks there were certain rules about velocity which provided for 6000 or 8000 ft. for saturated steam and 10,000 for superheated steam. Such information was very misleading.

Their experience has shown that the velocity should increase as the size of the pipe increased. For one particular case, if a 2-in. pipe was used, the velocity would be around 2000 ft. per min., otherwise the losses would be very excessive. With a 6-in. pipe the proper velocity would be about 6000 ft., and so on. On the 14-in. size they figured about 14,000 ft. velocity as the minimum. They had stopped there, however, as they did not wish to go as high as 20,000 ft. in ordinary practice.

E. G. Bailey[6] said that the steam meter had now become such an integral part of the plant equipment for measuring the output of boilers, steam consumption of turbines and various units as well as the steam distribution, that the conditions suitable for the installation of such meters should be considered not only in the selection of the proper size of pipe but also in the layout.

One meter manufacturer used limiting velocities of $V_{max} = 8000\sqrt{\text{sp. vol.}}$ and another $V_{max} = 10{,}500\sqrt{\text{sp. vol.}}$ With steam at 250 lb. pressure and 200 deg. fahr. superheat having a specific volume of 2.35 the maximum velocities would be 12,240 and 16,000 ft. per minute, respectively. These velocities were capable of being metered accurately only when the steam was flowing through straight pipe of reasonable length on either side of the primary device.

L. B. McMillan[7] stated that it was a matter of common knowledge

that heat was transmitted much more readily from saturated steam to a surface than from superheated steam. However, granting a large difference in transfer coefficients from saturated and superheated steam to pipe wall, the question was, how much difference would this make in actual heat losses?

The value of α for saturated steam used by the author was over twelve times that for superheated steam and it would be only natural to expect that the loss from the saturated-steam pipe would be far larger than that from a superheated-steam pipe at the same temperature. Such would be the case if the transmission of heat from steam to pipe wall were the only factor involved, but the heat must be transmitted from the outside of the pipe to the air, or through insulation to the air. Therefore the additional resistance to heat flow was so great outside of the pipe that the difference in inside resistances became very small in comparison.

In the case of bare pipes there were larger differences, but even with bare pipes the differences were of the order of only 10 per cent. These differences, however, were of little importance as few bare pipes were used for the transmission of superheated steam.

Most published tables on heat losses from bare pipes were based on loss per square foot per degree temperature difference between *pipe surface* and air. These were therefore correct for the stated condition, regardless of what was inside the pipe.

Referring to Table 4, in which a lower radiation loss per pound of steam was shown for superheated steam than for saturated steam, this result was based entirely upon the assumption that the velocity in superheated-steam lines was exactly double the velocity in saturated-steam lines. This table showed higher actual radiation losses on the superheated-steam lines, but on the basis of the doubled velocity so much more steam was passed through the superheated-steam lines that the loss per pound was shown to be less. An explanation of just why the author assumed a doubled velocity in the superheated steam line instead of some other ratio would be necessary in order to give significance to this table.

In fact, it was Mr. McMillan's understanding that the practice of calculating steam-line sizes on an assumed velocity was antiquated and that the preferred method was one based on allowable pressure drop.

L. L. Barrett[8] stated that those engineers who had occasion to consider the heat losses from bare pipe lines conveying steam would be grateful to the author for his presentation of extracts from Eberle's paper which had never before been translated into English.

Referring to the tables in the paper, the heat losses on which Tables 1 and 2 were based had been obtained by weighing the water condensed in the pipe line under test. This method was inaccurate, as stated by the author, and the later determinations of McMillan, Bagley, and Heilman were preferable. The constancy of the value of K for the covered 3-in. line in Table 2 was a good illustration of the inaccuracy of this table. Both McMillan and Bagley had shown that this value would vary considerably with the temperature difference.

The comparison in Table 4 was based on the assumption that all the condensation from the saturated steam lines was wasted. It could not be admitted that this was the general practice in power plant or marine work. In such cases it was almost the invariable practice to return the condensation to the boilers. Any other practice would be most wasteful and would result in a poor showing for the heat cycle of the plant.

It would be interesting to know on what basis the radiation losses for superheated steam in Tables 4 and 6 had been figured where the steam velocities were shown as 7000, 8000, and 10,000 ft. per min., as the highest steam velocity on which data were given in the paper was but 5910 ft. per min.

Referring to the author's summary (appended to the complete paper) no data were given to support the heat-transmission coefficient between steam and pipe wall of 400 for saturated steam there mentioned. The values of this coefficient found in the experiments of Clement and Garland at the University of Illinois ranged from 1649 to 2740 and the value found by McAdams and Frost at the Mass. Inst. of Tech. in 1922 was 2400.

[8] Mgr. Engrg. Dept., Keasbey & Mattison Co., New York, N. Y. Assoc-Mem. A.S.M.E.

The author's conclusion that the coefficient of heat transmission from steam to air remained practically constant up to a temperature of 350 deg. fahr. was disproved by the work of McMillan, Bagley, and Heilman, all of whom showed a very large increase in the coefficient between 100 deg. and 350 deg. fahr. in the case of bare pipe. The increase in the coefficient from 100 deg. to 350 deg. temperature difference was 60 per cent according to Heilman's paper.

The author, in his closure, said that it was very true, as had been stated by Mr. Barrett, that the analysis of radiation losses in pipe lines in the paper was not based on the experiments of Messrs. McMillan, Bagley, and Heilman, all of which were made with electrically heated pipes, and the object of which was mainly to determine the efficiency of various types of pipe covering. His paper was not intended for this purpose. Its object, particularly the first part dealing with radiation losses, was to show, first, that there was a difference between saturated and superheated steam as far as imparting of heat to a pipe wall was concerned; and second, that in comparing the radiation losses of saturated and superheated steam, not the direct heat in B.t.u. was to be considered, but the total heat losses in percentage of the heat conveyed in the steam through the pipe. As the Munich tests were believed to be the only extensive ones conducted with saturated and superheated steam flowing in the test pipe, only these tests could be considered and analyzed in the paper.

Mr. Barrett had looked at the paper only from the standpoint of pipe covering, and therefore had noticed only the data showing the radiation losses. If he would look upon the paper as an engineer and would consider steam velocities, temperature differences, pressure drops, etc., he would better realize the object of the paper and would understand the analysis presented.

Mr. Barrett objected to value of 400 given as the heat-transmission coefficient between the steam and pipe wall because other investigators had found it to be considerably higher, or up to 2700. From Table 1 of the paper it would be seen that at a temperature difference between the steam and the outside air of 250 deg., the heat loss per square foot of surface per hour in B.t.u. was 750. With a heat-transmission coefficient of 400, the temperature of the wall must be $750 \div 400 = 1.875$, or less than 2 deg. below the steam temperature. At a wall temperature equal to the steam temperature, the coefficient would be infinitely large. As it was very difficult to measure accurately the temperature of the steam and the pipe wall, and a difference of 2 deg. was likely to occur, the value of coefficient could not be definitely fixed. Four hundred was mentioned in this paper only as a comparison with the value of superheated steam, which was only 32 at a velocity of about 80 ft. per sec.

As Mr. Armacost had said, the difference between the data of the tests analyzed in the paper and those of Messrs. McMillan, Heilman, and others, was very slight.

Mr. McMillan wondered why the difference between the heat transmission of saturated and superheated steam had been gone into in such detail. As mentioned early in the paper, this subject was of considerable interest as far as the use of superheated steam for heating and drying purposes was concerned. So far as the author was aware, the influence of the velocity of superheated steam on the heat transmission, particularly in connection with the question of whether the pipe was wet or dry inside, had never before been discussed, and was believed to be of considerable interest to engineers.

The velocities taken in Table 4 were in accordance with general engineering practice. The pressure drop was only slightly higher than that for saturated steam and, with the exception of one case, did not exceed 1 lb. throughout the range of the table.

With reference to the question asked by Mr. C. W. Gordon[9] as to why the friction in pipe lines at high pressures was less, while in fittings it was higher than that derived by calculating according to standard formulas for moderate steam pressures, he would say that this was probably due to the fact that in fittings the steam changed its direction and a part of its kinetic energy was lost, and that this was more pronounced at higher pressures than at the lower ones.

Management Engineering in the Paper Industry

The Measurement of Performance a Factor in Good Management—Industry Should be Organized to Encourage Rather than Repress Individual Development

By R. B. WOLF,[1] NEW YORK, N. Y.

THE most difficult problem that the paper-mill manager has to solve is the problem of overcoming the resistance of the practical operators to the introduction of scientific manufacturing methods. He must depend upon his superintendents, department heads, and foremen for the carrying out of his ideas, and if he can produce in them a desire to improve existing conditions, rapid progress can be made.

The reason the so-called practical operator finds it difficult to follow the scientific or inductive method is that he has not been taught how. The things he knows about paper making he has learned by seeing the things happen. His knowledge, therefore, is made up of a great many more or less disconnected facts, which, due to a lack of scientific training, he has not learned to put together into principles or laws. This in no sense reflects discredit upon the practical man. He has simply lived his life in an environment where it has not been customary to use the scientific method of keeping accurate records of his past experiences. The lack of ability to develop general principles from particular instances can be overcome only if the management encourages the operators, particularly the department heads and foremen, to record the various happenings so that they can be studied in their relationship to one another.

In the past four or five years great progress has been made in measuring the quality elements in paper, and numerical values have been given to such elements as strength, weight, moisture, finish, formation, cleanliness, bulk, and color. In each case a numerical value indicates the nearness to an ideal 100 per cent standard.

One large company has for some time made it a practice to compare the output of each of its mills with the product of a number of outside mills, with whom samples are exchanged, recording in this way the individual performance of each producing unit. Of course such records stimulate interest in the factors which affect the various quality elements. For instance, both weight and moisture are affected by the amount of water in the stock flowing on to the wire of the paper machine, the slowness and freeness of the stock, the amount of agitation in the flow box of the paper machine, the stock proportions in the furnish, the pitch of wire, and many other factors of a similar nature. It is important to note that interest in recording these factors has been aroused by the discovery that the only way to control the quality elements is to control the factors which affect them. This control, however, is not possible, unless the management provides means for keeping individuals who are responsible for variations in quality constantly informed as to what is happening.

The science of paper making in the past has been too much like the old pseudo-sciences, where sense impressions governed. The immense waste attending the use of such methods makes it imperative for us to change them. There is plenty of evidence that the art of paper making is beginning to be based upon real scientific knowledge, and the publication of a complete set of textbooks by the Canadian and American Technical Associations is the best testimony that a genuine spirit of scientific inquiry is developing in the paper industry. As a result of this excellent piece of work it is now possible for the student of paper making to familiarize himself with the best paper-making practices of the past, and the manufacturer can avoid much costly duplication and experiment.

To insure continued progress, however, it is necessary that the group leaders become more skilful in recording and evaluating manufacturing processes. This evaluation of progress, however, is an individual thing and it is therefore necessary to understand the nature of the individual, particularly that very important individual, the superintendent or foreman, who will quite naturally block any effort to introduce methods which he does not himself understand. Any one who has ever tried it knows that scientific record keeping, by technically trained men, will bring to light many practices that should be changed, and this, of course, puts the head of the department on the defensive. He feels that he is *supposed* to know all about his job and in spite of assurances that he could not be expected to know what was not known before, he will, in the great majority of cases, remain on the defensive.

Departmental Cost Sheets Stimulate Economy

Our own experiences have taught us that the best way to produce an open-minded attitude is to introduce a system of departmental cost sheets, which will reflect the economy of operation in each department. No superintendent or department head will object to the introduction of such economy records, and the far-reaching effect of such a cost-keeping system will be seen by a few instances taken from actual experience.

In one plant the introduction of steam meters in order to charge the steam used to each operating department led to such an interest in steam usage that it was possible to avoid the installation of a new boiler, and finally to shut down the spare boiler which it had been previously necessary to keep in almost constant use. The department heads were no longer indifferent to leaky traps on the steam coils, poor insulation on steam pipes, the excessive use of steam in manufacturing processes, etc., for all of the steam used by the department had to be paid for and reflected itself in the cost sheet as uneconomical performance. Not only did the operating department head take an interest in the amount of steam used, but also in the cost of steam. So it followed that the head of the steam department soon found it necessary to know why the cost of making steam was high. Then came the installation of steam meters on each individual boiler unit, and the measurement of coal to each unit so that evaporating efficiency could be determined. Draft gages, CO_2 recorders, etc., of course, followed, for without them the reasons for low evaporation could not be known, but only guessed.

The important thing to remember is that intelligent cost keeping is sure to produce a demand from within the department for the introduction of scientific record keeping which will explain variations in cost, whereas the introduction of scientific methods without first stimulating an interest in economy of operation usually arouses suspicion.

Departmental cost sheets, which show the actual cost of stock in the paper, will soon bring about an inquiry as to the reasons for high shrinkage, and a demand for accurate records of the fiber losses invariably follows. One important development along this line has been the working out of a method for making continuous moisture determinations in the paper coming off the paper machines, making it possible for the machine operator to save stock by not overdrying the paper. The use of this method in the newsprint industry alone has saved literally hundreds of thousands of dollars, for, as shown by the figures of the News Print Service Bureau, an average of considerably over one per cent more paper is now obtained from the same raw materials.[1]

Maintenance of Individuality a Prime Necessity

In his paper on Non-Financial Incentives[2] the author showed the very great savings made in repair materials when cost records were furnished to responsible individuals in a large manufacturing organization, so further illustration is not needed. What it seems to him is needed, however, is a clear understanding of what constitutes individuality. If those entrusted with the direction of our industrial

[1] The R. B. Wolf Company, New York, N. Y., Mem. A.S.M.E.

Contributed by the Forest Products Division for presentation at the Spring Meeting, Montreal, P. Q., Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. All papers are subject to revision.

[1] Approximately 2,500,000 tons of news paper is made a year. Assuming an average price of \$35 per ton for raw materials in this paper, a conservative estimate of $1\frac{1}{4}$ per cent increase in the moisture test shows a saving of over \$1,000,000 a year.

[2] Trans. A.S.M.E., vol. 40 (1918), p. 925.

plants do not have a clear understanding of this principle, they cannot effectively instil the principles of sound economics into their organization.

John H. Williams pointed out before the Cost Accountants Association, at Cleveland, that the first thing to do before a cost system is set up is to determine managerial responsibility. Once this is done the group individuality becomes clearly defined and quality and quantity records are sure to follow. Science, in other words, will replace "rule of thumb."

There is, perhaps, no principle of life which is so difficult to understand as this principle of individuality. "Who can tell," says Bergson, "where individuality begins or ends; whether it is the cells which associate themselves into the organism, or the organism which dissociates itself into the cells?" The principle, however, must be understood, for otherwise mankind is doomed to eternal conflict with his fellow-men.

In no other period of the world's history has the group spirit found such material expression as in this twentieth-century development of corporate industry. In the past men have combined into groups for productive purposes, but never before have we seen such grouping of groups and these larger groups into still larger corporate units, and the startling fact is that most of this has taken place within the lifetime of the men who are still in active charge of industry. What is the meaning of it all, and what is to become of the individual men in the process? This, the author believes to be the most momentous problem confronting modern civilization, for if it is not solved, civilization as now constituted cannot last. To crush out the individuality of the workman is fatal to human progress and it is also fatal to destroy the individuality of our manufacturing or producing units.

One of the very first things to recognize about the principle of individuality as related to industry is that it has three modes of expression in any given plant:

First, it expresses itself through each individual worker

Second, it expresses itself through each individual group, or department, which has a specific function to perform; and

Third, it is expressed by the plant as a whole.

The next thing to recognize about individuality is that its purpose is to record a lapse of time. Progress must be made from one point in time to another point in time, and it is the very essence of individuality to preserve a record of the changes which have occurred between a sequence of time periods. To illustrate: the year is usually divided into twelve monthly periods and for each month we have records of Quantity of Paper Produced, Quality of Paper Produced, and Cost of Paper Produced. It is only by studying these records of *past* performance of the plant as a whole that we can get a sense of what has been accomplished and, what is more important, a vision of what may be accomplished in the future.

The plant, however, is made up of departments, each of which contributes its individual share to the enterprise. Therefore, to get the most effective results, similar monthly records should be kept for each department, such as the quantity, quality, and cost of pulp produced; the quantity, quality, and cost of steam produced; or the quantity, quality, and cost of the output of each department of the plant.

Finally, all departments are composed of individual men and we have found it equally necessary to the cause of sane and rational progress to record for the workman's benefit the quantity, quality, and cost of performing his work. It is not always practical to record all of these factors, but always one can be recorded, sometimes two, and sometimes all three. It goes without saying that the workman who is conscious of all three will see how his own job is related to the process as a whole and can work with a much greater degree of intelligence.

The periods or points in time between which the records enable us to note changes, vary in both duration and frequency of occurrence. In processes where rapid changes occur, as in the weight of paper on paper machines, or temperatures in cooking digesters, the periods are short and are usually measured by minutes; in the case of average temperatures, paper-machine speeds, or evaporation records the periods are longer and are measured by hours; and in the case of many quantity, quality, and cost records the periods represent averages for days, weeks, or months.

In each case, however, it should be noted that we are measuring the progress of a producing unit and that these individual producing units are either men, groups (operating departments or divisions), or the plant as a whole.

It is not difficult to visualize the concrete reality of the first of these producing units, the man. It is difficult, however, to visualize the essential unity of the department or the unity of the plant itself, of which the department is an individual member.

There is perhaps nothing more concrete and practical and at the same time more abstract and theoretical than this problem of developing these indivisible group individualities. The author feels sure that the way out is to come to a realization that the purpose of the individual is to create, whether the individual is a *man* creating (converting) pulp from wood on a grinder, a *department* creating chlorine liquor from salt and lime, or a *plant* creating paper from wood, clay, size, color, and all the various raw materials which furnish the energy or the substance used in the manufacturing process.

As indicated before, the answer seems to lie in increasing our skill in recording and evaluating the manufacturing process, so that consciousness of what has happened in "times" past may stimulate an interest in improvements to be made in "times" to come.

Just as the man's interest in the future economy of his own performance is aroused by making him conscious of the economy with which he has performed in the past, so must the group consciousness of economy be aroused by providing a record of past group performance. Unless group individuality (*esprit de corps*) is developed there can be no sense of responsibility and hence no progressive group accomplishment. It is obvious, therefore, that we must develop records for enabling the individuals who comprise the group to be conscious of what the group, *as a unit*, is accomplishing. Without this definite knowledge of progress made there can be no coöperative teamwork and the progress will be in the direction of quantity, with little thought of improvement in quality of performance or economy of operation.

What is true of the group or department is of course equally true of the plant as a whole, so each individual department must be conscious of the effect of its own activities upon the finished product. The point that must not be lost sight of is that this is not possible without a constant recording of the effect of variations in departmental products upon the finished product.

Quantity, quality, and cost should all be recorded, and if these records are kept *of* men, departments, and plant and made available *to* men, departments, and plant, there will be released very great creative power in the only way it can be released, namely, through the individual, whether that individual be a *man*, a *department*, or a *plant*.

"Our social economic system cannot march toward better days unless it is inspired by the things of the spirit. It is here that the higher purposes of individualism must find their sustenance."[1] Herbert Hoover, who says this, has a concrete record of accomplishment to his credit which makes these mystical words take on new meaning, especially when taken with his expressed conviction that "permanent spiritual progress lies with the individual."

Yes, the individual must be understood, and the whole problem of industry, it seems to the author, resolves itself into finding out how to enable the unit individual, the man, to become conscious of his relationship to the all-including group individual, the plant; and how to organize the plant so that it will be sufficiently sensitive to the welfare of the human units of which it is composed that it will not repress but encourage their individual development.

The secret seems to lie in stimulating group consciousness within the organic whole of the plant by continuously recording the group's relationship to the plant on the one hand, and the man on the other, and the immediate need seems to be for the education of foremen to intelligently direct the groups. This education, however, to be of use, must be largely obtained from a study of records of group experiences, for information obtained in this way constantly stimulates the individual to greater effort. The recorded results of this new effort will act again as a fresh stimulus, so that continuous progress in both knowledge of process and skill in the use of his knowledge is bound to follow.

The Oil Venturi Meter

Measurement of the Flow of Viscous Fluids with the Venturi Meter—Decrease of Coefficient with Turbulence—Influence of Viscosity—An Accurate Method of Calibration

By ED. S. SMITH, JR.,[1] LOS ANGELES, CAL.

THE venturi meter furnishes a means for accurately measuring the flow of liquids and gases in pipe lines within certain limits. These limits, however, must be known, and they are determined by the corresponding values of the turbulence, also known as Reynolds' criterion and defined by the method of dimensions as Qg/du. In the following paragraphs the author presents an accurate method of calibrating the venturi meter, shows the limit for accurate measurement, and brings out the fact that the viscosity of the fluid has considerable effect and must be accurately known. The theory underlying the method described is not essentially new, but has been discussed by W. J. Walker and W. N. Bond as noted in references at the end of the paper.

In order to use the venturi meter with accuracy there must be known not only the size and form of the tube but also the viscosity and density of the fluid. There are several standard viscosimeters in common use in the oil industry which are used to determine the viscosity of liquids with commercial speed and sufficient precision.

The values of the coefficient of the venturi meter have been determined for a wide range of turbulences. The coefficient approaches unity at high turbulences but drops rapidly just above the upper critical turbulence and approaches zero as the turbulence approaches zero. This falling off of the coefficient is due chiefly to the increase of the friction pressure loss of the tube relative to the theoretical pressure drop, i.e., that pressure drop causing the increase of velocity from the entrance to the contracted throat of the meter.

Fig. 3 is an example of the most convenient form of calibration for actual use, and is the result of two years' use of this method of calibrating the venturi meter with viscous oils.

Calibration by the Method of Dimensions

The increasing use of continuous processes in the oil-refining and other industries is bringing the venturi and other continuous flow meters into common use for the measurement of a large variety of fluids. As the viscosity of liquids may now be commercially determined, it is possible to use these meters with a method of calibration which is both simple and exact.

The method of dimensions has been in use for several years in the computation of friction pressure loss in pipe lines carrying viscous oils.[2]

The calibration has been extended to low values of the turbulence by employing data obtained by the author in tests conducted on a model venturi meter at the University of California. Grateful acknowledgment is made to Dr. Baldwin M. Woods, professor of aerodynamics, and to L. C. Uren, professor of petroleum technology, both of that institution, for their generous assistance.

The symbols and formulas used are as follows:

- Q = quantity, U.S. gal. per min
- q = quantity, cu. ft. per sec.
- u/g = kinematic viscosity, sq. cm. per sec.
- u = absolute viscosity, grams per cm-sec.
- g = density (specific gravity, approximately), grams per cu. cm.
- d = diameter of pipe, i.e., the same as the approach to the venturi tube, in.
- a = cross-sectional area of pipe, sq. ft.
- H = differential head of liquid in venturi tube from the approach to the throat, ft.
- h = differential head of mercury in manometer measuring H, in.
- C = coefficient for the venturi meter, see Equation [1]
- P = friction pressure loss in pipe line per 1000 lin. ft., lb. per sq. in.
- k = coefficient for friction pressure loss in pipe line, see Equation [2]

$$q = C \times a_2 \times \frac{a_1}{\sqrt{a_1^2 - a_2^2}} \times \sqrt{2 \times 32.2 \times H} \quad \ldots\ldots [1]$$

$$P = k \times g \times \frac{Q^2}{d^5} \quad \ldots\ldots [2]$$

Fig. 1 shows the value of the venturi-meter coefficient C as determined by actual experiments over a range of turbulence from 0.0003 to 200,000.

The friction-pressure-loss coefficient for pipe lines is also shown, the lower critical turbulence a occurring at 64 and the higher critical turbulence b at 85. From zero to 64 the flow is known as "viscous" or "streamline" flow, and the friction loss varies as the first power of the velocity. From 64 to 85 the flow may be termed "superturbulent," as the friction pressure loss varies as the cube of the velocity. From 85 to infinity the flow is known as "turbulent" or "hydraulic," and the friction pressure loss varies as a power of the velocity (the 1.75 power for smooth steel pipe lines such as are ordinarily used for oil transportation), with the square of the velocity as the upper limit for very rough pipe.

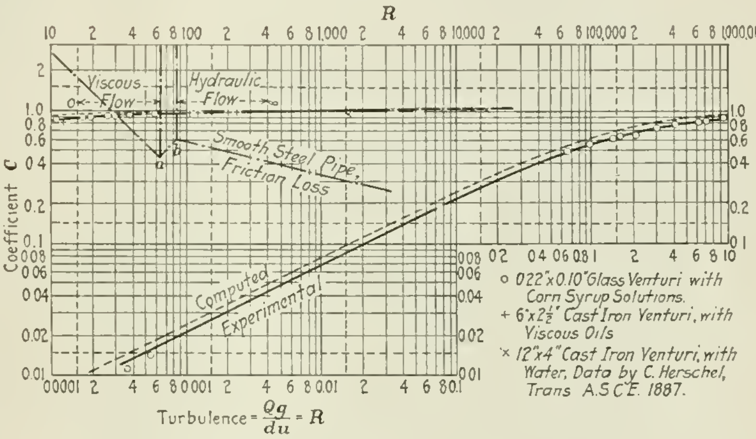

Fig. 1 Values of Venturi-Meter Coefficient C as Determined over a Range of Turbulence from 0.0003 to 200,000

As the coefficient of the venturi meter is partly dependent upon the friction pressure loss along the venturi tube, it is apparent that the law of variation of the coefficient with the turbulence will not be the same for the three types of flow and that consequently the graphical method of handling the coefficient is preferable to the use of an algebraic formula.

Fig. 2 provides an accurate calibration for the two types of venturi meters in common use in the United States, the Builders Iron Foundry and the Simplex Standard.

The Builders Iron Foundry tube has faired lines and consequently the higher coefficient. This calibration is for meters having a ratio of approach diameter to throat diameter of approximately 2.5 to 1, and is strictly correct for a 6-in. meter only—larger sizes having slightly higher coefficients and smaller sizes slightly lower coefficients. However, it is accurate enough for oil measurement under commercial conditions.

The Simplex Standard tube has a ratio of diameters of 2 to 1, and all sizes are made closely similar in form. The sharper changes from the cylinders of the approach and throat to the cone cause the coefficient to be slightly lower than for the other type of meter, but its accuracy is as high since it is necessary with both types of meter to use a calibration when measuring viscous oils.

Example in the Use of Fig. 2. Determine the quantity of oil flowing at 130 deg. fahr. through a 6-in. by 2½-in. venturi tube (Type B.I.F.) when the mercury-oil differential h = 4.2 in., the kinematic viscosity u/g = 0.11 sq. cm. per sec. (from 64 sec. Saybolt), the density of the oil flowing is g = 0.90 gram per cu. cm. (from 26 deg. B.), and the density of the same oil at 60 deg. fahr. above the mercury in the manometer is 0.94 gram per cu. cm. (from 20 deg. B. at this temperature).

Presented at the Pacific Coast Regional Meeting of The American Society of Mechanical Engineers, Los Angeles, Cal., April 16–18, 1923.

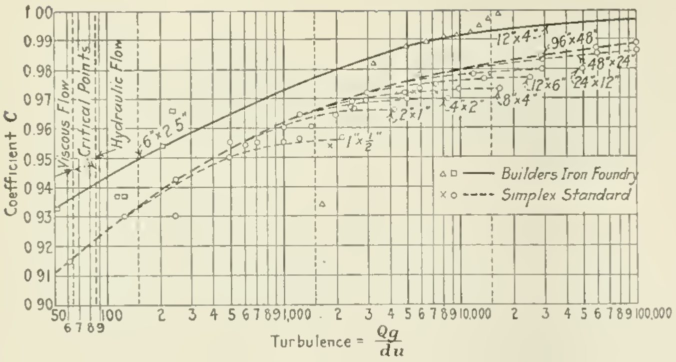

Fig. 2 Calibration for Two Types of Venturi Meters in Common Use in the United States

Since $d_1 = 6$ in., $a_1 = 0.196$ sq. ft.; also, from $d_2 = 2\frac{1}{2}$ in., $a_2 = 0.0341$ sq. ft. Substituting these volumes in Equation [1],

$$q = C \times 0.0341 \times 1.016 \times 8.02 \times \sqrt{H}$$

$$= C \times 0.278 \times \sqrt{H} \text{ cu. ft. per sec.}$$

For a first approximation, assume $C = 0.95$; then

$$Q = 448.9 \times 0.95 \times 0.278 \times \sqrt{\frac{13.6 - 0.94}{12 \times 0.90}} \times \sqrt{4.2}$$

$$= 263 \text{ gal. per min.}$$

But $Qg/du = \frac{263}{6 \times 0.11} = 400$, and from Fig. 2, $C = 0.962$; therefore

$$Q = 0.962 \times 278 = 267 \text{ gal. per min.}$$

which is the quantity flowing under the conditions stated above.

Fig. 3 consists of *Q-h* curves for each of several viscosities of oil. The full lines are accurate to 1 per cent. The broken lines are in the viscous-flow region and are of undetermined reliability. The density correction for the head *h* is applied by the graph at the left side of the figure. A graph for the conversion of Baumé density to specific gravity (density in grams per cu. cm.) is attached to the upper side of the density-correction graph and shows the correction for the increase of density with a rise of temperature of the oil above 60 deg. fahr. At the right of the density-temperature graph is a small sheet of logarithmic cross-section paper for plotting viscosities at various temperatures of the oil which is being measured. The kinematic viscosity of ordinary petroleum oils, when plotted against temperature on logarithmic cross-section paper, forms a nearly straight line. As an example three plotted points are shown for a viscous California oil. At some higher temperature than 200 deg. fahr., this line is discontinuous for most petroleum oils and another nearly straight line holds for higher temperatures. The conversion from Saybolt viscosity to kinematic viscosity is given on the upper margin of this graph. The viscosity of oil at any temperature, as shown on this graph, is used to indicate the proper curve to use on the *Q-h* graph. This same group of auxiliary graphs may be used with any size of venturi meter, it being necessary to change only the *Q-h* graph.

Example in the Use of Fig. 3. Determine the quantity of oil flowing under the same conditions as in the example illustrating the use of Fig. 2.

Referring to Fig. 3, follow the arrowed dot-and-dash line for the 4.2-in. mercury-oil deflection from the left side of the density-head diagram to the 0.90 vertical density line, then up the diagonal to the corrected deflection $h = 4.68$ in. Follow this horizontal dot-and-dash line to its intersection with the diagonal 0.11 kinematic viscosity line (obtained by interpolation). Reading vertically down from this intersection it is seen that the quantity of oil flowing under these conditions is 267 gal. per min.

Limits of Accuracy of the Calibrations

The data submitted in Fig. 2 for the Builders Iron Foundry venturi tube are accurate to within 1 per cent for tubes of similar form (2.5:1 ratio of approach to throat diameter) for 2-in. to 12-in. diameter tubes in the region of turbulent flow, since the data in this region are calibrations of full-size venturi tubes with lathe-turned bronze or cast-iron throats.

This calibration applies strictly to 6-in. diameter tubes only; because the tubes to be similar in form must have the roughness increase directly with the size of the tube, i.e., the size of the rugosities must be in proportion to the diameter of the tube. The use of equally rough (or smooth) surfaces for all sizes of meters causes the coefficient to be slightly higher for larger meters for all turbulences in the region of turbulent flow. The degree of roughness does not appreciably affect the coefficient of the venturi tube in the viscous-flow region.

The data in the viscous-flow region are not as accurate as those in the turbulent-flow region. The former are from a calibration made by the author on a 0.22-in. by 0.10-in. home-made model glass venturi-meter tube with water and corn-syrup solutions. The venturi tube was drawn from a straight glass tube and, while not exactly similar in form to the Builders Iron Foundry tubes, approached it closely enough to show definitely the type of variation of the coefficient to be expected for full-scale venturi tubes. The kinematic viscosity was determined with home-made pipette viscosimeters calibrated with water. In spite of the care used to avoid the effects of surface tension and velocity head, and because these viscosimeters measured solutions more than a thousand times as viscous as water, the probable accuracy of the viscosity determinations is approximately 90 per cent. This would mean an expected error of about 10 per cent in the turbulence for the values of the coefficient in the viscous-flow region.

For the purpose of checking the viscous-flow data obtained with the model glass venturi tube, the theoretical coefficient of a 6-in. by 3-in. Simplex venturi tube was computed. It was assumed that the only sources of loss of head from the approach to the throat were those due to the friction loss along the tube and the building up of the kinetic energy of the fluid in the throat. Poiseuille's formula for the friction loss of fluids in viscous flow in cylindrical tubes was used without modification for the approach and the throat. The friction loss in the cone was computed using the integral calculus and the same formula. From the sum of the change

Boiler-Furnace Design

The Tendency in Modern Power Stations Toward Larger Combustion Space—Factors Governing Furnace Volume—The Construction of Boiler-Furnace Walls

By EDWIN B. RICKETTS,[1] NEW YORK, N. Y.

THE FUNCTION of the boiler furnace is to supplement the grate or fuel burner in transforming the energy of the fuel into heat and to transfer that heat to the boiler; and the measure of the efficiency of a furnace is the degree of completeness of combustion at the point where the gases enter the boiler tubes and the degree of availability for absorption by the boiler of the potential heat in the fuel at the point where it is delivered to the boiler for absorption—in other words, the percentage of excess air which is necessary to produce complete combustion at the point of exit from the furnace.

Last fall in connection with the preparation of the Stokers and Furnaces Section of the Prime Movers Committee Report, the author undertook an investigation for the purpose of determining what relation, if any, existed between the relative volume of the furnace and the efficiency of a boiler. This investigation occupied most of the time of several men for three or four months, but in spite of the large amount of time and thought expended, none of them was able to draw any definite conclusions from the data available. However, the importance of and general interest in the question justify reviewing briefly some of the facts which this investigation has so far brought to light in the hope that by broadening the field of the investigation others may solve the problem where, due to his lack of information, the author has been unsuccessful. A few years ago it was a very rare thing to find boilers provided with more than 1 to $1^1/_2$ cu. ft. of furnace volume per rated hp., but the tendency in modern power stations is very strongly toward much larger combustion space. An idea of what is becoming general practice today may be obtained from Table 1, which gives the cubic feet of furnace volume per rated hp. in a number of our newest power stations. In the chain-grate stoker field it will be noticed that this ratio runs from 2 in the case of the American Sugar Refining Company's plant in Baltimore to a maximum of 5.75 at Waukegan. With underfeed stokers it varies from 2.17 at Dodge Bros. to 4.80 at the Delaware station. With pulverized coal at Lakeside 4.56 cu. ft. was provided, which is being increased to 6.52 at Cahokia, and the author knows of installations at present still in the preliminary stage which will probably have a ratio as high as 10.

Table 2 gives, so far as the author has been able to learn, the highest B.t.u. fired per cubic foot of furnace volume per hour on tests where the efficiency of boiler furnace, grate, and superheater was approximately 80 per cent (78 to 82 per cent). Of the coal-firing systems pulverized coal is seen to require by far the largest furnace volume, whereas the same efficiency has been obtained on hand-fired Scotch marine boilers when burning seven times as much coal per cubic foot as has been found best suited for powdered-coal installations.

Factors Governing Furnace Volume

The furnace volume required for the complete combustion of any fuel is a function of many variables, among the more important of which may be mentioned the physical state and chemical composition of the fuel, the type of fuel-burning equipment used, the shape of the combustion chamber, and the means provided for mixing the fuel and air in the furnace.

Physical State and Chemical Composition of the Fuel. On account of its chemical composition and physical state fuel oil when burned in modern mechanical atomizer burners is almost ideal in the furnace volume required for its complete combustion. As much as 265,000 B.t.u. per cu. ft. per hour has been obtained on a White Foster boiler with an efficiency of 76 per cent. This is due to the fact that a large part of the work which in old-style burners was performed by the furnace is now accomplished in the burner itself. Oil is heated to about its flash point and blown into the furnace thoroughly atomized and mixed with the requisite quantity of air for combustion, resulting in a very sharp and intense flame accompanied by complete combustion within a few feet from the mouth of the burner.

Next in order to oil are the lump grades of low-volatile coal. With fuel of this kind the greater part of the combustion takes place within the fuel bed itself or within a very short distance above it. The gas and air leaving the fuel bed are thoroughly mixed and very little furnace volume is required for the completion of combustion. With the higher-volatile solid fuels, particularly if they are fired in the form of slack, large amounts of gaseous products are distilled from the fuel bed and frequently the air and gas are in a more or less stratified form, requiring either a considerable distance of travel or the provision of certain mixing arrangements in order that the gas may be completely consumed before reaching the cooling surface of the boiler.

Type of Fuel-Burning Equipment. Of the types of mechanical fuel-burning equipments in common use, the mechanical atomizer oil burner, for the reasons stated above, requires the least help from the furnace. Next in order probably comes the underfeed type of stoker. In underfeed stokers provided with means for continuous ash discharge, due to the depth of the fuel bed and the multiplicity of air openings, a large part of the combustion takes place on the grate and a fairly uniform mixture of air and gases is delivered to the furnace so long as the fire is kept free from holes and large clinkers. Some stratification may take place when too much air is admitted from side-wall ventilating systems, but this difficulty is usually easily overcome by altering the size and position of these air openings.

TABLE 2 B.T.U. FIRED PER HOUR PER CUBIC FOOT OF FURNACE VOLUME AT EFFICIENCIES OF ABOUT 80 PER CENT WITHOUT ECONOMIZERS

Fuel-burning system	B.t.u. per cu. ft. of furnace volume
Pulverized coal	22,000
Chain-grate stokers	37,500
Underfeed stokers	64,000
Locomotives	70,000
Oil—steam atomization	85,000
Scotch marine boiler, hand-fired	144,000
Oil—mechanical atomization	176,000

Chain-Grate Stokers. That part of the combustion which takes place on the grate of a chain-grate stoker is considerably more complicated than it is in the case of an underfeed type of stoker. Fuel enters the furnace at the front end of the grate where it must be ignited by reflected heat from an incandescent arch. In this ignition process large volumes of gas are driven off and there is usually a considerable deficiency of air. As the fuel passes further on into the furnace fairly complete combustion takes place on the

[1] Asst. to Chief Operating Engineer, N. Y. Edison Co., Mem. A.S.M.E.

Presented at a meeting of the Metropolitan Section of The American Society of Mechanical Engineers, New York, March 27, 1923. Slightly abridged.

grate in the center zone, while in the rear end of the stoker the last of the carbon is burned out, accompanied by a considerable excess of air. There are thus three streams of gas leaving the grate, each being very different in composition, ranging as they do from a stream of gas at the front end mixed with insufficient air for combustion to another mixed with a large excess of air at the rear of the furnace. If provision is not made in the furnace for bringing together and mixing these gaseous streams incomplete combustion may result, as well as a large excess of air.

Pulverized-Fuel Systems. In the systems for burning pulverized fuel which are finding the most successful applications today, the fuel together with probably 25 or 30 per cent of the air requisite for combustion is wafted into the furnace in such a way as to give it as long a travel as possible before reaching the tubes, and the air necessary to complete combustion is brought into the furnace through a multiplicity of openings so arranged as to bring fresh streams of air in contact with the coal particles at successive intervals as they travel through the furnace; while the particle of powdered coal is very small, if it is to be consumed with a minimum of excess air, it is obvious that it must have a long period in the furnace in order to find and combine with those air molecules which are provided for its combustion.

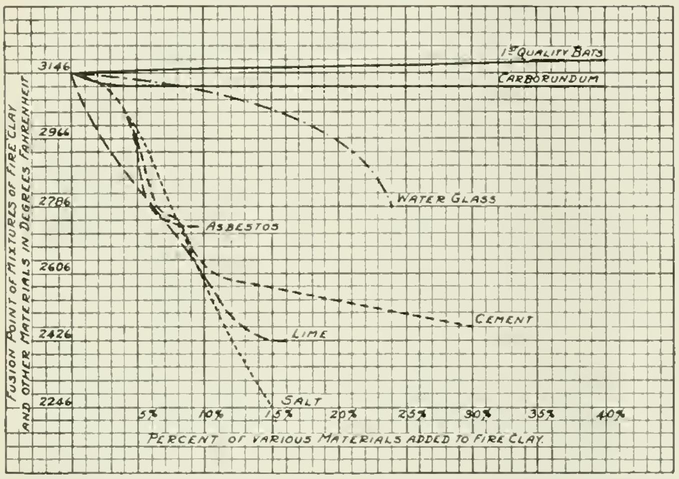

Fig. 1 Effect on the Melting Point of the Resulting Mixture of Adding Various Materials to Fireclay

Shape of Combustion Chamber and Mixing Arrangements. It is obvious that a thorough mixture of the fuel and air must take place somewhere in the burning system. If this is not done by the burner or grate, it must be brought about within the furnace. In the mechanical atomizer oil burner practically all of the mixing is done in the burner itself. Consequently no mixing arrangements are required in the furnace. In the underfeed stoker a number of arch and steam-jet mixing schemes have been tried, but it has usually been found that complete combustion will take place without any special mixing device if sufficient height of furnace is provided between the grates and the tubes. With chain-grate stokers an ignition arch is always provided and frequently a reverse arch over the rear end of the stoker; in some cases a third arch is added over the center of the combustion chamber in order to mix the gaseous streams coming from the three main subdivisions of the grate, and it has usually been found that better results can be obtained the more elaborate the mixing system provided. In the powdered-coal systems now in general use very little of the mixing is done in the burner. There are a number of systems which have been used in an experimental way, in which a much larger proportion of the mixing is done in the burner. With these systems it is claimed that a much smaller furnace volume will be required than is now considered necessary, and while it is hoped that the advocates of these systems will be successful in demonstrating this statement, so far they have not done so on any commercial scale.

On account of the variations in the work which the furnace has to do when used in connection with the various fuel-burning systems, it is obviously impossible to make any general comparison of the effect of furnace volume on efficiency. Consequently the effect of furnace volume must be studied separately for each of the systems. Very much more reliable test data were available on plants using underfeed stokers than with any other class of equipment, and it was found possible to plot quite a large number of tests where underfeed stokers were used in connection with 14-high Babcock & Wilcox boilers. None of these furnaces was complicated by arches or other mixing devices, thus eliminating a large number of variable elements, and while the curves show a slight tendency toward better efficiency with higher furnace volume, the information is by no means conclusive and the difference indicated may easily be accounted for by test errors or differences in skill of the operators. Furnaces having 3 or 6 cu. ft. per rated hp. cost a great deal more to build and to maintain than furnaces of smaller sizes. Personally, the author has always been an advocate of large furnaces and it would seem, judging from the results given in Table I, that most of those who have to do with the construction of modern power plants agree with him on this point. Engineers should be in a position to prove that any extra expenditure which they make in construction or maintenance is justified by the better economies obtained.

The Construction of Boiler-Furnace Walls

In considering this subject the first two questions which present themselves are, why is a wall needed around a boiler furnace, and what are some of the more important characteristics which a perfect wall should possess? A wall is needed around a furnace to direct the heat produced by the burning fuel to the surfaces provided for absorbing it, to prevent this heat from being dissipated in all directions where it would be wasted, and to prevent excess air from entering the furnace and commingling with the products of combustion.

A perfect wall would then be one which, under all conditions of service, would be impervious to the flow of gas, air, or heat units; it would not crack, spall, or soften, and would not be injured by molten slag.

It is well known that our walls fail to meet fully the above requirements and we may profitably consider for a few moments some of the reasons for the shortcomings of present-day walls and some of the ways in which these shortcomings may be overcome.

In Table 3 are given some of the principal characteristics of refractory materials. It would seem at first glance that from this list an almost ideal combination of materials could be selected, and if cost were no object the construction of good boiler walls would be greatly simplified. Unfortunately, however, the cost of some of the more desirable materials is such as to prohibit their use except in small quantities for special purposes. Cost and distribution of raw materials make it necessary to rely on fireclay products for the bulk of our boiler-wall work.

While the firebrick themselves may fail in a number of ways (several of which ways will be discussed later), usually the weakest part of the wall is the jointing material. Up to the present time fireclay of approximately the same composition as the brick has usually been found to be the most satisfactory material with which to bond the wall, and this material is always more easily disintegrated than the firebrick. Consequently it is advisable that firebrick be obtained with as close uniformity in dimensions as possible so that the amount of jointing material may be reduced to a minimum.

Many attempts have been made to obtain a material better suited to this purpose than fireclay, and, while some of these compounds have given very satisfactory results under certain conditions, in many cases the user is paying an exorbitant price for a material having refractory qualities inferior to that of fireclay which forms the base of most of these so-called high-temperature cements. Fig. 1 shows the effect on the melting point of the mixture resulting from the addition of various materials to fireclay.

The present-day tendencies in power-plant practice are very materially increasing the severity of the conditions under which refractories are used in boiler-wall construction. These tendencies are the result of the increasing cost of fuel, labor, and equipment, which has made profitable economies in all three of these items which were not to be thought of a few years ago and may be briefly summarized as follows:

1 In order to reduce the amount of boiler equipment for a given output the rate of operation has been largely increased, bringing

about increases in furnace temperature and the area of walls exposed to high temperature.

2 Furnace walls are much tighter than formerly and are in many cases protected from radiation and air infiltration by layers of heat insulation and airtight steel casings, causing dangerous temperatures to penetrate much more deeply into the walls than was the case with the type of construction used a few years ago.

3. The reduction of excess air to a minimum and the conservation of low-level heat by preheating the air for combustion, a practice which is common in Europe and which is meeting with increasing favor in this country, will probably add several hundred degrees to present furnace temperatures.

An idea of the temperature gradient through boiler-furnace walls can be obtained from Fig. 2 which shows the temperature in the walls at the Delray station of the Detroit Edison Co. These walls are solid firebrick 28 in. thick with no insulation or steel casing. The tests were made with a slight draft inside the setting, at low ratings, the draft being increased with the rating. Considering these results, which were very accurately obtained by embedding thermocouples in the wall at various distances from the fire face,

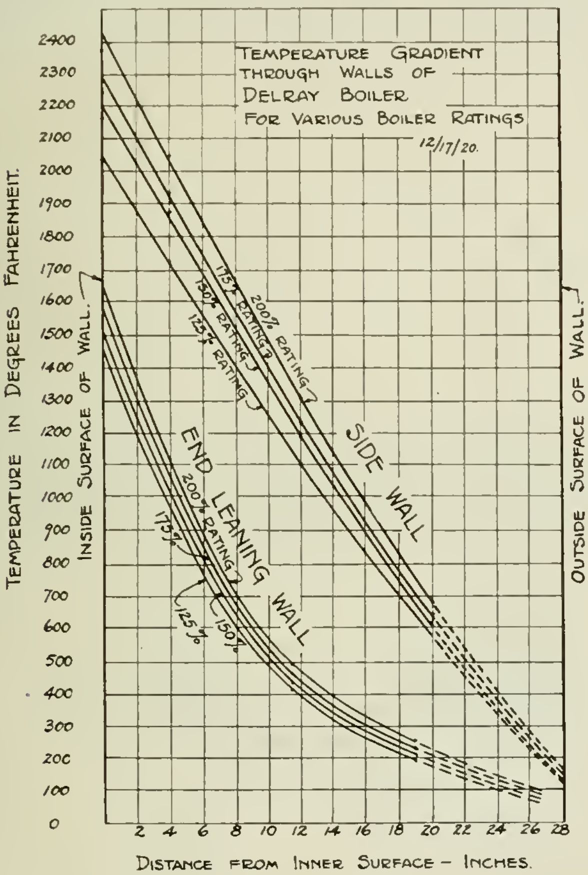

Fig. 2 Temperature Gradient through Walls of Delray Boiler for Various Boiler Ratings

it can readily be seen that when ratings are pushed up to 400 per cent with the addition of possibly 200 deg. by air preheaters a furnace-wall temperature close to 2900 deg. fahr. will result if we continue to use the type of wall construction now generally employed.

Furnace-wall temperatures are affected to a considerable extent by the relative pressures on the two sides of the wall. This effect is clearly shown by some tests made by R. M. Howe on an experimental furnace at the Mellon Institute.

The temperature of the furnace wall was measured at a point 1/2 in. back from the inside edge of the furnace under varying conditions of draft in the furnace with results as follows:

The furnace temperature was 2440 deg. fahr., with a slight draft the wall temperature was 2030 deg., with 0.05 in. pressure 2300 deg., and with 1 in. pressure it rose to 2380 deg. The importance of avoiding a positive pressure in boiler furnaces cannot be overemphasized as it is one of the most prolific causes of wall failure.

Assuming that the furnace wall has been skillfully constructed with high-grade fireclay materials, what are the principle causes of wall failure, and how may they be avoided?

As shown in Table 3, the melting point of first-class fireclay refractories is well above furnace temperatures of which there is

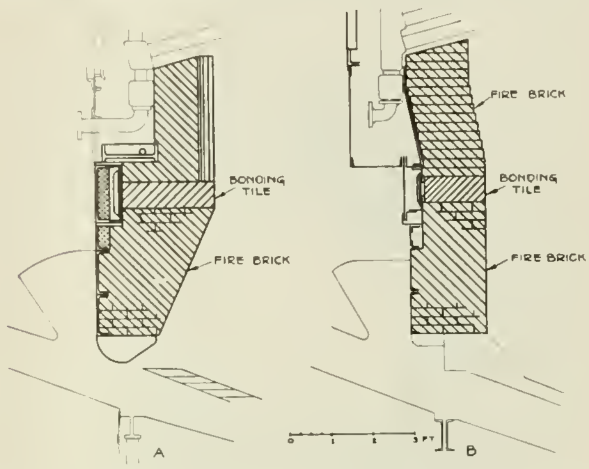

Fig. 3 (A) Section through Front Wall of Underfeed Stoker that Failed after a Few Weeks' Use, and (B) Section of Wall Replacing It, Which has Given Good Service for Several Years

any immediate prospect; consequently, except in cases where an oil or gas flame impinges directly against the furnace wall, a condition which is usually readily remedied by the selection of suitable burner equipment, there will be little trouble from straight fusion of the furnace lining.

Again referring to Table 3, it is seen that fireclay bricks begin to soften under load at 500 to 600 deg. below their melting point. With the old-style low-set boilers this was not a very important feature because the surface exposed to high temperatures was small and the superimposed loads light. With modern high-set boilers, however, this characteristic of firebrick has assumed increasing importance. The liability to failure from this cause is a function of the depth of penetration in the wall of a temperature which would cause softening and of the shape of the wall. A study of Fig. 3 will show what is meant by the latter statement. To the left is shown the front wall of an underfeed stoker setting which is corbeled in such a way as to impose a very heavy load on the course of brick just above the ram-box caps. It will be readily seen that a slight softening of the lower rows of brick will cause the whole front wall to fall into the furnace. The life of this wall was only a few weeks and it has been replaced by the one on the right which has given several years' service with no trouble.

A study of a large number of reports on the life history of walls all over the country has indicated that the wall which leans in toward the furnace is a constant source of trouble.

The erosion of firebrick by molten ash is responsible for more furnace-wall failures than all the other causes put together. Where coals are used having a high ash-fusion temperature, say 2700 to 2800 deg. fahr., ash erosion is not important; but such coals are scarce now and are becoming more so every day, and furnaces must be so constructed that they will function successfully with coals the ash of which begins to soften at 2100 deg. and runs at 2300 deg.

The effect of ash erosion is most pronounced where a pulverized-coal or forced-draft-stoker flame strikes the furnace wall. These flames carry small particles of molten ash which penetrate any cracks or pores in the brickwork. The surface of the wall then

TABLE 3 THERMAL PROPERTIES OF VARIOUS REFRACTORIES

Material	Fusion point, deg. fahr.	Point of failure under 50 lb. per sq. in. load, deg. fahr.	Thermal conductivity at 1832 deg. fahr., B.t.u. per hr. per deg. fahr. per inch	Specific heat at 212 deg. fahr.	Resistance to spalling
Fireclay	3092	2462–2552	11.3	0.199	Good
Silica	3092	2912	12.7	0.219	Poor
Magnesia	3929	2696	22.9	0.231	Poor
Chrome	3722	2597	16.5	...	Poor
Bauxite	3245	2462 or more	11.3	...	Good
Zirconia	4667	2750	Low	...	...
Carborundum	4064	Above 3002	67.0	0.186	Good
Alundum	3722	Above 2822	High	0.198	Good

becomes a mixture of firebrick and ash, which has a melting point much lower than firebrick.

Coal ash is not a definite chemical compound but a mixture of many compounds. It consequently has no definite melting point like ice but changes state gradually, there frequently being an interval of 200 to 300 deg. between the first signs of softening and the point where the viscosity has been so reduced that it will readily flow.

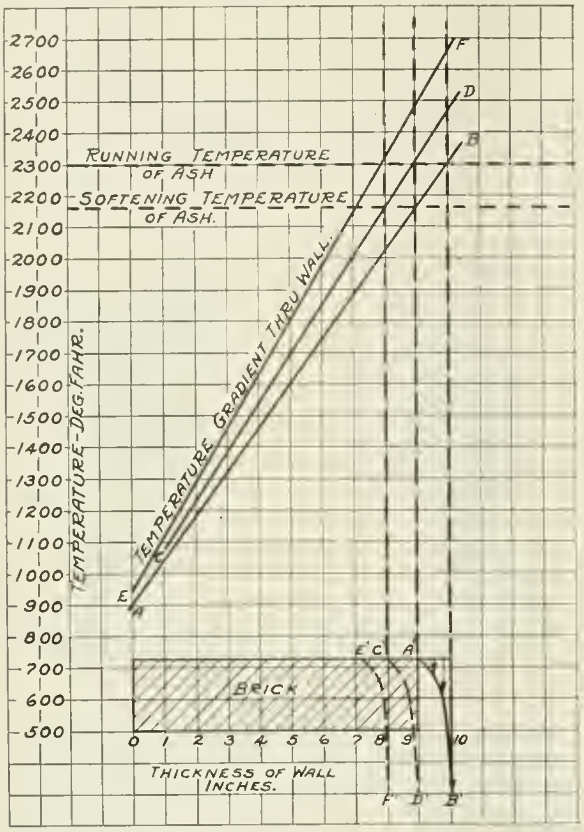

Fig. 4 Manner in Which Erosion of Furnace-Wall Firebrick by Molten Ash Takes Place

Ash erosion is a function of the depth of penetration of the ash-flow temperature into the furnace lining, the porosity of the wall, and the relative composition of the refractory and the ash with which it comes in contact. The manner in which this erosion takes place is well illustrated in Fig. 4, for which diagram and the explanation following the author is indebted to an article by Henry Kreisinger in the 1922 Prime Movers Committee report.

If the surface of the furnace lining is below the running temperature of the ash, the molten ash coming in contact with it is cooled to the temperature of the brick and becomes a thick, viscous fluid adhering to the brick and moving slowly over the surface. Owing to its high viscosity the ash does not penetrate into the brick and will not wash it away, but forms a pasty coating over the surface of the brick. The thickness of this coating depends on the interval between the softening temperature and the running temperature of the ash, and on the rate at which heat passes through the layer of pasty ash and the brick. The surface of the coating away from the brick is at the running temperature, and any further deposit of molten ash will run down over the coating without harming the brick. This condition is shown in Fig. 4 by the temperature gradient *AB*. The length of the arrows near the surface of the brick indicates the speed at which the various layers of the coating of the ash move. The heads of the arrows form a curve *A'B'*.

If the surface of the brick is at the temperature of the running ash, the ash penetrates to a small extent into the brick and the abrasion of the furnace lining begins. This condition is illustrated by the temperature gradient *CD*. The curve of the moving slag is shown by the dotted line *C'D'*.

A temperature condition very destructive to the brick lining is shown by the gradient *EF*. The temperature of the running ash is one inch within the brick and the molten ash penetrates into the brick rapidly and washes the brick away.

The depth of penetration of dangerous temperature in furnace walls with a given furnace temperature is largely influenced by the material of which the wall is constructed, its thickness, and the velocity of air currents against the outside of the wall.

The effect of these items is shown in Fig. 5. In preparing this diagram it was assumed that the furnace was operated in such a manner as to maintain a temperature of 2500 deg. fahr. at the inner edge of the wall; that the coal burned has an ash-softening point of 2100 deg. and the ash flows at 2300 deg. fahr. To the left of the figure are shown various wall thicknesses of solid firebrick. In the center are walls composed of a combination of firebrick and insulating material which is assumed to have one-tenth the heat conductivity of firebrick, and on the right is illustrated the hollow-wall construction, where the air for combustion absorbs the heat radiated through comparatively thin walls. A study of these diagrams shows clearly the danger of using insulation in furnace walls where the walls are not provided with any cooling arrangement, and the advantage which results from employing the hollow ventilated wall construction where high combustion temperatures are being dealt with.

If we would obtain the highest efficiency coupled with long wall life, the walls must be so constructed that air cannot leak into the furnace and a minimum of heat will be radiated from the walls. This must be done while burning the fuel with a mininum of excess air which has been preheated several hundred degrees; and it is obvious that walls made of fireclay brick will not stand such punishment unless some means are provided for reducing the wall temperature relative to the combustion temperature in the furnace.

In the Lopulco system of burning pulverized coal a combination of air and water cooling of furnace walls has worked out very satisfactorily. This system of cooling the walls by heating air for combustion is well suited to conditions where it is desireable to introduce a large part of the air for combustion as secondary air, but would not be very desirable in combustion systems where all or a large part of the air is primary air, such as stokers, mechanical atomizer oil burners, and certain powdered-coal systems. Another difficulty with air-cooled walls is that it makes it more difficult to use low-level heat which is available at slight expense for preheating combustion air.

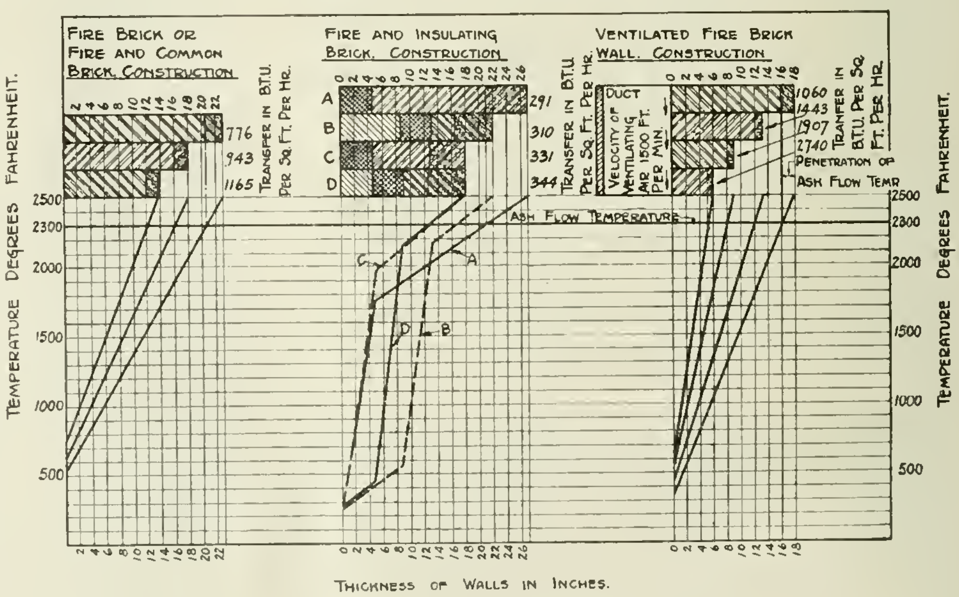

Fig. 5 Effect of Type of Furnace-Wall Construction on Penetration of Dangerous Temperatures into Brickwork

In the author's opinion the present tendency of boiler-furnace design is toward a furnace in which combustion will take place entirely surrounded by water- and steam-cooling surfaces.

Discussion

Mr. Ricketts' paper was presented on March 27 at a meeting of the Metropolitan Section of The American Society of Mechanical Engineers, and for helpful discussion and sustained interest the session was one of the best ever held under the auspices of that section. Kingsley L. Martin, chairman of the Fuels Committee of the Section, presided.

In presenting his paper Mr. Ricketts gave the following additional ratios of cubic feet of furnace volume to rated boiler hp.,

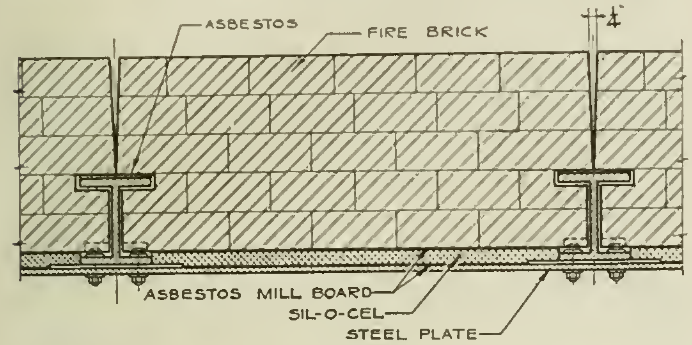

Fig. 1 Plan of Furnace Wall at Hell Gate Station, United Electric Light & Power Co.

(The tapering expansion joint closes when the boiler is in service.)

these representing furnace design of plants built some years ago:

	Cu. ft. per rated boiler hp.
Waterside Station, New York Edison Company	1.05
Essex Station, Public Service of New Jersey	1.95
Dodge Bros., Mishawaka, Ind.	2.17
Muscle Shoals	2.17
Connors Creek, Detroit Edison Co.	2.75
L. Street, Boston	2.93
Springdale Plant, Pennsylvania Power Co.	2.95

The discussion was opened by V. M. Frost[1] who emphasized the desirability from an overall economic standpoint of using ordinary, first-quality brick in furnace construction, rather than the more expensive so-called "super-refractory" brick; also the desirability of obtaining from the brick manufacturers a more uniform product, true to shape and dimensions, which would very materially assist in obtaining better service and longer life from the common refractories.

He also outlined the possibilities of the use of air-cooled walls as a means of securing better service from the ordinary brick, which would stand up better under compression loads if the heat of the furnace did not penetrate too deeply, as indicated in Mr. Ricketts' paper.

In his work Mr. Frost used the ratio of combustion volume to heating surface, and stated that he had found a value of 0.4 to 0.5 to be a satisfactory one for this ratio. In a furnace designed on this basis under a boiler of 3000 sq. ft. of heating surface, over 2000 lb. of coal per hour had been burned, without slagging or melting of the brick.

John H. Lawrence[2] presented a sketch, Fig. 1, showing the method of constructing the walls of the Hell Gate Station by which the strain on the wall was reduced and expansion provided for. Mr. Lawrence pointed out that a particular trouble in brickwork maintenance was caused by erosion of the front wall just above the stoker.

E. S. Cooley[3] told of the recent realization on the part of paper manufacturers of the importance of fuel saving. The steam plant of the paper mill must furnish steam at 90 lb. to cook the wood and at 15 lb. pressure to dry paper. In a large paper mill there was a remarkable opportunity for economy in fuel. In the design of furnaces Mr. Cooley emphasized the importance of making proper allowances for expansion and contraction. He had successfully used an expansion joint of asbestos millboard. He also told of his experience in installing oil burners under low-set boilers and of securing high efficiencies by allowing the entire lower sets of tubes to be exposed to the flame.

C. G. Spencer[4] commented on Fig. 1 of Mr. Ricketts' paper and stated that in considering the ratio of furnace capacity to boiler horsepower the characteristics of the fuel must be kept clearly in mind. At the Cahokia plant, which had the large ratio of 6.05 cu. ft. per rated hp., the coal used had a long flame of from 50 to 60 ft., the temperature of the ash was 2000 deg. fahr., and the coal had a sulphur content of 5 per cent and an iron content of 18 per cent. Mr. Spencer also stated that it was his belief that an air-cooled wall would give the longest life. He described an economical method of repairing side walls in which a ganister of refractory material was applied with a cement gun.

A. W. Patterson[5] discussed a number of drawings which he had

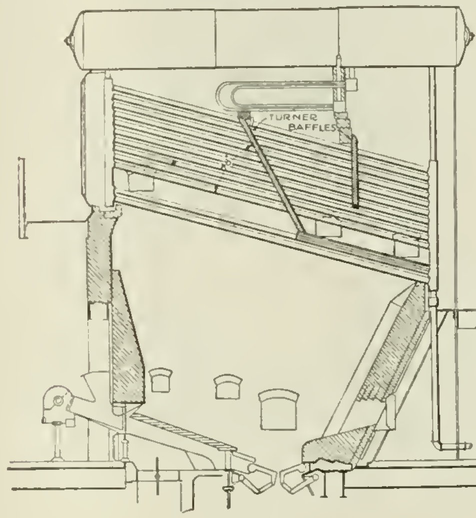

Fig. 2

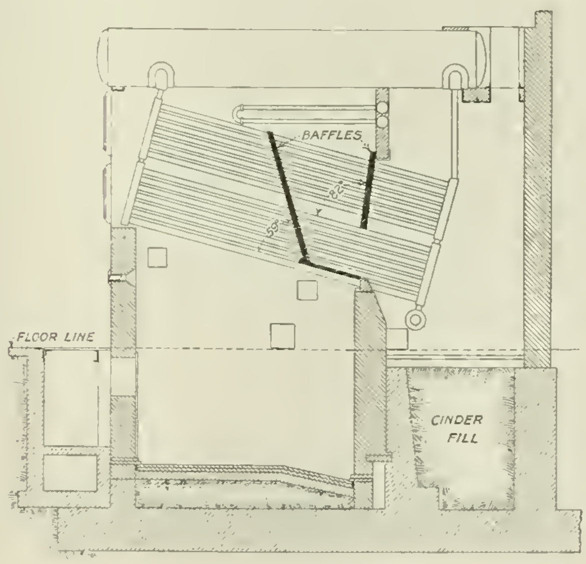

Fig. 3

projected on the screen and which were taken from existing installations, the purpose being to illustrate the possibilities of harmonizing baffle and furnace design to secure long life for the furnace and low maintenance costs. In the first, a vertical baffle, the bottom of which was connected with the bridge wall by means of a flat shelf, was replaced by an inclined one similar to that shown in Fig. 4, with the lower end resting on the bridge wall. In the second the baffling was arranged roughly like that of Fig. 2. In both cases the baffle was laid out on the principle of exposing additional heating surface to the radiant heat of the furnace, thereby lowering somewhat the furnace temperature and absorbing heat

which would otherwise have to be taken up by the brickwork. Also the lower velocities due to increased opening in the entrance to the first pass decreased the possibilities of slag and a tendency toward positive pressure in the furnace.

The setting shown in Fig. 2 was used on eight 1000-hp. and six 750-hp. boilers with underfeed stokers. The bridge wall and back wall were one with a backward slope. This gave rigidity and a reflecting surface throwing the heat out of the furnace against the tubes. The front wall was built in two separate parts, one under

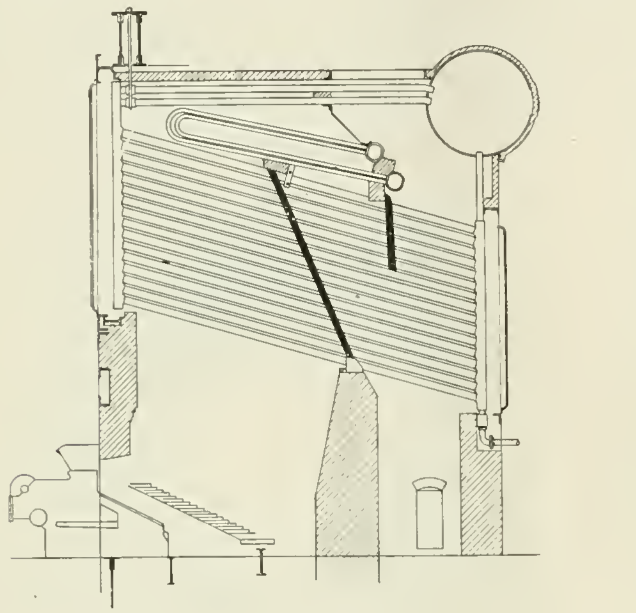

Fig. 4

the header and the other from the stoker up. This relieved the brickwork of weight and the backward slope of the protecting wall added to rigidity. The entire roof of the furnace was heat-absorbing; the entering velocity in the first pass was low. These boilers had been in operation for a number of years with excellent operating efficiency and low maintenance.

Fig. 3 showed the solution of a furnace problem for low-set boilers in connection with the application of oil burning. The higher ratings made necessary a considerable furnace volume; also height and depth. It was learned that the foundations were in excellent condition and were so built that the furnaces could be installed in the foundations. This was done by the proper use of insulating materials combined with firebrick. It was noted that the bridge wall was supported by a concrete pier. The sidewalls had protecting piers of insulating material and firebrick. The baffle design was made to conform to the furnace by a combination of a flat shelf and inclined front baffle, the design being such that a suitable soot pocket could be secured behind the bridge wall.

The boiler shown in Fig. 4 had a builder's rating of 1500 hp. and was installed in the Middle West. A considerable amount of slagging in the lower rows of tubes occurred due to the character of coal available. This slag caused a tendency toward positive pressure in the furnace and trouble was experienced in maintaining the front wall. The baffles were accordingly redesigned as shown in Fig. 4, increasing the entrance to the first pass about 50 per cent and changing the rear baffle to prevent restriction of gases in passing through; a slight backward corbeling was also given to the bridge wall to provide rigidity of the bridge wall and to conform to the new baffle location. Originally the front baffle was vertical, dropping from the top point of the present inclined baffle. At its lower end the old baffle was connected by a baffle following the tubes to the vertical bridge wall which occupied nearly the position of the present one.

These changes, which reduced the velocity of the gas entering the first pass, and possibly the somewhat lower furnace temperature, entirely eliminated slagging, which in turn prevented the occurrence of positive pressure and materially increased the life of the brickwork. It was also found that the stoker repairs were somewhat reduced and that possibly a somewhat lower flue-gas temperature resulted. During the past twelve months (the second year's operation), this boiler was on the line 86 per cent of the time as compared with about 70 per cent average time of the other boilers in this plant. The total cost of maintenance of boiler, furnace and stokers was about one-third the average for about five other boilers in the plant.

Other drawings shown by Mr. Patterson were front and side elevations of a 1000-hp. boiler, in the brickwork of which the use of molded blocks was carried out quite completely, the blocks being 6 by 6 by 18 in. The jointing was reduced about 30 per cent as compared with ordinary firebrick, and the larger size, it was thought, formed a better bond with the outside walls. The furnaces were made with an air space and cast-iron ties were inserted to form an additional bond between the inside and outside sections of the wall. The side walls were supported with relieving arches. The front wall under the header was of the suspended-arch type. Perforated blocks were used along the clinker line of the bridge wall.

The boilers shown in Fig. 5 were of approximately 1600 hp. each. The original baffling arrangement was such that positive pressure occurred and there was considerable brickwork maintenance. The baffles were redesigned, securing lower velocities at the entrance to the first pass and a lower draft drop through the entire furnace. This change eliminated the slag and positive-

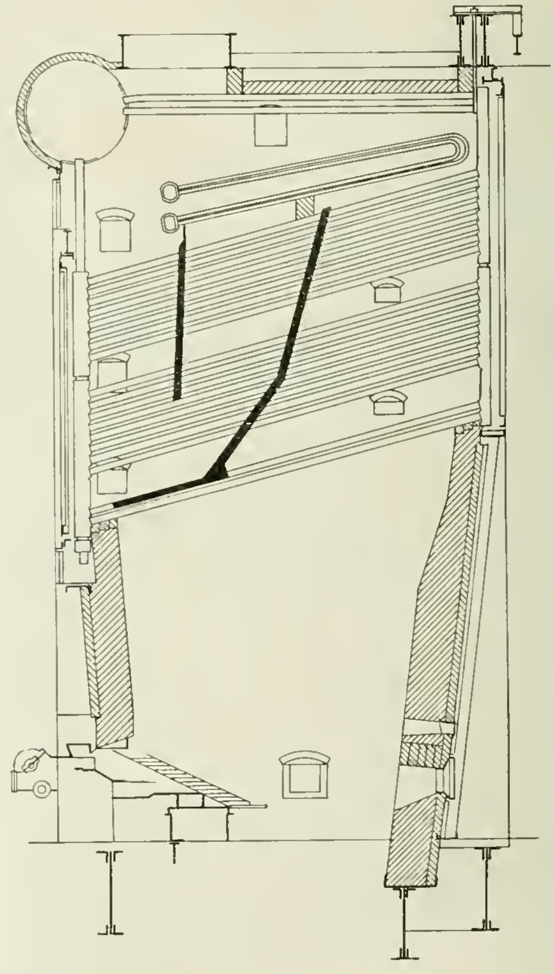

Fig. 5

pressure condition and reduced brickwork maintenance. It was interesting to note the funnel shape of furnace, both front and rear walls being inclined, giving additional rigidity.

The principles involved were the same for boilers operating with powdered coal.

Other discussions were submitted by George Bell, T. B. Stillman, H. D. Savage, E. Wise Sayer, and A. A. Adler. The last mentioned pointed to the excellent results attained in Scotch marine and locomotive boilers where the firebox is surrounded by heating surfaces.

SURVEY OF ENGINEERING PROGRESS

A Review of Attainment in Mechanical Engineering and Related Fields

The Generation and Utilization of Cold

A GENERAL discussion on the generation and utilization of cold was held jointly by the Faraday Society and the British Cold Storage and Ice Association on October 16, 1922. The subject was treated under two headings, namely, laboratory and industrial methods of liquefaction, and practical applications of low temperatures. The subjects discussed belong particularly to the region of low temperatures such as are involved in the liquefaction of gases rather than that of medium temperatures as used in ice making and the like.

Prof. J. Kamerlingh Onnes of the Leyden cryogenic laboratory spoke of the lowest temperature yet attained. He gave a brief history of the efforts made in the liquefaction of helium, together with a description of apparatus employed. In this work, it may be mentioned, he was assisted by a gift of helium from the United States Navy. With the apparatus recently developed considerable amounts of liquid helium can be obtained and the author describes in full the apparatus and precautions used. With this it is believed that the lowest temperature obtained is below 0.9 deg. K., and the question whether it would be possible to descend below 1 deg. K. is thus answered positively. If it had been possible to have gone further only one-sixth of a degree, the limit obtainable in the ordinary way with helium would have been reached.

The apparatus and methods in the Leyden cryogenic laboratory are described in a paper with this title by C. A. Crommelin. The purpose of the laboratory is and has always been to be able to produce any temperature below 0 deg. in order to be able to make accurate physical measurements at these temperatures. And the claim is, for accurate measurements at least, a constancy of 0.01 deg. during several hours. The best way to fulfil this claim is to make use of liquefied gases boiling, well stirred, under different pressures and keeping these pressures exactly constant. In Leyden only pressures of one atmosphere and lower (often as low as a few millimeters, and in the case of helium a few tenths of a millimeter) are used, as the construction of cryostats for considerably higher pressures than one atmosphere is difficult and may even present danger. The region of temperatures covered by each substance is therefore the region between the boiling point and its triple point.

The article describes in some detail the liquefaction of air, the hydrogen plant, the liquefaction of helium, the liquefaction and purification of neon, and the various cryostats used at the laboratory.

Prof. C. F. Jenkin presented a paper on ethyl chloride, containing among other things a pressure-temperature curve, and stated that he is carrying out a complete investigation of the thermal properties of this fluid and that complete θ-ϕ and I-ϕ charts will shortly be published.

In the discussion which followed Prof. A. W. Porter suggested a new method for obtaining a truer extrapolation in determining the extremely low temperatures, using for this purpose one of the various theoretical curves which are adopted for representing vapor pressures.

The next group of papers dealt with industrial methods of liquefaction and practical applications of low temperatures. This group started with a semi-historical paper by K. S. Murray on industrial methods of liquefaction, dealing largely with the history of the British Oxygen Company. It also described the features of the Claude and the Linde processes, and referred briefly to the Norton process.

The manufacture of hydrogen by the partial liquefaction of water gas and coke-oven gas was described by Georges Claude. In this process water gas compressed to a suitable degree is in the first instance deprived of its carbon dioxide and moisture. It is then sent into a heat exchanger in which it is cooled by circulating in the opposite direction to the hydrogen and carbon monoxide which have already been separated. The gas then enters the bottom of a sheaf of vertical tubes, the lower portion of which plunges into a bath of carbon monoxide boiling under atmospheric pressure. By the combined influence of the pressure and of the temperature of the liquid bath a large portion of the carbon monoxide of the ascending gases is liquefied and flows back into a collector located below the vertical tubes. This liquid is forced into a vaporizer where it replaces the liquid which is being evaporated. The remaining gas containing hydrogen and a little of the residual carbon monoxide continues to rise in the sheaf of vertical tubes, where it encounters a temperature which is being more and more lowered by special means. Under that influence the remainder of the carbon monoxide is liquefied and the hydrogen, which theoretically ought to be sensibly pure, escapes.

In working this process two sources of inconvenience were encountered. In the first instance when the hydrogen is entering the expansion engine at extremely low temperature the frigorific efficiency of the expansion is very low, in addition to which there is an abnormal friction in the engine which still further lowers the frigorific efficiency. In the second place, the calorific mass of the gases leaving the tubes and circulating about the rising gases is smaller than the mass of the latter by the entire amount of the carbon monoxide which has been liquefied by their action. As a consequence, the ascending gas cannot, even assuming a perfect heat exchange to take place, leave the sheaf of tubes at the temperature at which the expanded gases enter the tube. The author describes how these and other troubles have been overcome in practice. The process has been developed and put into practice in a plant at Grande Paroisse, France, where an apparatus for the production of 500 cu. m. of hydrogen per hour is in operation, feeding a unit for five tons of ammonia per day.

The author mentions also that he has already successfully tried an apparatus where hydrogen is produced from coke-oven gas, which is of importance because it permits the recovery of by-products which are lost now.

Edgar A. Griffiths discusses in detail the production of liquid oxygen for use on aircraft, in particular for high-altitude flying. Of interest in this same connection is the paper by A. J. Bremner describing the Heylandt liquid-air plant, as this was intended to supply oxygen for use with the "Aerophor" liquid-air self-contained breathing apparatus.

The paper by Cosmo Johns deals with another application of oxygen, namely, that of enriching air supplied to metallurgical furnaces, such as copper-smelting, blast furnaces, open-hearth, bessemer, etc. In this connection the author calls attention to the fact that it is not pure oxygen that is required, as it would be amply sufficient if the oxygen content varied between the range of 20 and 40 per cent. What is required, however, is not pure oxygen in steel bottles but enriched air in hundreds of tons, as the production of one ton of pig iron requires 140,000 cu. ft. of air at normal temperature and pressure.

Attention is also called to the papers, Thermometric Lag with Special Reference to Cold Storage Practice, by Ezer Griffiths and J. H. Awbery, Some Materials of Low Thermal Conductivity, by Ezer Griffiths, and A Note on the Importance of the Study of the Crystal Structure and Properties of Metals at Low Temperatures, by Cosmo Johns.

In the discussion which followed Dr. J. A. Harker called attention to a fact which may be of considerable importance, namely, that in four or five different plants which he had visited, working on the Claude process where expansion engines were in use, he had noticed in almost every instance that the energy recovered was turned into a resistance coil and accomplished no useful purpose,

except possibly that of warming the room. It was never used as it was figured in the textbooks and turned into the line to diminish the power requirements in the way that theoretical people talk about.

H. Brier told about an experiment which was made about 1890 with enriched air on a small bessemer converter in Glasgow. Oxygen was then introduced in different percentages into the air blast. At no time was any great quantity of oxygen used, but the results were most disastrous. After a very short time the tuyeres and bottom of the converter were consumed and blew out, and those in attendance very naturally stood away from the converter expecting the charge to follow; but only a moderate flow of liquid came out into the bottom of the pit, and this was found to be the liquid formed by the melting of the tuyeres and lining, all combustible metal having disappeared, leaving only a black skull in the top of the converter.

Cosmo Johns, in dealing with the question of enriched air stated that it was the increase in the partial pressure of the oxygen that was the really significant factor in the use of oxygen-enriched air. The available evidence strongly supported the view that variations in the concentration or partial pressure of the oxygen would alter the order in which the metals and metalloids were oxidized in the bessemer process for basic-steel making.

Dr. Richard Linde, in dealing with the development of the oxygen and nitrogen industries in Germany, gave the following figures: At present more than 2,500,000 cu. m. (nearly 100,000,000 cu. ft.) of oxygen are put upon the German market every month, in steel cylinders. In addition, a large number of engineering works and shipbuilding wharves make their own oxygen for autogenous metal working, and that oxygen production may be estimated at 1,000,000 cu. m. per month. Finally, the chemical industries require very considerable amounts of oxygen which the works likewise generate in their own plants; this oxygen will also exceed 1,000,000 cu. m. per month. Thus Germany is at present producing at least 50,000,000 cu. m. (1,750,000,000 cu. ft.) of oxygen per year.

The amount of nitrogen produced by the liquefaction of air and utilized almost exclusively for the manufacture of fertilizers is considerably larger, Dr. Linde estimating the annual German demand for nitrogen at 300,000,000 cu. m. (more than 10,000,000,000 cu. ft.). (*Transactions of the Faraday Society*, vol. 18, pt. 2, no. 53, Dec., 1922, pp. 139–273, illustrated, *tdA*)

Short Abstracts of the Month

AERONAUTICS (See also Internal-Combustion Engineering)

Marcel Besson H-5 Quadruplane Flying Boat. It is stated that this machine has recently been successfully tried out in France. The problem was to design one that would, without being too cumbersome, be capable of carrying heavy loads and a large number of passengers, as many as twenty. This problem was solved by arranging the planes in quadruple form, one pair close behind the other, and each pair stepped and staggered in relation to the other. Interference between the forward and rear pairs of planes was expected, but the trial flights demonstrated that there was little or none of it.

The main planes are of comparatively thick section and have a high aspect ratio. The upper and third planes are located a little less than the chord width in advance of the second and bottom planes. Each pair of planes has an arrangement of X interplane struts, while struts also connect the rear spars of the forward planes to the front spars of the rear planes. The whole wing cellule is divided into three bays on each side. The arrangement of struts enables the wire bracing to be reduced to a minimum. The lowermost plane is set at a dihedral angle—about $1^1/_2$ deg. Ailerons are fitted to all four planes; these ailerons, it will be seen, are long and narrow, and although their individual effectiveness may be slight, their combined action should give ample control.

One advantage claimed for the grouping of the main planes as adopted by M. Besson is that the travel of the center of pressure for each plane is small, and therefore the total c. p. travel is also small, whereas this would be much greater if only two planes, giving the same combined total area, were employed. Consequently it is said that, for a large machine, this arrangement makes for easier piloting.

The tail group of the Besson quadruplane is also interesting. It consists of two horizontal and three vertical surfaces. Of the former, the upper and smaller is used as an elevator only, while the lower and larger surface (of 26 ft. 3 in. span) serves as a stabilizer and has an auxiliary "elevator" for adjusting the incidence for longitudinal trimming. The three vertical surfaces comprise a central triangular fin, to the trailing edge of which is hinged a rudder and two similar but smaller units mounted one on each side of the central one. The hinged flaps on these outer surfaces are normally in neutral position but may be adjusted at the will of the pilot for the purpose of trimming the machine should the failure or fall in power of one or other of the engines necessitate this.

The engines at present fitted are four 250-hp. Salmsons. During the tests the machine, which weighs fully loaded just over 10 tons, took off a run of some 500 yd. and attained a speed of 81 m.p.h. with full load. (*Flight*, vol. 15, no. 7/738, Feb. 15, 1923, pp. 89–90, 2 figs., *d*)

AIR MACHINERY

Formula for the Rate of Exhaustion of a Large Tank by a Reciprocating Air Pump, E. Buckingham. The conditions for the validity of the formula are as follows: (1) The piston and the valves do not leak; (2) there is no appreciable throttling except at the valves; (3) the volume to be exhausted is very large in comparison with the piston displacement; (4) the temperature of the air in the tank is constant; (5) the temperature in the pump at the end of any suction stroke is constant; (6) the pump discharges to atmospheric pressure, and the air in the tank starts at atmospheric pressure.

Let P = atmospheric pressure
N = number of completed pump cycles
p = pressure in tank after N cycles
x = p/P = degree of exhaustion
l = limiting or lowest attainable value of x
a = fraction of 1 atmosphere required to lift the discharge valve
b = fraction of 1 atmosphere required to lift the intake valve
c = ratio of clearance to piston displacement
t = ratio of absolute temperature in the pump at the end of a suction stroke to absolute temperature in the tank
v = ratio of volume of tank to piston displacement
n = exponent in the equation of the compression line, pv^n = constant

In any one problem the last six quantities are pure numbers and independent of the units used. a, b, and c are always small; if the valves are operated positively, $a = b = 0$; if the pump is oil-sealed, $c = 0$. The temperature ratio t never differs much from unity. The volume ratio v is supposed to be large. The exponent n is between 1.0 and 1.4.

The formulas obtained are:

$$N = A \log_{10} \frac{C}{(x - b)^{1/n} - B}$$

and

$$l = B^n + b$$

where

$$A = \frac{2.303\ ntv}{1 + c}$$

$$B = \frac{c}{1 + c}(1 + a)^{1/n}$$

$$C = (1 - b)^{1/n} - B$$

CORROSION

Corrosion Tests of Metals in Mine Waters. The results of corrosion tests on 45 different metals and alloys in acid mine waters from coal mines, made in the course of a coöperative investigation by the Carnegie Institute of Technology, the United States Bureau of Mines, and an advisory board of coal-mining engineers, are summarized in Bulletin 4 of the Coal-Mining Investigations series, just published by the Carnegie Institute of Technology, Pittsburgh, Pa.

Water from coal mines is usually decidedly acid in character, and causes considerable trouble and expense owing to its corrosive action on mine equipment. These waters contain free sulphuric acid, and ferrous, ferric, and aluminum sulphates, in addition to sulphates of calcium, magnesium, sodium, and potassium, together with silica, and usually some chlorides. On standing, dilution, aeration, or warming, insoluble iron compounds tend to precipitate, principally as hydrous ferric oxides. The occurrence of iron sulphates and free sulphuric acid is due to the action of water and air on the pyrite or marcasite associated with the coal. These substances are oxidized to ferrous sulphate, ferric sulphate, and sulphuric acid.

In the coöperative investigation made by the Bureau of Mines and the Carnegie Institute of Technology three test specimens of each of the 45 metals and alloys were completely immersed in flowing water at each of three coal mines in western Pennsylvania for periods ranging from 98 to 135 days. The waters from these mines covered a wide range of acidity, from one esteemed to be below the average of that region to a water which is considered to be extremely acid. Inspections were made at regular intervals, and the degree and nature of corrosion was noted. At the completion of the test the specimens were removed, cleaned, and the extent and nature of the corrosion recorded. Samples of the mine waters were collected at each inspection, and the degree of acidity determined. Complete analyses were also made on the waters from the three mines.

All alloys tested of the brass type, containing considerable zinc, were corroded extensively by the mine waters. Bronzes, containing considerable tin, were also corroded, but to a less extent than the brasses. Evidently copper-zinc alloys are less desirable for use in mine water than copper-tin alloys.

Cupro-nickel alloys were corroded about to the same amount as the brasses. Nickel-silver alloys, which contain copper, zinc, and nickel, were also corroded extensively. Aluminum alloys showed a marked tendency to pronounced pitting.

The materials which showed a marked resistance to the corrosive action of the acid mine waters include a high-chromium steel, two highly alloyed chromium-nickel-silicon steels, a high-silicon cast iron, and a nickel-chromium-iron alloy. All of these materials, except the high-silicon cast iron, contain large amounts of chromium. These resistant materials have certain disadvantages for general use in coal-mine equipment, such as the brittleness and hardness of the high-silicon cast iron and the relatively high cost of the others; however, these resistant materials should prove satisfactory for use in pump parts and other equipment where these factors are not a serious consideration.

Economic considerations, such as cost, ease of fabrication, and physical properties, will be factors in determining the suitability of a metal or alloy for use in equipment exposed to the action of acid mine water. (Abstract from Bulletin 4 of the *U. S. Bureau of Mines*, by W. A. Selvig and George M. Enos, *ep*)

ENGINEERING MATERIALS (See also Corrosion)

Aluminizing Iron Articles. The following is quoted from the Notes and Memoranda column of a recent issue of *The Engineer*, which does not, however, give the source of the information.

"Articles made of a 15 per cent aluminum-iron alloy develop, on being heated to redness, a thin but highly resistant surface layer of aluminum oxide which does not scale, and prevents further oxidation of the metal, so that no appreciable alteration of the surface is noticeable after heating at a high temperature for one hour in a strongly oxidizing atmosphere. The alloy gives good castings and may, with care, be forged. Similar results are obtained by treating soft-iron articles by the Alitier process, which consists in heating the metal for some time, surrounded by a powder containing aluminum, whereby the latter penetrates the surface of the iron for a certain distance and forms a surface layer of iron-aluminum alloy that behaves in a similar manner to the 15 per cent alloy described above. An iron crucible treated by this method was practically unattacked after heating to 1000 deg. cent. for sixty hours, whereas a similar untreated crucible was destroyed in twenty-four hours." (*The Engineer*, vol. 135, no. 3500, Jan. 26, 1923, p. 93, *g*; cp. the process known in America as "calorizing.")

Condenser Tubes—Manufacture and Specifications

Condenser Tubes, Their Manufacture and Specifications, Technical Staff of the Chase Metal Works, Waterbury, Conn. An interesting description of the general process of manufacture, with special reference to Admiralty brass tubing and including a discussion of the causes of condenser failures.

The authors endorse the change recommended by Committee B-2 of the American Society for Testing Materials, i.e., that the minimum percentage of tin in the Admiralty mixture be decreased from 1 per cent to 0.9 per cent. This change was recommended in order that manufacturers might keep the average tin content as closely as possible to 1 per cent, which seems to be the ideal proportion for this mixture. This the authors feel to be an advantage and recommend the proposed change.

As regards the question of grain size, it is stated that the last drawing and annealing operations determine the final grain size of Admiralty condenser tubes within the usual tolerances.

To prove this statement the following test was made: A tube was picked at random from a pile of tubes that had just received the last but one drawing operation. This tube was cut off, one-half was annealed at a low temperature which gave a fairly small grain size, the other half was annealed at a high temperature which gave a larger grain size. Both these tubes were given the usual final drawing operation and afterward cut into lengths and given different annealing treatments. Although the annealing tests were made with tubes that had widely different grain size to start with, still the final grain size was in no case greater than 0.025 mm. This proves that the last drawing operation and the last anneal are sufficient to control the final grain size of a condenser tube within the usual tolerances.

These and many other tests of a similar nature show (1) that the final drawing and annealing are sufficient to control the final grain size within the usual tolerances, and (2) that the final grain size is absolutely determined by the last two drawing operations and the last two anneals.

This is also the opinion of the U. S. Naval Engineering Experiment Station at Annapolis, Md., which states that, in their experts' opinion, differences of method in the early stages of production, such as the casting process, have no bearing upon the grain size of the finished tube, and that the latter stages of production (drawing and annealing) are the controlling factors.

Entirely separate from the question of the production of such fine grains is the question of their desirability. The authors' search of the technical literature, the results of laboratory experiments, and the examination of failed condenser tubes have disclosed no evidence whatever that a tube of any particular grain size will last longer than a tube of any other particular grain size, other things being equal. It must be clearly understood that grain size is only a measurement of the annealing of temper of a metal. The temper of a finished condenser tube should necessarily fall between certain limits, but by diminishing the size of the grains a point is finally reached where there is a real objection to too fine a grain-size requirement, because in order to produce exceedingly fine grains it is necessary in the final operations to draw the material very hard, preceded preferably by relatively light anneals. This means an increased wear on the dies, an increased tendency toward scratching, and increased difficulty in getting narrow dimensional tolerances. All these things increase the cost of manufacture, for which the user will have to pay and for which he gets no return in increased life of the tube in service.

While a certain range in grain sizes may be desirable, it does not seem advisable to specify a definite size or maximum limits on

grain size and to lay such stress on the necessity of having tubes meet this requirement. This is specially true when it is considered that the determination of grain size in alpha brass is itself a relatively inaccurate measurement where errors of 10 to 20 per cent are common.

The real progress in condenser-tube manufacture has not been in discarding the cast-shell process but in the improvement of that process itself. Within recent years a large amount of research has been done in this connection and great progress has been made in the art of casting shells on a core. At the Chase Metal Works this research has resulted in the development of a special sand core, a special core dressing, and a method of casting by which cast shells are produced absolutely clean and sound. This improvement in the core and core dressing makes a tube as clean on the inside as it is on the outside; in fact, this improved core gives a satin finish and smoothness on the inside surface that the iron mold will not always produce on the outside surface.

In the same way that the grain size of the finished tube is shown to be produced by the last two drawing and annealing operations only, it may be proved that all the physical properties, including the ability to withstand the hammer, pin, and compression test, are likewise determined by the same two operations.

It is obvious from the above that a sound condenser tube can be made to comply with any reasonable specifications, irrespective of its casting or early stages of manufacture, by the annealing and drawing operations.

There are two changes in specifications the authors strongly favor: the inclusion in specifications of a mercurous nitrate immersion test, and decreasing the minimum tin content from 1 per cent to 0.9 per cent. They believe these to be valuable changes and added safeguards to the purchaser, and they do not believe the other changes that have been proposed will result in insuring the purchaser that he will get a better tube or one which will last any longer in service. There are undoubtedly things which future experimentation may bring out to improve the quality and service of condenser tubes. When any such improvements are discovered, the authors' policy dictates that they promptly urge their adoption. (*Raw Material*, vol. 6, no. 3, Mar., 1923, pp. 97–103, illustrated, *gd*)

FOUNDRY

Casting Hubs Entirely in Cores, H. E. Diller. Description of a process in which the core has entirely displaced the mold in the sense that the entire mold is formed of cores without even the use of a flask.

The process refers to casting iron hubs on steel wheels. Because of the lack of space it is impossible to describe in complete detail the whole process. One feature is the use in the mold of an extra cover acting as a pouring core. This pouring core also has holes for the downgate and blow-off, and a strainer is placed in the hole for the downgate. This strainer is used, however, only on hubs which have to be machined.

The cores are made of a mixture of approximately 50 per cent old sand and 50 per cent new sand, bonded with a mixture of pitch binder and a binder produced by the Robeson Process Company, of New York. The original article describes in detail the equipment used for making and baking the cores, and also the somewhat unusual methods in melting the metal and finishing the castings. (*The Foundry*, vol. 51, no. 5, Mar. 1, 1923, pp. 169–175, 12 figs., *dp*)

FUELS AND FIRING

Terminology in Coal Research, Marie C. Stopes and R. V. Wheeler. The authors have been responsible, either severally or jointly, for the introduction of a number of terms into the literature of coal. In the present article they give the definitions of these terms.

Of particular interest are the definitions and discussion of fusain, durain, clarain, and vitrain, these being illustrated by photomicrographs in black and in color.

The article is not suitable for abstracting as it deals chiefly with British coals, but the definitions of the constituents, of course, apply to American coals as well. (*Fuel in Science and Practice*, vol. 2, no. 1, Jan.-Feb., 1923, pp. 5–9, and 1 colored plate, *g*)

HYDRAULICS

Elimination of Water Hammer in Delivery Pipes

Device for Eliminating Water Hammer and Excessive Pressure in Delivery Piping, E. Maynard. The device described (Fig. 1) consists of a cone *A* placed over the delivery pipe. This cone is divergent, of variable length, and of a diameter suitably selected with respect to that of the pipe. It carries a small collar *B* supporting a steel plate *C*, perforated by parallel slots *D*, these slots being separated by bars *E* of triangular section in order that the water flowing may easily subdivide in order to pass over the grate thus formed. The total section of the slots must evidently be at least a little greater than the section of the pipe in order to reduce the loss of head due to the presence of the grate. Over the divergent cone *A* is placed a convergent cone *F* connected with the

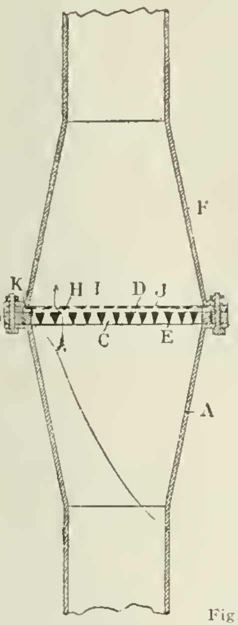

Fig. 1

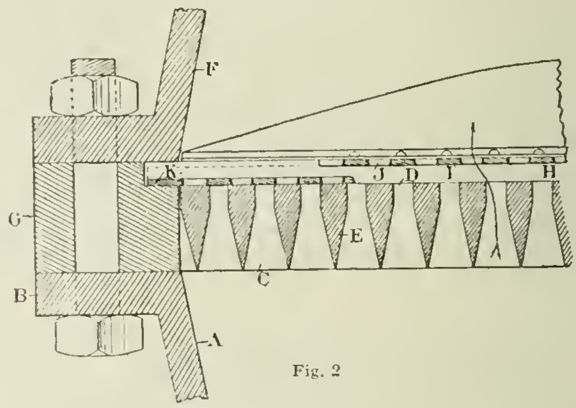

Fig. 2

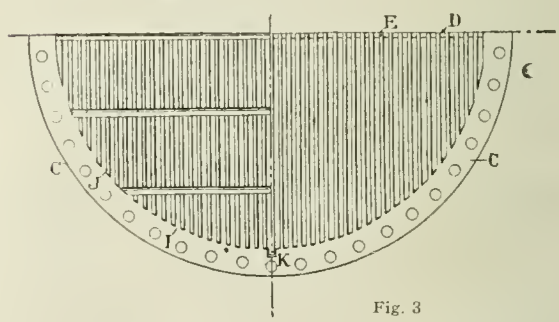

Fig. 3

Figs. 1, 2 and 3 Maynard-Tailleur Device for Eliminating Water Hammer in Delivery Pipes

delivery pipe. There is, however, a free space, say, 15 mm. (0.6 in.), between the upper part of the grate *C* and the bottom ring of the divergent cone. In this space *H* is placed a movable steel plate *I* provided with perforated parallel slots *J*, which do not, however, correspond to the slots in the grate above referred to. This plate can rise from 10 to 12 mm. (0.39 to 0.405 in.), but only under the effect of the pressure of the water produced in the delivery. This movable plate *I* is guided by four posts moving in vertical slots.

Figs. 1 to 3 show this system of grate valves. It is easy to understand how it operates. While the water is being delivered a movable plate which covers the slots in the grate is raised and remains raised in order to provide a passage for the water. When, however, the pumps begin to move slower or stop altogether the velocity of ascension of the water rapidly diminishes, and the plate, the inertia of which is small but which has a certain weight nevertheless, begins to move downward in the liquid and falls to the grate, the slots of which it closes the instant the velocity is reduced to zero, this action being rapid because of the short distance that the descending plate has to travel. As it is possible to regulate

the weight of this plate in a suitable manner so that it will fall to the grate at the precise instant when the velocity of the water is reduced to zero or changes in direction, it becomes possible to obtain a complete elimination of water hammer.

This result is of particular importance as it will make it possible to obtain marked economies in the construction of steel delivery pipe, for it will no longer be necessary to provide excessive strength to take care of water hammer.

The original article contains a numerical description of an application of this method which is patented in France. (*Revue Générale de L'Electricité*, vol. 7, no. 6, Feb. 10, 1923, pp. 211–213, 4 figs., *d*)

Complete Theory of the Centrifugal Pump, L. Bergeron. An extensive article not suitable for abstracting. The author is an instructor in applied hydraulics at the Central School of Arts and Manufactures in Paris and is considered to be one of the best experts on centrifugal pumps in France. (*France-Belgique*, vol. 1, no. 1, Jan., 1923, pp. 16–36, 12 figs., *g*)

INDUSTRIAL MANAGEMENT

Factory Organization. A collection of papers presented at the meetings of four organizations, one of which is The American Society of Mechanical Engineers (meetings of the other three societies being held in Germany).

The conclusion at which the editor, in commenting on these meetings, arrives is that America and Germany are the two countries where most of the work is being done for laying the foundation for the solution of the entire problem of organization.

It is significant that the majority of German papers are devoted not so much to scientific management proper, as it is understood in America, as to the organization of factory and cost accounting. The American Society of Mechanical Engineers papers are presented in detail. (*Werkstatts-Technik*, vol. 17, no. 5, Mar. 1, 1923, pp. 129–159, *g*)

INTERNAL COMBUSTION ENGINEERING

18-Hp. Cherub Aero Engines. Description of a two-cylinder engine developed by the Bristol Aeroplane Company, in particular for use on small aircraft of the glider type.

The engine is a flat twin air-cooled unit with cylinders of an aluminum alloy, with detachable head. The valve mechanism is of interest. A single camshaft with four integral cams, and driven by gearing from the crankshaft, lies inside the crankcase. The cams operate fingers, which, in turn, operate rocking shafts. The rocking shafts are returned by coiled springs and the mechanism is such that when the cylinders warm up there is no increased clearance between the rocking shafts and valves. Twin concentric springs are used for the valves and the whole mechanism is enclosed and automatically lubricated.

Two types of engines have been designed—one with the driving boss running at crankshaft speed to be used in conjunction with the chain-driven propeller, and the other with a two-to-one reduction gear enclosed in the crankcase. The engine has a bore of 85 mm. and stroke 94 mm., develops 18 hp. at 25 r.p.m., and weighs complete 85 lb. (*The Engineer*, vol. 135, no. 3506, Mar. 9, 1923, p. 270, 1 fig., *d*)

New British Lifeboat Motor, W. O. Horsnaill. Description of the motors recently installed in the lifeboats of the Royal National Lifeboat Institution and claimed to be the most reliable gasoline machinery in existence.

The motors are rated at 90 b.hp. at 800 r.p.m. and have six cylinders with a bore of $5^1/_2$ in. and a stroke of 7 in. Not only are they entirely enclosed but all the ports are watertight up to the level of the carburetor inlets, of which there are two and which are carried upward nearly to the top of the engine. To make assurance doubly sure the engine is installed in a watertight case with the control and instrument connections brought through watertight fittings. One of the features of the engine is the combination in one casting of a common tank-type water jacket with a complete crankcase, the latter entirely enclosing the crankshaft.

The two features which deserve particular attention are lubrication and water circulation. As regards the former, it should be borne in mind that automatic and effective lubrication of every moving part is a vital necessity in a lifeboat motor. It is impossible to open the case on a rescue trip and give an extra dose of oil to any part which has run dry. In this case a combination of pressure feed and splash lubrication has been adopted. (The details are given in the original article.)

As regards water circulation, the water circulates in a closed circuit which includes multi-tubular coolers in wells open to the sea, alternative sea connections being provided. The pump draws from either the coolers or the sea, delivering to the center of the tank jacket near the bottom. Thence the water rises through holes to the head and eventually reaches the jacket of an exhaust box which covers the two manifolds. An interesting feature is the grading of the holes to the head to give an equal quantity of water to all parts, according to their distance from the point of supply. From the exhaust box the water may go either overboard or back to the pump suction, the direction being regulated by a thermostat.

The reverse gear is of the epicyclic type with a multiple-plate clutch for the ahead drive. Much trouble has been experienced with reverse gears in lifeboats, hence meticulous care has been taken to guard any possibility of failure. Every part subject to torque is splined to its spindle—this feature including even the control gear—and every internal nut grooved and split-pinned, while outside screws have lock nuts or spring washers. An unusual feature is a locomotive-type shoe brake to hold the pinion gear box for going astern. The control shaft is fitted with a heart-shaped cam which nearly closes the carburetor throttles in the neutral and opens them out for going ahead or astern. A ball thrust block is fitted at the after end of the reverse-gear case, beyond which is a coupling, splined to the shaft and surrounded by a stuffing box to secure watertightness at this point.

A capstan on the fore deck is worked by a clutch in the flywheel. This clutch is fitted with a pinion which meshes with another on a horizontal shaft, the forward end of which drives the capstan through worm gear. By means of hand control gear the clutch is forced into a cone in the flywheel with greater or less pressure according to the pull on the capstan. It will be easily understood that the 90 hp. of the engine would easily break any ropes being hauled or even the capstan gear unless some slipping device was provided. (*Pacific Marine Review*, vol. 20, no. 3, March, 1923, pp. 126–128, 5 figs., *d*)

MACHINE SHOP

Hobbing Tangent-Rack Gears. The Hotchkiss crown-wheel gear was described in Mechanical Engineering, vol. 44, June, 1922, p. 387. The present article illustrates the system used to generate this gearing by means of a conical hob which was devised by H. E. Taylor, chief engineer of the firm. The article describes both the principles of generation of this gear and the machine used. (*Engineering*, vol. 115, no. 2978, Jan. 26, 1923, p. 106, 7 figs., *d*)

MARINE ENGINEERING (See Internal-Combustion Engineering)

METALLURGY

New Method for Case-Hardening. Description of a process developed by Dr. Assar Gronwall, a Swedish scientist, inventor of the Electrometall type of electric shaft ore-smelting furnace. The process is based upon experiments which proved that as the gases enclosed in the case-hardening pots become saturated with carbonic acid, which happens fairly rapidly, the process gradually stops.

The new method consists of converting the carbonic acid as formed to carbon monoxide. This is done by putting catalyzers of a special metal in the form of thin sheets, ribbon, or wires, into the casing box with the carbonaceous matter surrounding material to be case-hardened. The catalyzer then acts in such a way that the carbonic acid, when coming in contact with the metal, passes into carbon monoxide. An iron object may be case-hardened deeper on a certain spot by placing catalyzer there. In the case of gear wheels, they were case-hardened only on the outer parts of the cogs.

The catalyzer is not consumed during the operation and therefore the expense for the new method consists only of the outlay for the original catalyzers and the license to operate.

With this method it is claimed that less carbonizing material is needed, that the temperature can be kept lower than in the usual method, and that the time required is about half that formerly necessary. The tests at the Technical Academy, Stockholm, consisted in treating pieces of steel from the same bar in an electrically heated furnace, first by the usual case-hardening method and second, with the addition of a catalyzer. The amount of case was considerably deeper in the second set of samples, although time occupied, temperature, and other conditions were exactly the same. (*Iron Trade Review*, vol. 72, no. 9, Mar. 1, 1923, p. 660, *d*)

PHYSICS

Glue Bubbles, Carl Barus. The work of Dewar (Journal A.S.M.E., April, 1918, p. 349) and others on soap bubbles have shown that important information can be derived from the behavior of these bodies. The present article deals with glue bubbles, and, in particular, the measurement of pressure increments within the bubble, which the author claims can be done by an interferometer which he has designed.

Glue bubbles can be obtained directly and are sometimes obtained so that they actually last indefinitely; these solid glue bubbles may be ultimately detached. The author discusses the growth of the bubble and shows graphically the result of the successful dilution of the original liquid glue. It would appear that the surface tensions remains low and nearly constant until a dilution of the order of 0.005 is reached, and therefore with further dilution the surface tension increases very rapidly. (*Science*, vol. 57, no. 1466, Feb. 2, 1923, pp. 151–153, 1 fig., *e*)

POWER-PLANT ENGINEERING (See also Engineering Materials)

Some Deductions from Indicator Diagrams, Alberto Keens. Extensive discussion of a practical nature of the indicator diagram and what it teaches. The author has made no special attempt to present anything except a clear practical discussion of his subject, containing such information as would be of use, for example, to a sea-going engineer or an engineer in charge of steam engines; special attention being paid to the salient factors upon which the smooth and economical running of the engine depends.

The paper is not suitable for abstracting but would prove to be of considerable interest to students in engineering and all those who wish to clarify their practical knowledge of the indicator diagram. (*Institute of Marine Engineers*, paper read Jan. 30, 1923, abstracted through advance copy, illustrated by numerous diagrams, *p*)

POWER TRANSMISSION

Mechanical and Electromechanical Oscillations, Henrich Schieferstein. On page 254 of Mechanical Engineering, April, 1923, there appears an abstract describing the general principles of the Schieferstein method of power transmission by oscillations. The present article describes the same subject in greater details and illustrates by drawings and photographs some of the machinery employed. Among other things it mentioned the use of oscillating planes for aircraft. (Abstract of paper read before the Verein deutscher Naturforscher in Leipzig, Sept. 19, 1922, abstracted through *Zeitschrift f. Technische Physik.*, vol. 3, no. 12, 1922, pp. 377–380, 11 figs., *d*)

PUMPS

High-Speed Pump with Ring Valves. This pump, built by the Pulsometer Engineering Company, Reading, England, is of the reciprocating single-acting plunger type fitted with rubber ring valves working on gun-metal seats. The pumps of this type are built in sizes to deliver from 250 to 2000 imperial gallons per hour at heads up to 100 ft. They are designed to run at speeds from 300 to 500 r.p.m., which makes them suitable for belt driving from high-speed electric motors. The pump casing is cast in one piece with the enclosed crank chamber. The front part of the gun-metal plunger acts as a crosshead working on a guide extending into the crank chamber, and thus relieves the plunger and stuffing box from all side strain. The connecting rod is of gun metal with a marine-type large end which works on the pin of a balanced crank.

The suction valves are in the internal grooves and work in compression, while the delivery valves are in the external grooves and work in tension. The aggregate area of the water passages is large, so that the only movement of the valves consists in a very slight compression or elongation of the rubber. The pumps can therefore work at very high speeds with absolute silence under all conditions. (*Engineering*, vol. 115, no. 2981, Feb. 16, 1923, pp. 217, 6 figs., *d*)

Gyroscopic Pumps

Gyroscopic Pumps, Morris Gendrin. In view of the fact that little information is available in English as to these pumps, a somewhat extended abstract of the article is deemed advisable.

In the first place, certain mechanical principles have to be recalled. All movements of an aggregate of material points may be referred to a system of axes arbitrarily movable in space. We have the right to do this, provided we assume that at each of the material

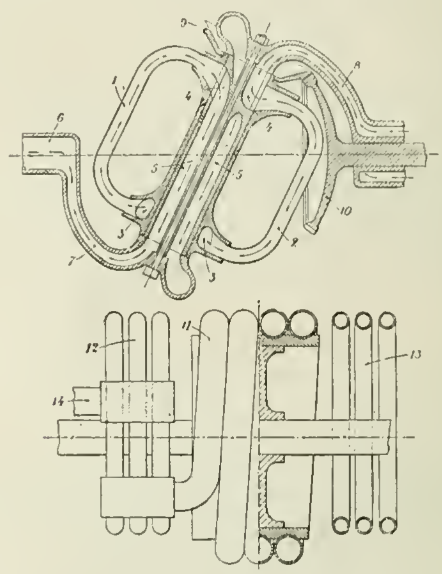

Fig. 4 Diagrammatic Views of Two Types of Gyroscopic Pumps

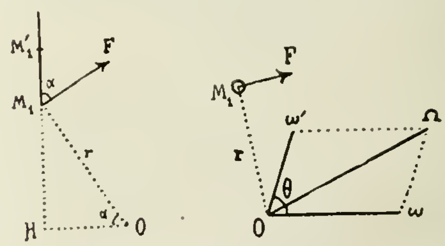

Figs. 5 and 6 Diagrams of Forces Acting in a Gyroscopic Pump

points M two apparent forces are applied, namely, the inertia of entrainment and the component centrifugal force.

The force of inertia of entrainment is the product of the mass times acceleration of entrainment with the sign changed, the acceleration of entrainment itself being the acceleration of a point referred to movable axes which coincide with the point M at the instant under consideration.

The component centrifugal force is the product of the mass by the complementary acceleration with the sign reversed. If, beginning with the instantaneous axes of the rotation of entrainment, the vector OV be equal to the relative velocity of the point M, the complementary acceleration is equal to twice the velocity which the point V would have under the action of the instantaneous rotation of entrainment. A rotation is often represented by a vector OA projected on the axis and equal to the angular velocity. If the axis

is fixed and the movement uniform, the force of inertia is merely a centrifugal force as generally known.

Assume now, however, that either the direction or the magnitude of the vector OA varies, the point O remaining fixed, which means that A has a certain velocity AB; also take $O\beta'$ equal to AB. It can then be shown that the acceleration is equal to the magnitude which it would have if OA were fixed, plus a component equal to the velocity which would be impressed on the point M by a rotation $O\beta'$. Whereas the centrifugal force tends to draw away from the axis all the material points, the second component tends to make them rotate all in one direction and it is this force that is used in gyroscopic pumps by their inventor, Emil Faure.

Principle of Gyroscopic Pumps. A movable part consists of an aggregate of passages, and for purposes of discussion it is convenient to consider the axes referred to these passages. Under these conditions there occur a certain number of forces producing a displacement of the fluid. These forces may be considered here in succession: first, external forces, in this case gravity; next, the difference of pressures between two adjoining sections of the same passage; third, the action of walls perpendicular to the velocity (owing to a proper selection of the axes) which, however, does not affect the movement of the fluid in the passage. The same definition applies to the component centrifugal force. Next comes the ordinary centrifugal force as used in centrifugal pumps; this is produced by a potential. In gyroscopic pumps, however, there are only two groups of forces that come into action, namely, the pressures and the components due to variations of the velocity of rotation. In other words, an effort is made to obtain a difference of pressure by constantly varying the instantaneous velocity of rotation. Two extreme types have been considered by Faure: in one the direction of rotation alone varies; in the other the magnitude of rotation alone varies (for example, oscillating rotation).

First Type—Description. A certain number of passages 1 and 2 (Fig. 4) mounted two by two in series inside of the curved body 3, constitute the inlet to the pump. Their free ends communicate with the cylindrical valve 4 forming part of the central tube 5. The motor drives the hollow shaft 6 and this governs the rotation of the conduits 7, 5, and 8 which are connected to the valve. The gear connected to the inductor meshes with gear 10 which is stationary, and thereby gives the inductor a second movement about the relative axis formed by the central tube 5.

The cylindrical valve 4 is so arranged as always to give to the fluid circuit the shape shown by the figure. At the same time the bisector planes of the two orifices of the valve form a certain angle with the plane of the axes of rotation, the purpose of this being to reduce for a certain output the losses of kinetic energy due to impact of the fluid against the walls of the valve. (This arrangement is somewhat similar in principle to the shifting of the brushes of electrical machines.) The pressure may be adjusted to any value below the maximum, and this without changing the velocity, by regulating the position of the valve by rotating it about its axis.

Operation. Assume that an observer standing on the right-hand side sees the shaft 6 rotating in the direction of the hands of a clock. An observer standing above the machine will see the indicator turn in the same direction. The two rotations, of entrainment and relative, are represented by the vectors ω and ω' and they combine into an instantaneous rotation Ω. The extreme end of the vector Ω driven by the rotation ω has a velocity $\omega\omega'\sin\theta$ perpendicular to the plane of the figure and away from the observer. In accordance with the theoretical considerations set forth above, a material point M projecting into M_1 is acted on by a force $F = m\omega\omega'r \sin \theta = Kr$ (Fig. 6). This explains why the liquid in Fig. 4 follows the path indicated by the arrows. With this in mind it is very easy to carry out the calculations. Here merely the result will be given. The work which a force F exerts in producing a displacement $M_1M'_1$ of a point M_1 is equal to—

$$M_1M'_1 + Kr \cos \alpha = K \times M_1M'_1 \times OH = 2K \times \text{area } OM_1M'_1 \quad (a)$$

As a result the work applied to a mass m of a liquid is equal to $W = 2m\omega\omega' \sin \theta S$, where S is the projection of area of the circuit on the plane of the figure. If V is the volume of this liquid mass having a density ρ, then $W = V(p - p_0)$, and consequently $p - p_0 = 25\omega\omega'\sin\theta S$. If the liquid flows through a circuit the sectional area of which is 1 sq. dm. and the two shafts (perpendicular) make 10 r.p.s., the pressure will be 0.8 kg. or 8 m. of water, which shows that it is possible to obtain considerable pressures without making the velocity excessively high.

The second type of pump, shown in the lower half of Fig. 4, namely, one where the velocity of rotation alone varies, is also described in the original article, but cannot be discussed here owing to lack of space. (*France-Belgique*, vol. 1, no. 1, Jan., 1923, pp. 69–71, 3 figs., *dA*)

RAILROAD ENGINEERING

Willamette Geared Locomotives. Brief description of geared locomotives manufactured for logging purposes by the Willamette Iron and Steel Works, Portland, Ore. The locomotive uses a side drive and is equipped with a three-cylinder vertical engine

Fig. 7 Geared Locomotive Built by the Willamette Iron and Steel Works, Portland, Ore.

capable of developing approximately 900 hp. The boiler carries a working pressure of 200 lb. and is built in accordance with the requirements of the A.S.M.E. Code. The Walschaerts type of valve gear has been adapted. A photograph of the locomotive is reproduced in Fig. 7. (*Railway Age*, vol. 74, no. 16, Mar. 24, 1923, pp. 809, 1 fig., *d*)

New Cars of Special Design for the London Electric Railway. The London Electric Railway Company (Associated Underground Companies) not long ago gave an order for one car each to five leading rolling-stock construction firms, giving them practically permission to build cars to their own designs, in addition to which one car built to the design of the Underground engineering staff was also placed in service.

Among the features introduced may be mentioned the position and width of the doors, which is uniform in all the cars, namely, a pair of double doors spaced along each side of the car. A further feature is the attempt which has been made to provide as silent running a car as possible. Dr. Low, on behalf of the company, has taken photographs of the sound heard in an ordinary underground subway car when in motion and it was found possible to locate the principal causes of noise. Steps were taken to reduce this and the experience thus gained has been utilized in designing the sample cars. The original article gives an internal view of the cars which are extremely unlike anything used in America. The cars are described as being "de luxe."

The ventilation in the cars is so designed that there will be no need to have windows open while traveling. The original article describes the five cars in detail. (*The Railway Gazette*, vol. 38, no. 6, Feb. 9, 1923, pp. 195–199 and 202, 8 figs., *dA*)

Mikado Locomotives vs. Electrification on the D. L. & W. About 40 per cent of the traffic on the Delaware, Lackawanna & Western consists of anthracite coal mined in the vicinity of Scranton. Scranton and the coal mines are located in a valley with heavy grades—about $1^1/_2$ per cent—in both directions, the grade toward the east being considerably longer than the west-bound grade.

In order to equalize the operating capacity of the road plans were drawn for the electrification of some 40 miles of gradients near Scranton, the intention being to furnish electric-locomotive helper and pusher service to the summits for the east- and west-bound traffic. It was found, however, that the cost of the project would be in excess of \$5,000,000, as a result of which the company decided to postpone electrification for the time being and to purchase in-

stead 40 powerful Mikado-type locomotives. This was done and coal trains are now made up and taken through solid from Scranton to the west or to the seaboard. The new Mikado locomotives with the helper service are hauling trains of 2900 tons through from Scranton to the Secaucus yards, near Hoboken.

With these powerful locomotives a larger tender is used, the capacity having been increased from 10,000 gal. of water and 12 tons of coal to 12,000 gal. of water and 14 tons of coal. This increased capacity enables the locomotives under ordinary conditions to take a train to the summit east of Scranton without taking water and to run 130 miles from Scranton to Secaucus yard without taking coal.

The 40 new locomotives are noticeably heavier than those already in service, and in terms of tractive force are the most powerful Mikado locomotives ever constructed. They were designed by the American Locomotive Company to meet the special traffic conditions on the D. L. & W. and were built at the Schenectady works.

The new Mikado locomotives have 10,600 lb. greater tractive effort than those previously used by the same road. An increase in tractive force of the main cylinders was obtained by changing the piston travel from 30 in. to 32 in. and raising the steam pressure from 180 lb. to 200 lb. The weight of the locomotive was also increased with the result that there is now an axle load of 68,000 lb., which would not have been permissible except for the favorable track and bridge conditions prevailing on the Lackawanna. A booster is also installed, in addition to which are used an Elvin mechanical stoker and a Baker valve gear, together with other modern special equipment.

These D. L. & W. Mikado locomotives will naturally be compared with those for the New York Central Lines, one of the most striking designs brought out in 1922 and for which orders were placed for 191 for the various roads comprising that system. The New York Central locomotives weigh 334,000 lb. in working order, have 28-in. by 30-in. cylinders and 63-in. driving wheels. They also are equipped with boosters and have a total rated tractive force of 74,500 lb., or 63,500 lb. without the booster. Other heavy Mikado-type locomotives recently ordered are those for the Central of New Jersey weighing 342,500 lb., having 27-in. by 32-in. cylinders and a rated tractive force of 59,000 lb., and those for the Northern Pacific weighing 337,000 lb., having 28-in. by 30-in. cylinders and a rated tractive force of 57,000 lb. But few Mikado locomotives having a tractive force of over 60,000 lb. have been built. (*Railway Age*, vol. 74, no. 9, March 3, 1923, pp. 511–513, 5 figs., *dc*)

REFRIGERATION

An Oscillating Ammonia Compressor

Oscillating Ammonia Compressor, H. J. Macintire. A description of what is claimed to be a new type of compressor. The action of the machine is as follows: Referring to Fig. 8, the suction gas enters through pipe *A* into the hollow rotor shaft *B*, which has a long slot *D* through which the gas may pass into the compressor cylinders *C* when the rotor has rotated far enough for that purpose. It will be noticed that the rotor makes with the cylinder *E* four compression chambers *C*, which are single-acting. The gas enters when the ports are uncovered and is discharged through disk-type discharge valves into the annular space *F*, from which it passes to the oil-filled chamber *G*. The compressed ammonia

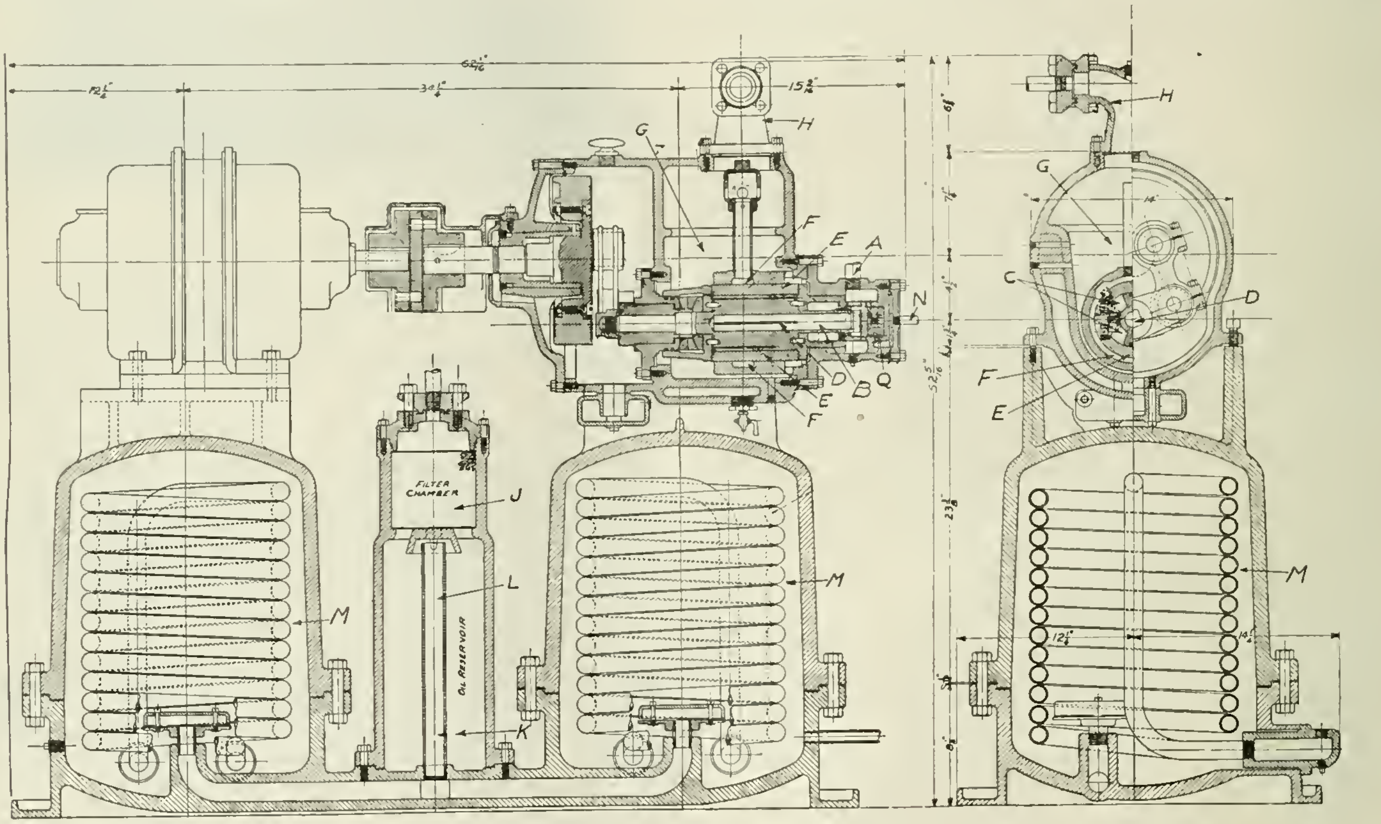

Fig. 8 Oscillating Ammonia Compressor

with entrained oil then passes into the dome *H*. From *H* it is led through a pipe connection to the filter chamber *J*, which is filled with material suitable for the collection of mist particles and the formation of drops. The oil then falls in drops into the oil reservoir *K*, while the ammonia gas is taken through the standpipe *L* into the two shell and coil condensers *M*. The oil from the reservoir *K* is then returned to the compression chamber. It is first led by means of a pipe *M* into the end of the cylinder casing, from which, by means of an oil-measuring device *Q*, it is given passage into the suction gas at *B*.

The rotor is driven by means of a four-bar linkage mechanism, and is designed to rotate through a 69-deg. arc at a speed of 850 oscillations per minute. The compressor is operated practically flooded in oil, reliance being placed on the efficiency of the filter to remove all traces of oil from the ammonia. The ordinary stuffing box is replaced by a self-aligning metal seal *R*. Any oil leaking by this seal will collect in the sump *S*, from which it can be drained occasionally. The shell and coil condensers, in the smaller design, make a convenient frame on which to support the motor and compressor.

It is claimed that the field for such a compressor is in the smaller

designs, especially in view of the noiseless operation of the compressor.

In the discussion which followed, the author in reply to a question stated that he had had but three or four weeks of experience with the device under conditions where gas must leave the cylinder highly impregnated with oil, but the liquid ammonia showed up in the gage glass perfectly clear. (*Refrigerating Engineering*, vol. 9, no. 8, Feb. 1923, pp. 252–253, 2 figs., *d*)

Specific Volume of Saturated Ammonia Vapor, C. S. Cragoe, E. C. McKelvy, and G. F. O'Connor. Data of extensive experiments carried out at the Bureau of Standards some years ago. The paper presents a discussion of previous measurements and data of the present investigation. Among other things, a form of empirical equation expressing specific volume as a function of temperature has been derived.

A form of empirical equation was sought which would represent the results closely and which would also satisfy the terminal conditions at the critical temperature. The equation should, at that temperature, give a finite value for the specific volume u' and approach the value $-\alpha$ for the derivative $\frac{du'}{d\theta}$. In view of the approximate reciprocal relationship between specific volume and vapor pressure, an equation similar to the vapor pressure-temperature equation suggested its possible usefulness with an additional term which would make it satisfy the second condition mentioned above. As in the case with vapor pressure, no simple relation has been found which can be used even over a comparatively small interval of temperature.

An equation of the form—

$$\log u' = A + \frac{B}{\theta} + C \log \theta + D - \sqrt{\theta_c - \theta} + E(\theta_c - \theta)$$

where θ_c is the critical temperature, was found to meet the above requirements.

The measurements were carried out by two methods, one involving a direct determination of the mass of vapor contained in a known volume, and the other an optical method involving measurements of the index of refraction of the vapor, from which the density of the vapor could be determined. The values for the specific heat were calculated from the Clapeyron equation, using other data obtained at the Bureau. The experimental results found by the two methods are in fair agreement with the calculated values above 0 deg. cent., differing at most by about 0.3 per cent. Below 0 deg. cent. the results found by the direct method are systematically lower and those found by the optical method are systematically higher than the Clapeyron values, amounting to about 2 per cent at — 50 deg. cent. The calculated values were chosen, therefore, as the most probable values. The possible sources of error in the two methods are discussed.

The final results are represented closely by the empirical equation:

$$\log_{10} u' = 300\left[\frac{6.46344}{\theta} - 0.106887 + 0.0356803 \log_{10}\theta\right]$$
$$+ 0.0862366\ \sqrt{406.1 - \theta}\ +\ 0.002667\ \ (406.1 - \theta)$$

in which u' is expressed in cubic centimeters per gram and θ in degrees absolute (deg. abs. = deg. cent. + 273.1). (*Refrigerating Engineering*, vol. 9, no. 8, Feb., 1923, pp. 239–248 and 258, bibliography, 4 figs., *e*)

SPECIAL PROCESSES

Forging Steel Tubing Instead of Drawing It, Chester Warner. Description of a process developed by the author in collaboration with E. Warner. It is claimed that by this process large square, round and other internal sections can be made in wall thicknesses of $^3/_4$ in. and up, and in lengths up to 8 ft.

In this process a block of steel of the required weight is pierced with a hole $^1/_4$ to $^1/_2$ in. larger than the size it is to be at the finish. It is carefully inspected and then reheated and placed under a high-speed hammer, where the roughing mandrel is inserted and the block roughed out to the length of the tool, after which the tool is withdrawn and the tube reheated. This last is done very slowly to insure uniform temperature throughout the entire tube. The tube is then again taken to the hammer, the finished mandrel inserted, and the tube drawn to size. Water is employed in this operation as a cooler. If the tube sticks it is only necessary to allow tube and tool to cool, after which the tube may be withdrawn with ease.

It is stated that in no operation has the waste exceeded 10 per cent, and that the ends have been found free from cracks when as little as $^3/_8$ in. has been cut off from them.

Difficulty was at first experienced with the steel used in the mandrels which must withstand severe use. They must not only retain hardness under high temperatures but also keep a smooth, clean surface—not crack or warp. These qualifications have not yet been fully attained, but progress has been made; the mandrels, however, will crack once in a while. The tubes have a slight taper, the dimensions of which for the various sizes are not given. (*Raw Material*, vol. 6, no. 3, Mar., 1923, pp. 90–91, 5 figs., *d*)

STEAM ENGINEERING (See Thermodynamics)

THERMODYNAMICS

Internal-Combustion Heat Losses and Specific Heat of Working Fluid. A somewhat general discussion from which only certain points can be abstracted on account of lack of space.

It is frequently stated that the gaseous medium of closed-vessel tests is highly transparent to its own radiation. The writer questions this assumption for two main reasons, the first being that the diathermancy of the gases will decrease with increasing density. This explains the apparently lower values of specific heat at the higher densities. The reason for the relatively high explosion pressures attained by Professor Petavel in his experiments thus lies in the diminished radiation losses at high densities. In the case of any gases consisting of particles of H_2O the interception of radiated heat by such particles must, at least, be appreciable. Indeed, the fact that the specific heats at constant pressure and constant volume may be written

$$\left(\frac{dK_p}{dP}\right)_T = -T\left(\frac{d^2V}{dT^2}\right)_p$$

and

$$\left(\frac{dK_v}{dV}\right)_T = T\left(\frac{d^2P}{dT^2}\right)_v$$

respectively, is a strong argument against any variation of specific heat with density at high temperatures, since the departure from the usual gas law at such temperatures can scarcely be to the extent required to make the argument valid.

The second reason for non-belief in the high transparency of the gases to their own radiated heat is based on the conviction that during the first half-second of the explosion at least, heat losses in closed-vessel tests are almost wholly radiation losses. This conviction is upheld principally by the fact that test results on explosion vessels of different dimensions can be thereby reconciled. For high transparency, total heat losses on this view, should, in explosion-vessel tests, be proportional to l^3. Actually they are not so proportional. Various figures put forward by different experimenters for the value of the index n in the relation

$$\text{Total heat losses} \propto l^n$$

all agree that n is less than 3. If heat losses in such closed-vessel tests are practically all radiation loss at the outset, as the writer contends, high transparency would give the l^3 law. The only possible argument will be proportional to l^2, and so, in effect, will reduce the index n to some value between 3 and 2.

The author proceeds to show from both experimental and analytical evidence that this reduction in the value of n may be explained by relatively low discrepancy of gases to radiated heat, while holding at the same time that the initial conduction loss (enclosed-vessel test) is practically negligible.

The author surveys some engine tests for purposes of comparison with explosion-vessel tests and derives the following values of the specific heats at constant pressure and constant volume:

$$K_p = 316 + 0.0623\ T \text{ ft-lb. per lb. per deg. cent.}$$
$$K_v = 220 + 0.0623\ T \text{ ft-lb. per lb. per deg. cent.}$$

He plots the internal-energy lines based on the specific-heat values and compares with them lines derived from various authorities, the results showing large discrepancies between these different values. He points out, however, that his values are practically coincident with the values of the specific heats of carbon dioxide, nitrogen and air as measured by Professor Dixon and others, by measurements of sound velocity in the medium. (*The Engineer*, vol. 115, no 3504, Feb. 23, 1923, pp. 191–192, 3 figs., *tA*)

Fundamental Properties of Water Vapor

Fundamental Properties of Water Vapor, Prof. M. Strauven. An analytical discussion, only part of which can be referred to here. Among other things, the author carries through a careful comparison of the systems of values of Callendar and of Eichelberg, and shows that the difference between the two sets of values may be as high as 1 per cent. It is, however, of greater importance to determine not so much the absolute values of I (total energy) as its variations between two given states (the fall of total heat). In practice, expansions beginning with the state of superheated steam end quite often in saturation, a region for which the expression for I takes the form—

$$I = q + xr + Apv.$$

From this the author proceeds to consider the three cases of adiabatic expansion and shows that the differences in results between the Callendar and Eichelberg equations may be, under certain conditions, as high as 6 per cent, which occurs mainly, however, when the initial and final expansion pressures differ but little from each other. This is due to the fact that the absolute values of I in the Callendar and Eichelberg equations are sensibly equal for the high and the low temperatures, but give different results for the region of intermediate temperatures.

The author considers next the specific heats of superheated steam and comes to the conclusion that the values of C_p (Callendar) at high pressures do not agree with the direct measurements of the Munich tests. On the other hand, however, the Munich tests agree perfectly for the region of low pressures with the values experimentally obtained by Callendar. Callendar defended his values by pointing out that the values of C_p at saturation were obtained in the Knoblauch tests by means of a purely empirical extrapolation of experimentally obtained isobars. This objection was answered, however, when Eichelberg succeeded in working out an equation of state of dry steam instead of the extrapolation formula of C_d obtained from this equation of state, and the Callendar equation may be put in the form of—

$$C_p = C_{p_0} + 0.334 \frac{p}{T^{13/3}}$$

The Thomson-Joule effect is discussed next and it is stated that the divergence between the experimental values of Callendar and the calculated values of Eichelberg is comparatively small, which is noteworthy since the determination of the Thomson-Joule effect by means of a throttling calorimeter is an extremely delicate operation, and, for example, the presence of 1 per cent of moisture in the steam at the entrance to the calorimeter may cause a variation of 10 deg. in the temperature of the steam at the exit. Because of this the agreement between the Callendar and Eichelberg values is all the more interesting.

The properties of dry saturated steam are discussed next. In this connection attention may be called to the discussion of the *I-S* diagram as proposed by Schuele, in particular the discussion as to the values of r from the Munich experiments and the Eichelberg equation. There is a material difference between the two, especially above 180 deg., the Schuele values being usually considerably higher. It is the opinion of the author that the only way to determine the cause of these differences is to carry out new experiments on the heat of vaporization of steam at high temperatures. At the same time he points out that the values adopted by Schuele for the high temperatures lead to the conclusion that in that region the total energy at constant temperature may, under certain conditions, increase with the pressure, but the specific volume of a vapor, the conditions of temperature and pressure being equivalent, is always inferior to that of a perfect gas having the same characteristic constant R, and from this the author deduces that with an increase in pressure and constant temperature the total energy gradually decreases, which is contrary to the conclusion resulting from Schuele's values but is in accordance with the relations of Eichelberg and is proved by the values obtained by Callendar. Since, further, the heat of vaporization r appears in the calculation of the entropy of steam, it would follow that Schuele's *I-S* diagram must give values for high pressures which are materially different from those obtained by Eichelberg, and this difference may be in excess of 2 per cent—and even more under certain conditions.

The conclusion at which the author arrives is that of giving preference to the values derived from the equation of state of Eichelberg. He points out at the same time, however, that this equation has been experimentally proved only for pressures up to 25 atmos. and should have further experimental confirmation before being used for extrapolation to higher pressures. From this point of view it would be desirable to study experimentally at high pressures and high temperatures the Thomson-Joule effect, the heat of vaporization, and the value of the exponent in the adiabatic equation. (*Revue Universelle des Mines*, vol. 16, nos. 4–5, Feb. 15 and Mar. 1, 1923, pp. 289–301 with 1 plate of diagrams, and pp. 363–376 with numerous tables and curves, *tA*)

VARIA

Polytopical Clocks with Time Spiral Showing World Time, R. Hirsch. Description of a world-time clock with rotating face and without hands exhibited in the German Museum at Munich. In this clock a map of the world is printed on the face and the clock is so arranged that once the desired city is found on the map the time in that place can be read off, though, it must be stated, not with ease.

Another type of clock for a similar purpose has hands and a stationary 24-hr. face. The hands are fastened on a map of the world in the places representing the locations of the different towns. The map is, however, of a somewhat unusual type, in that while the meridians appear as usual the latitudinal lines have retained their circular shape, but attain their largest diameter at the south pole instead of at the equator. This clock must turn from right to left corresponding to the rotation of the earth from west to east. It also deviates from the ordinary clocks inasmuch as it must be fitted with a special movement, permitting of one rotation of the hour hands within 24 hr.

A method is also described for converting any ordinary 12-hr. watch or clock into a world-time clock without alteration of the movements or works. To achieve this purpose, besides the normal hour hand for the local time several additional hour hands are provided which are fixed at the proper angular distance from the main hour hand and which turn together with the latter. (*Engineering Progress*, vol. 4, no. 3, Mar., 1923, pp. 51–52, 3 figs., *d*)

Doctor of Engineering "Honoris Causa." The German Association of Technical and Economic Societies has issued a protest against the liberal grants of the degree of honorary doctor of engineering by German technical schools where the reason for granting the degree is not the scientific or technical achievement of the recipient but his willingness to make to the institution of learning contributions in coin of the realm. (In particular is mentioned the case of a member of a Berlin firm manufacturing confectionary who has been granted an honorary degree of doctor of engineering by the Technical High School at Carlsruhe, although apparently his name was entirely unknown in connection with any technical or scientific achievements.) It is claimed that such policy on the part of high German institutions of learning will bring disrespect on them and deprive the honorary degrees of any true value. (*Giesserei Zeitung*, vol. 20, no. 2, Jan. 9, 1923, p. 18, *g*)

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general, *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

Viscosity of Lubricating Oils at High Pressures

Progress Report of Special Research Committee on Lubrication

THE A.S.M.E. Special Research Committee on Lubrication was organized in 1915 to investigate the fundamental problems of lubrication phenomena, and has issued progress reports in 1919 and 1921. These may be consulted for information as to the scope of the work in hand and previous results obtained.[1]

The present report contains a further account of the experimental work at high pressures, which has been continued during the past year by M. D. Hersey at the Massachusetts Institute of Technology. This report covers the measurement of the viscosity of several different lubricating oils at temperatures up to 100 deg. cent. and pressures up to about 50,000 lb. per sq. in.

Essentially the same apparatus previously referred to has been employed, the viscosimeter being of the rolling-ball type due to A. E. Flowers, while the pressure measurements were based on the change of electrical resistance of a suitable manganin coil. This method of pressure measurement was originated by Prof. P. W. Bridgman and has since been satisfactorily used elsewhere. A new pump, specially designed for this work through the kindness of Professor Bridgman, was installed at the beginning of the year.

All the above details naturally require a more voluminous report than can be prepared at this date, as the work is still in progress[2] and improvements are constantly being made. The present report, therefore, is only intended to show the general character of the results which are being secured.

Three fixed oils—lard, sperm, and castor—and three mineral oils—Veedol, Texaco, and Mobiloil A—have thus far been tested. Table 1 gives the approximate relative viscosity of these oils at intervals of 500 kg. per sq. cm. and at different temperatures.[3]

TABLE 1 APPROXIMATE RELATIVE VISCOSITY OF VARIOUS LUBRICATING OILS

Pressure, kg. per sq. cm.	Lard 22 deg. cent.	Lard 100 deg. cent.	Sperm 22 deg. cent.	Sperm 100 deg. cent.	Castor 22 deg. cent.	Castor 100 deg. cent.	Veedol (med.) 22 deg. cent.	Veedol (med.) 100 deg. cent.	Texaco (med.) 24 deg. cent.	Texaco (med.) 100 deg. cent.	Mobiloil A 24 deg. cent.	Mobiloil A 40 deg. cent.	Mobiloil A 100 deg. cent.
0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0	1.0
500	2.4	1.5	1.9	1.4	1.9	1.3	3.2	1.7	4.0	1.3	5.3	7.8	1.3
1000	4.2	1.9	...	...	3.6	2.2	11.7	3.3	14.7	1.7	28.6	21.2	3.4
1500	9.7	2.3	...	...	...	3.5	...	6.1	...	3.0	...	322.0	8.2
2000	...	3.0	...	...	...	5.2	...	9.9	...	5.3	...	...	64.0
2500	...	4.2	...	...		9.0	...	15.5	...	9.0	...	...	...
3000	...	6.1	...	...	...	...	...	25.4	...	16.0	...	...	...
3500	...	...	...	...	...	...	...	...	...	21.2	...	...	...

Approximate values only are available, as several small corrections remain to be computed, particularly those due to the compressibility of the oils, but it is not thought that the figures quoted are subject to changes greater than 5 per cent.

By "relative viscosity" is meant the ratio of the absolute viscosity at a stated pressure and temperature to the absolute viscosity at atmospheric pressure and that same temperature, e.g., 100 deg. cent.

Thus, the data for lard oil show that at 1000 kg. per sq. cm. (14,200 lb. per sq. in.) and 22 deg. cent. its viscosity is four times as great as at atmospheric pressure and 22 deg. cent.; whereas, by contrast, Texaco at 1000 kg. per sq. cm. and 24 deg. cent. has 14.7 times as much viscosity as it had at atmospheric pressure and 24 deg. cent. and therefore shows a more pronounced pressure effect than lard oil. Again, lard oil maintained at 100 deg. cent. experiences a 1.9 fold increase of viscosity under 1000 kg. per sq. cm., while the corresponding effect for Texaco is only to increase its viscosity 1.7 times.

It is to be noted that our present use of the term "relative viscosity at 100 deg. cent. and 1000 kg. per sq. cm. pressure" means that the viscosity under high pressure is being expressed in terms of the viscosity at atmospheric pressure and 100 deg. cent., *not* in terms of the viscosity at atmospheric pressure and 22 deg. or 24 deg. cent. This seems to be a fair way to compare different lubricants in respect to the influence of pressure upon them, though other methods of correlation are being considered.

Table 2 supplements Table 1 by giving the approximate absolute viscosities of the several oils at different temperatures under atmospheric pressure. Table 1, for example, does not show how much more viscous Texaco at 100 deg. cent. and 1000 kg. per sq. cm. may be than lard at 100 deg. cent. and 1000 kg. per sq. cm. By reference to Table 2, however, it can be deduced that under those conditions Texaco is only 0.7 as viscous as lard, while in like manner it is found that lard oil at 100 deg. cent. and 1000 kg. per sq. cm. is 0.4 as viscous as at 22 deg. cent. and atmospheric pressure.

At moderate temperature all of the oils were found to become exceedingly viscous, or else suddenly plastic, at some fairly definite pressure and hence, practically speaking, to have solidified. These solidifying pressures are recorded in Table 3.

The original observations on which this report is based are about 250 in number, exclusive of check observations, and will later be prepared for publication in the form of curves, showing absolute viscosity as a function of pressure and temperature. The viscosimeter has been calibrated for this purpose with due allowance for variations in the density of the oil, as explained in previous papers.[1]

TABLE 2 ABSOLUTE VISCOSITY OF VARIOUS LUBRICATING OILS AT DIFFERENT TEMPERATURES UNDER ATMOSPHERIC PRESSURE

	Viscosity c.g.s. 22 deg. cent.	Viscosity c.g.s. 100 deg. cent.
Lard	0.67	0.15
Sperm	0.39	..
Castor	7.8	0.23
Veedol	0.97	0.09
Texaco	1.1[1]	0.12
Mobiloil A	2.0[1]	0.10

[1] Viscosity at 24 deg. cent.

TABLE 3 APPARENT SOLIDIFYING PRESSURES OF VARIOUS LUBRICATING OILS

	Temp., deg. cent.	Pressure kg. per sq. cm.	Pressure lb. per sq. in.
Lard	22	1600	22,800
Castor	22	1400	19,900
	100	2900	41,200
Veedol	22	1300	18,500
Texaco	24	1500	21,300
	100	3900	55,500
Mobiloil A	24	1200	17,100
	40	1500+	21,300+
	100	2100	29,800

Acknowledgments for individual assistance are due primarily to H. B. Henrickson of the Bureau of Standards in connection with the earlier development work, and more recently to C. W. Staples, a graduate student at Massachusetts Institute of Technology during 1922 (W. P. I. '19), and Henry Shore, M.I.T., '24. Mr. Staples was largely responsible for the pump development and other mechanical problems, while Mr. Shore gave particular attention to the temperature control and other electrical problems introducing various improvements which will be described later.

Research Committee on Lubrication.

[1] The problem of "oiliness" was discussed in the first report, together with experiments by Albert Kingsbury at high rates of shear, and by M. D. Hersey on viscosity at high pressure. The latter results are available in detail in *Jl. Wash. Acad. Sci.*, vol. 6, pp. 525–530, 1916, while the report itself may be found in MECHANICAL ENGINEERING, vol. 41, June, 1919, p. 537. A second report, issued in December, 1921, may be obtained in pamphlet form from The American Society of Mechanical Engineers, 29 W. 39th Street, New York.

[2] The experiments have been resumed by Mr. Hersey at the Physical Laboratory of the U. S. Bureau of Mines, Pittsburgh, Pa.

[3] The kg. per sq. cm. or "atmosphere" is the unit almost universally found in high-pressure literature: it is about 14.2 lb. per sq. in., so that 1000 kg. per sq. cm. is approximately equivalent to 6.4 tons per sq. in. in the British system.

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

Résumé of the Month

A—Research Results

The purpose of this section of Engineering Research is to give the origin of research information which has been completed, to give a résumé of research results with formulas or curves where such may be readily given, and to report results of non-extensive researches which in the opinion of the investigators do not warrant a paper.

Building Materials, Concrete A1-23. Tests of Heavily Reinforced-Concrete Slab-Beams. This paper presents the results of tests of 26 slabs, tested as simple beams, having four types of reinforcement. The slab beams were approximately 4 in. thick and $27^1/_2$ in. wide, and the four types of reinforcement consisted of (*a*) plain round bars laid direct between two supports, (*b*) expanded metal with the long dimensions of the diamonds parallel to the direction of the span, (*c*) plain round bars laid in two bands making 45 deg. with the direction of the span of the beam and 90 deg. with each other, and (*d*) plain round bars laid in one band making 45 deg. with the direction of the span.

The immediate purpose of the tests was to obtain data applicable to the design of slab members in concrete ships, and for this reason the slabs did not represent conventional design. This introduced difficulty in the interpretation of the test data, but several methods of interpreting the tests have led to conclusions which are in agreement with each other as to the general nature of the results.

On the whole the test results show a fair agreement with the analysis based upon the secant method of calculation. Expanded-metal reinforcement distributed the tension cracks in the concrete of the slab beams more uniformly throughout the length of the beam than did reinforcing bars laid direct between supports.

This Technologic Paper of the Bureau of Standards, No. 233, by Willis A. Slater and Fred B. Seely, may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C. Price, 15 cents.

Ferrous Alloys A1-23. Effect of Manganese on the Structure of Alloys of the Iron-Carbon System. A third Bureau of Standards Technologic Paper, No. 464, in the series on the Preparation and Properties of Pure Iron Alloys, has just been issued. It was prepared from experimental data collected by Messrs. Henry S. Rawdon and Frederick Sillers, Jr. This paper is concerned with the effect of manganese as a hardening element determined in an extensive series of alloys varying from 0 to 1.6 per cent carbon and 0 to 2 per cent manganese. Address Superintendent of Documents, Government Printing Office, Washington, D. C. Price 10 cents.

Fuel Utilization A4-23. Economic Combustion of Waste or By-Product Fuels. Because of the decreasing supply and increasing cost of high-grade fuels, the efficient utilization of those that are of low grade is becoming a problem of major importance to many industries and to the commercial progress of the nation. The data in this paper, consequently, are published as a contribution to the literature on the conservation of national resources. The term "waste fuel" as used in this paper means any combustible material that is not ordinarily included in the list of commercially marketable fuels.

David Moffat Myers prepared this bulletin which is known as Technical Paper 279 of the Bureau of Mines. Address Superintendent of Documents, Government Printing Office, Washington, D. C. Price 10 cents.

Hydraulics A1-23. Loss of Head in Valves and Pipes. A bulletin just issued by the Engineering Experiment Station of the University of Wisconsin on this important subject was prepared from experimental data gathered by Prof. Charles I. Corp and Roland O. Ruble of the University staff. The bulletin presents the results of 2200 tests on 48 different gate and glove valves. Results of 425 tests to determine pipe friction are also included.

Iron and Steel A4-23. Effect of Manganese on the Structure of Alloys of the Iron-Carbon System. See *Ferrous Alloys A1-23.*

Non-Ferrous Metals A2-23. Preparation of Light Aluminum-Copper Casting Alloys. A very large amount of experimental work on this subject has been conducted for the Bureau of Mines by Robert J. Anderson. His report which has just been received is known as Bureau of Mines Technical Paper 287. The author sums up his findings as follows:

Aluminum-alloy foundries in the United States employ three methods for introducing copper into aluminum in making light aluminum-copper alloys: (1) The use of copper directly; (2) the use of 33:67 copper-aluminum alloy; and (3) the use of 50:50 copper-aluminum alloy. The writer suggests that 60:40 copper-aluminum alloy might be suitable for the purpose. A suitable method for preparing rich alloys on a large scale is described in detail. The various methods used at different foundries have been compared.

This paper of 44 pages includes many micrographs and may be obtained for 10 cents from the Superintendent of Documents, Government Printing Office, Washington, D. C.

Non-Ferrous Metals A3-23. Solder for Aluminum. Most of the metals commonly used in solders, except magnesium, are electropositive to aluminum. They therefore accelerate corrosion in the presence of moisture, and soldered joints of aluminum should be protected by varnish.

Various compositions of zinc-tin and zinc-tin-aluminum solders give the best results. This Circular of Bureau of Standards, No. 78 may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C. Price, 5 cents.

Paints, Varnishes and Resins A1-23. Moisture-Resisting Coatings for Wood. See *Forest Products A1-23.*

Paper A1-23. Study of Commercial Dial Micrometers for Measuring the Thickness of Paper. Specifications are given for a standard instrument. From a study of the mechanisms of instruments and the results of this investigation it is felt that two or more types of the mechanisms studied can be used in instruments that will meet the specifications. The paper also contains specifications for a standard procedure to determine the mean thickness of a sample of paper.

The Bureau of Standards Technologic Paper No. 226 was prepared by Messrs. P. L. Houston and D. R. Miller and may be secured from the Superintendent of Documents, Government Printing Office, Washington, D. C. Price 10 cents.

Petroleum and Allied Substances A1-23. Oil Shale—An Historical, Technical and Economical Study. In January, 1920, the State of Colorado and the U. S. Bureau of Mines entered into a coöperative agreement for the conduct of laboratory investigations on the oil shales of Colorado. Under this agreement a laboratory has been installed and equipped at the State University, Boulder, Colorado, and a research staff organized. It is the primary purpose of the investigational work to determine the most favorable conditions of retorting Colorado oil shales to yield the most of the best products from them.

This bulletin, known as No. 210 of the Bureau of Mines, was printed by the State of Colorado as part of the coöperative agreement. It represents the assembled results of the investigations up to the present, together with material of a general nature necessary in a well-rounded presentation of the present state of knowledge of the subject. Copies can be obtained from the U. S. Bureau of Mines, Boulder, Col.

Railroad Rolling Stock and Accessories A1-23. Properties of Chilled-Iron Car Wheels. Part II, Wheel Fit, Static Load, and Flange Pressure Strains—Ultimate Strength of Flange. This report, Bulletin No. 134, of the Engineering Experiment Station, University of Illinois, Urbana, Ill., prepared by Messrs. J. M. Snodgrass and F. H. Fuldner, presents two additional phases of the investigation of the properties of chilled-iron car wheels conducted at the University of Illinois. This investigation had for its object the determination of the strains which may occur within a car wheel and the limitations of present designs, with the view of improving the chilled-iron car wheel and making it more satisfactory under present and future service requirements. The work was done under a coöperative agreement between the Association of manufacturers of Chilled Car Wheels and the University. Price per copy, 40 cents.

Refrigeration A1-23. Specific Volume of Saturated Ammonia Vapor. Several years ago the Bureau of Standards began the determination of the various thermodynamic properties of ammonia to establish an experimental basis for engineering tables to be used in the refrigerating industry. The present paper is the last of a series of papers on the determination of those properties under saturation conditions.

The specific volume, or the numerical reciprocal of density, of the saturated vapor was measured in the temperature interval —50 to +50 deg. cent. by two methods; one a direct method and the other an optical method. Ammonia of high purity was used in all of the measurements.

This Scientific Paper of the Bureau of Standards, No. 467, by C. S. Cragoe, E. C. McKelvy, and G. F. O'Connor, may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C. Price, 5 cents.

B—Research in Progress

The purpose of this section of Engineering Research is to bring together those who are working on the same problem for coöperation or conference, to prevent unnecessary duplication of work, and to inform the profession of the investigators who are engaged upon research problems. The addresses of these investigators are given for the purpose of correspondence.

Fuels B1-23. Carbonizing Experiments on Lignite. As the result of a coöperative agreement between the Bureau of Mines and the Uni-

versity of North Dakota a series of experiments are being conducted at Grand Forks, N. D. on the carbonizing of lignite.

In conducting these experiments it was ever kept in mind that definite information was sought regarding a number of variables of unknown value and briefly, it was the aim to: (1) produce a well-carbonized lignite; (2) obtain a maximum throughout; (3) note the influence of the quality of lignite used on the performance of the oven and on the character of the carbonized product; (4) note the influence of the size of the lumps of lignite charged upon the character of product obtained and upon capacity; (5) eliminate the smoke nuisance; (6) study the performance of the cooler and the discharge apparatus ascertaining facts relative to its adaptability in preference to other types; (7) find out what the chief factors are that influence the production of a good quality of carbonized lignite, and make such changes in the oven structure as its operation indicated were necessary; (8) note the character, quality, yield and size of particles of the carbonized lignite produced; and (9) make certain laboratory studies during such delays in operation as are incidental to experimental work of this nature.

The program as outlined is being carried out, but on account of the fuel situation and other factors only a few different lignites have been tested. The same limitation applies to the study of the effect of sizes, but in spite of this fact the desired data relative to this factor are well in hand.

The results so far obtained are reported in the Bureau of Mines, Reports of Investigations, Serial No. 2441.

Heat Transmission B1-23. Heat Transmission Through Boiler Tubes. The effects of boiler scale, soot and oil upon the heat transmission through boiler tubes is the subject of an investigation being undertaken at the University of Illinois. Prof. A. C. Willard of the Department of Heating and Ventilation is conducting this research and Messrs. H. O. Croft and C. H. Cather are in direct charge of the experiments.

Instruments and Apparatus B2-23. Saybolt Universal Viscosimeter. A conference was held at the Bureau of Standards, November 14 with members of the American Petroleum Institute, as a result of which a committee of 5 members of the Institute was appointed to coöperate with the Bureau in expediting the more accurate standardization of the Saybolt universal viscosimeter.

The Institute and the Bureau are also coöperating with the Society of Automotive Engineers and the Interdepartmental Committee on Petroleum Products in the development of a numbering system for lubricating oils based on their viscosity.

Metallurgy and Metallography B1-23. Etching Reagents for Alloy Steels. The Bureau of Standards has been making a study of the problem of finding an etching reagent by which chromium carbide could be distinguished from vanadium carbide in a positive and satisfactory manner. Etching in a hot solution of potassium permanganate and sodium hydroxide for one minute darkens chromium carbide to a strong brown-red or brown color, while vanadium carbide remains uncolored and apparently unattacked. Another but less positive means of distinction is that obtained by electrolytic etching with a weak current in a dilute aqueous solution of ammonia or sodium hydroxide. The chromium carbide is eaten out, leaving a dark brown-red or brown cavity, while the vanadium carbide is eaten out apparently at a slower rate, leaving cavities which appear light.

F—Bibliographies

The purpose of this section of Engineering Research is to inform the profession of bibliographies which have been prepared. In general this work is done at the expense of the Society. Extensive bibliographies require the approval of the Research Committee. All bibliographies are loaned for a period of one month only. Additional copies are available, however, for periods of two weeks to members of the A.S.M.E. These bibliographies are on file at the headquarters of the Society.

Corrosion F1-23. Protective Metallic Coatings for the Rustproofing of Iron and Steel. A selected bibliography on corrosion of iron and steel and its prevention by metallic coatings forms an appendix to Bureau of Standards Circular No. 80. Apply Superintendent of Documents, Government Printing Office, Washington, D. C. Price 20 cents.

Petroleum and Allied Substances F1-23. Oil Shale—an Historical, Technical and Economic Study. A new bibliography dated July, 1922, forms an appendix to Bulletin No. 210 of the U. S. Bureau of Mines. It has been made as short as possible, consistent with the presentation of literature that covers oil shale from all angles. Address U. S. Bureau of Mines, Boulder, Colorado.

CORRESPONDENCE

Contributions to the Correspondence Department of Mechanical Engineering are solicited. Contributions particularly welcomed are discussions of papers published in this journal, brief articles of current interest to mechanical engineers, or comments from members of The American Society of Mechanical Engineers on activities and policies of the Society in Research and Standardization.

Velocity of Steam in Pipes

To the Editor:

In an abstract on page 190 of Mechanical Engineering for March, 1923, there is raised the question of steam velocity in pipes.

In a paper on The Flow of Fluids Through Commercial Pipe Lines, by Wilson, McAdams, and Seltzer [*Jl. Ind. & Eng. Chem.*, vol. 14, p. 105 (1922)], the fact is brought out and supported by experimental results that the friction factor f in Fanning's equation is a function of DvS/z, where D = inside diameter of pipe in inches, v = average linear velocity in pipe line in feet per second, S = specific gravity of fluid, and z = viscosity in centipoises. Given a knowledge of these factors, any pipe-line problem for any fluid can be solved.

The difficulty in applying this equation to the flow of steam is our lack of knowledge of its viscosity. While the temperature coefficient of viscosity is known for several other gases, an extensive search of the literature has shown only a few determinations for steam at room temperature and 100 deg. cent. It would seem that this would be an interesting problem for the physics department in a university. The determinations should be made up to a temperature of 600 deg. cent., and at least three points taken between 400 deg. and 600 deg. The data up to 400 deg. cent. will probably follow a different law from those above 400 deg. Above the critical temperature (375 deg. cent.) Sutherland's equation for the temperature coefficient of viscosity may be expected to apply. The apparatus should be calibrated with air.

It would certainly be very desirable to add a better knowledge of the viscosity of steam to that of the other properties which are being so carefully worked out. Any one desiring to take this matter up will find a complete bibliography on the general subject in Bingham's recent book on Viscosity and Fluidity.

What is needed is not more empirical formulas, but the facts to put a fundamentally correct formula on a working basis.

After the experimental work on viscosity has been done by a physicist, then a careful correlation of the existing data should be undertaken by an engineer.

Geo. H. West.

Mathematical Determination of the Modulus of Elasticity

To the Editor:

The writer feels gratified at the interest aroused by his proposed method of bending tests with thin strips, published in the December issue of Mechanical Engineering, as evidenced by the much appreciated comments of Prof. Wm. R. Bryans in the February issue, and of Messrs. E. A. Richardson and S. Timoshenko in the April issue.

While acknowledging the correctness of the writer's deductions, Professor Bryans asserts that the basic equation, $M = EI/\rho$ correctly applies only to infinite radii of curvature, and for finite values of ρ the results obtained can only be approximate.

To the writer's knowledge there is no such limitation in regard to ρ; the only assumptions underlying the above equation are: (1) The neutral plane of the loaded beam passes through the center of gravity of the given cross-section; and (2) the modulus of elasticity E is the same for expansion and compression. Here is the simple deduction of this basic equation: As seen in Fig. 1, the length

of the fiber element a-a before the beam is bent is $\rho d\alpha$; when the beam is bent its length becomes $(\rho + e)d\alpha$; therefore its relative expansion (or contraction, if situated below the neutral line) is:

$$\frac{(\rho + e)d\alpha - \rho d\alpha}{\rho d\alpha} = \frac{e}{\rho}$$

The fiber tension at the point α of the cross-section m-m will therefore be $E\frac{e}{\rho}\, dA$, where A denotes the cross-sectional area of the beam. Its moment M relative the axis O of the cross-section is $E\frac{e^2}{\rho}\, dA$, which, extended to all fibers of the cross-section, will be $\frac{E}{\rho}\,\Sigma e^2 dA = \frac{EI}{\rho}$, or $M = EI/\rho$. No limitation as to the magnitude of ρ enters into this deduction. Mr. Timoshenko makes the same statement, but the deduction is given here in full, for the sake of clearness.

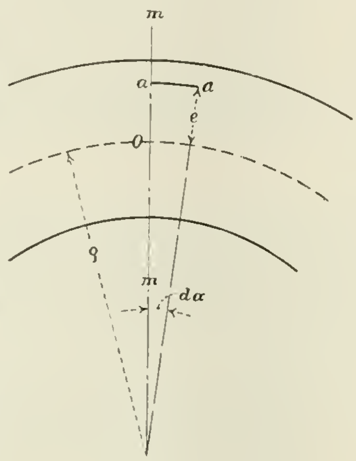

Fig. 1

Mr. Richardson in his comments very ably shows the possible effect of an error in the computation of I, the moment of inertia, concluding, as does also Professor Bryans, that the proposed method is far from mathematical precision.

Extending Mr. Richardson's method of calculation to the area $A = bh$ of the cross-section of the strip, the difference in the error percentages is—

$$\frac{dI}{I} - \frac{dA}{A} = \frac{db}{b} + 3\frac{dh}{h} - \left(\frac{db}{b} + \frac{dh}{h}\right) = 2\frac{dh}{h}$$

Here all depends on the thickness h and the measurement variation dh, both controllable factors. While the question as to how correctly a measurement may be taken may not properly be argued, it nevertheless must be conceded that even if the proposed method be not considered as an unconditional substitute for existing laboratory methods, it surely affords a sound practical expedient. Theoretically the chief point of interest of the method is its novelty: it makes possible for the first time the exact integration of the differential equation of the elastic curve, without the customary approximation of assuming $[1 + (\partial x/\partial y)^2]^{1.5} = 1$; also the determination of the cord tension of an archer's bow when the modulus of elasticity of the bow material is known.

The disadvantage of employing I instead of the cross-sectional area may be compensated by the large and easily measurable deformations in this method. This may account for the fact that in the two recorded tests with thin wooden strips, using a pocket rule and an ordinary spring balance, the results obtained were so near those given in engineering tables.

Mr. Timoshenko in his extensive and instructive comments considers the limitation imposed by the elastic limit and determines analytically and by certain experimental data the influence of the cross-sectional deformations on the bending of thin strips, showing how the above-mentioned basic equation may be made theoretically more correct by the introduction of a certain coefficient.

With regard to the elastic limit, attention is here called to the fact that in the bending-test device for thin strips illustrated in the December issue, provision is made for easily verifying in each test whether the bending is within or outside the elastic limit, without the need of any calculations, thus affording the possibility of its experimental determination; though some preliminary idea as to what the radius of curvature is likely to be near the elastic limit, as shown by Mr. Timoshenko, is naturally desirable.

As to the coefficients m and k introduced by Mr. Timoshenko to account for cross-sectional deformations, we are here on uncertain ground, but it may be of interest to note that this simple bending-test device for thin strips readily lends itself to the determination of these coefficients. As the differential elastic-curve equation has been integrated without any assumed approximation and the equations obtained are theoretically exact—in the absence of influencing cross-sectional deformations—and all factors are directly measurable, with the exception of E, the modulus of elasticity, which may either be taken from existing tables or determined directly by means of an extensometer, therefore all factors in these equations will be known except the said coefficients, which could accordingly be determined.

It would be gratifying if Mr. Timoshenko would publish a detailed description of his bending experiments with thin strips.

David Guelbaum.

Syracuse, N. Y.

Second Revision of A.S.M.E. Boiler Code, 1923

A HEARING is held by the Boiler Code Committee at least once in four years, at which all interested parties may be heard, in order that such revisions may be made as are found to be desirable, as the state of the art advances. The year 1922 became the period of the second revision and the Boiler Code Committee held a Public Hearing in connection with the recent Annual Meeting of the Society in December, 1922, to which the membership of the Society and every one interested in the steam-boiler industry was invited to attend and present their views.

For the convenience of every one interested, a printed schedule of the various proposed revisions had been published and distributed to all those who were invited to attend the Public Hearing and the opportunity was given thereat for the most careful consideration of all of the proposed revisions. As a result of the suggestions received at the Public Hearing, a number of modifications of the previously announced revisions were offered and in addition suggestions were received for still further revisions of the Code. All of these suggestions for modifications and new revisions have been carefully considered by the Boiler Code Committee and the result in modifications of revisions and additional revisions are here published.

It is the request of the Committee that these revisions be fully and freely discussed so that it may be possible for any one to suggest changes before the rules are brought to final form and presented to the Council for approval. Discussions should be mailed to C. W. Obert, Secretary to the Boiler Code Committee, 29 West 39th St., New York, N. Y., in order that they may be considered by the Boiler Code Committee.

The revisions here published are limited to the paragraphs appearing in the 1918 Edition of the A.S.M.E. Boiler Code, and the paragraph numbers refer to the paragraphs of similar number in that edition. For the convenience of the reader in studying the revisions, all added matter appears in small capitals and all deleted matter in smaller type in brackets.

Modifications of Revisions

Par. 9 REARRANGE PARAGRAPH AS PRINTED IN JULY 1922 AND APRIL 1923 ISSUES OF MECHANICAL ENGINEERING AS FOLLOWS:

9 The use of bessemer steel is prohibited for the pressure parts of boilers. When the maximum allowable working pressure exceeds 160 lb. per sq. in., cross-pipes connecting the steam and water drums of water-tube boilers, headers, cross-boxes and all pressure parts of the boiler proper over 2-in. pipe size, or equivalent cross-sectional area, shall be of wrought steel, or cast steel of Class B grade, as designated in the Specifications for Steel Castings. Malleable iron may also be used when the maximum allowable working pressure does not exceed 200 lb. per sq. in., provided the form and size of the internal cross-section perpendicular to the longest di-

Note: Matter in caps—added matter; Matter in smaller type in brackets—to be deleted.

mension of the box is such that it will fall within a 7-in. by 7-in. rectangle.

Seamless tubes or lap-welded pipe may be used for drums or other pressure parts of a boiler provided such tubes or pipes conform to the specifications for welded and seamless steel and wrought-iron pipe, and provided also that the outside diameter of the tubes or pipes does not exceed 20 in.

Par. 21 Replace revised form printed in April 1923 issue of Mechanical Engineering with the following:

21 *Tubes* and nipples *for Water-Tube Boilers. a* Tubes and nipples for use in water-tube boilers for all pressures in excess of 160 lb. allowable working pressure shall be seamless steel. Up to and including 160 lb. pressure lap-welded steel or iron may be used.

b The maximum allowable working pressures for steel or wrought-iron tubes or nipples used in water-tube boilers shall be for the various diameters and minimum gages measured by Birmingham wire gage, as given in Table 2. Redrawn pipe not to exceed $1\frac{1}{2}$ in. standard pipe size which meets the pipe specification may be used for water-tube boilers for a working pressure not to exceed 200 lb. per sq. in., when screwed in the sheet, provided the wall thickness is at least 50 per cent greater than the minimum wall thickness required by Table 2. The maximum allowable working pressure for copper tubes or nipples used in water-tube boilers, shall be for the various diameters and minimum gages measured by Birmingham wire gage as given in Table $2\frac{1}{2}$, but not to be used for pressures to exceed 250 lb. Copper tubes shall not be used with superheated steam.

Table 2 Change heading to read as follows:

Table 2 Maximum Allowable Working Pressures for Steel or wrought-iron Tubes or nipples for Water-Tube Boilers.

Table $2\frac{1}{2}$ Change heading as given in April 1923 issue of Mechanical Engineering as follows:

Table $2\frac{1}{2}$ Maximum Allowable Working Pressures for Copper or wrought-iron Tubes or nipples for Water-Tube Boilers.

Par. 185 Replace revised form printed in December 1922 and April 1923 issues of Mechanical Engineering with the following:

185 When shell plates exceed 5/8 [9/16] in. in thickness in horizontal-return-tubular boilers, the portion of the plates forming the laps of the circumferential joints, where exposed to the fire or products of combustion, shall be planed or milled down as shown in Fig. 8, to a thickness of not over 9/16 [1/2] in. provided the requirement in Par. 184 is complied with. Where plates are planed or milled down it shall be for the entire circumference of the joint, and the fillet at the edge of the planing may [shall] be not less than 1 in. radius.

Par. 230 Insert the following before the added matter given in the December 1922 issue of Mechanical Engineering:

Sling stays, if used between crown bars and boiler shell or wrapper sheet, shall be proportioned so as to carry the entire load without considering the strength of the crown bars.

Par. 253 Replace first section of revised form in December 1922 issue of Mechanical Engineering with the following:

All holes in braces, lugs and sheets for rivets or staybolts shall be drilled full size with plates, butt straps and heads bolted up in position, or they may be drilled or punched not to exceed 1/4 in. less than full size for plates over 5/16 in. in thickness and 1/8 in. less than full size for plates not exceeding 5/16 in. in thickness and then drilled or reamed to full size with plates, butt straps and heads bolted up in position.

Par. 257 Add the following to the revised form given in December 1922 issue of Mechanical Engineering:

or splitting the calked sheet.

Par. 259 Replaced revised form given in July 1922 issue of Mechanical Engineering with the following:

259 A manhole reinforcing ring, when used, shall be of wrought or cast steel [or wrought iron], and shall be at least as thick as the shell-plate thickness required by Par. 180.

Par. 278 Insert the words "with bevel seats," after the words "intermediate lift" at the end of the seventh line of the matter given in the April 1923 issue of Mechanical Engineering.

Par. 325 Revise second sentence of revised form in July 1922 issue of Mechanical Engineering as follows:

The shearing and crushing stresses on the rivets or studs used for attaching the lugs or brackets shall not exceed 8 per cent of the strength given in Pars. 15 and 16.

Par. 332 Omit next to last section of revised form given in April 1923 issue of Mechanical Engineering beginning with "Portable Boilers of 100 hp."

Par. 333*c* Replace revised form given in April 1923 issue of Mechanical Engineering with the following:

c On traction, portable or stationary boilers of the locomotive type or Star water-tube boilers—on the furnace end, above the handhole. Or on traction boilers of the locomotive type—on the left wrapper sheet forward of the driving wheel. In addition to the stampings herein provided, portable boilers of 100 hp. or less shall, when possible, have the stamping herein provided applied on a non-ferrous plate 3 in. × 4 in. in size which shall be as nearly as practicable, irremovably fastened to the boiler near the water-column connections.

New Revisions

Par. 17 Revised:

Thickness of Plates. The minimum thickness of any boiler plate under pressure shall be 1/4 in. The minimum thickness of plates in stayed surface construction shall be 5/16 in.

Par. 184 Add the following section:

d The distance from the centers of rivet holes of circumferential joints to the edges of the plate shall not be less than the diameter of the rivet holes.

Par. 190 Revised:

190 A horizontal-return-tubular boiler shall not have a continuous longitudinal joint over 12 ft. in length. With butt and double strap construction longitudinal joints of any length may be used, provided the tension-test specimens are so cut from the shell plate that their lengthwise direction is parallel with the circumferential seams of the boiler, and the tests meet the standards prescribed in the specifications for boiler-plate steel.

Par. 219 Revised:

219 When stay rods are screwed through the sheets and riveted over, they shall be supported at intervals not exceeding 6 ft. In boilers without manholes, stay rods over 6 ft. in length may be used without support if screwed through the sheets and fitted with nuts and washers on the outside provided the least cross-sectional area of the stay rod is not less than that of a circle 1 in. in diameter.

Par. 263 Revised:

263 The minimum width of bearing surface, for a gasket on a manhole opening shall be 11/16 [1/2] in. No gasket for use on a manhole or handhole of any boiler shall have a thickness greater than 1/4 in. when compressed.

Revisions on Miniature Boiler Code

M-19 Revise first section to read:

M-19 All boilers referred to in this section shall be plainly marked with the manufacturer's name, maximum allowable working pressure, which shall be indicated in arabic numerals, followed by the letters "lb.," and serial number. All boilers built according to these rules shall be marked A.S.M.E. Std.—Miniature. Individual shop inspection is [not] required for miniature boilers in the same manner as for power boilers.

Technical Literature

In a recent issue of the *Carnegie Technical Journal*, Prof. W. Trinks directs attention to the dearth of good technical books which give information about the various specialties of engineering. He traces the reason for this to the fact that the compensation received by authors is not sufficient to attract competent men. What books are written, are written for altruistic reasons or to achieve a reputation. Textbooks dealing with fundamentals are of course in a different class. Furthermore, the progress of engineering art and science is so rapid that technical books become obsolete at an alarming rate. He draws attention to the paucity and inadequacy of engineering libraries in the country, and points out the large number of good technical books in foreign tongues.

Professor Trinks' statements serve to emphasize the value of the technical press and the proceedings of the technical societies, both of which present valuable information concerning current developments. The intelligent clipping and indexing of this material should therefore be the duty of the alert practicing engineer. The monthly and annual printed indexes of engineering literature, such as the Engineering Index in Mechanical Engineering, should be of inestimable value in this respect. In view, therefore, of this value of current engineering literature, does it really seem necessary that time should be spent on specialized technical books which become obsolete quickly and yield but a relatively small compensation to the author?

Exception would probably be taken by many American engineers to Professor Trinks' high opinion of foreign books. The fact remains, however, that foreign printing costs and the attitude of foreign engineers are conducive to a greater volume of good technical books of the specialized type.

As to American engineering libraries, satisfactory facilities are provided in most of the large cities. New York, Boston, Pittsburgh, Cleveland, Chicago, and Washington all possess adequate collections of technical books which are available for reference. Recently Denver has taken steps to establish an engineering library.

The photostat service of the Engineering Societies Library aims to provide desired information where it is not possible to send out the book or periodical in which it appears. At the present time it is the practice of the Library to loan duplicate copies of its books to members of the National Engineering Societies, and obviously a helpful step in this respect would be the broadening of this loan service.

A.E.S.C. Completes Sixth Year of Successful Service

The increasing scope and influence of the American Engineering Standards Committee as a clearing house for engineering and industrial standardization is shown by the 1923 Year Book of this organization. Its success should be extremely gratifying to those who originated the committee in 1917 with a view to coördinating the standardization work of the national engineering societies. From its humble start with four coöperating bodies it now reports 23 member bodies, 205 participating agencies with duly accredited representatives and 917 individuals engaged in committee activities. And the end is not in sight, for the possibilities of industrial development through standardization and simplification are unfolding in a manner that has led the A E S C (without punctuation), as it desires to be designated, to develop a new financial policy whereby industrial organizations may become sustaining members and contribute directly to the work.

The success of this Committee's activity is due to the fundamental principle of procedure by which the A E S C as an organization does not initiate projects but rather administers and forms policies for the carrying out of the work. The actual work of securing agreement on standards falls to the sectional committees, organized by the national societies and associations which accept sponsorship for them. The A E S C participates by determining whether the work should be undertaken, by designating the sponsors, and by ultimately approving the result as an "American Standard" or a "Tentative American Standard."

The sectional committees are organized to assure representation of all interests, and the project is initiated with a conference which brings all of the conflicting ideas together and affords an opportunity for ironing out differences.

The A E S C has a very broad function in its coöperation with foreign national standardization bodies. Progress has been made in ball-bearing standardization, different proposals having been presented to various foreign bodies as the basis for international agreement.

This coördinated standardization movement has passed through many vicissitudes. However, its present firm establishment gives ample assurance that the important function which it is to perform will be carried out in a manner entirely worthy of the engineering profession.

State Rights and Water Power

The recent correspondence between the Governor of New York and the Governor of Pennsylvania on state water-power rights bids fair to become classic. Governor Smith of New York holds out for state rights in the water power from navigable streams and proposes to develop the water powers of his state for the exclusive use of New York. Governor Pinchot agrees with the engineering conclusion that interconnected systems are necessary for cheap, reliable hydroelectric power. His words, which we quote below, are worthy of careful consideration.

> After eighteen years of study and work on this problem, I have come confidently to expect the growth of a nation-wide interlocking power system........The freedom of commerce among the several states, the unrestricted exchange across state lines of service, goods and resources, guaranteed by the Federal Constitution, is the strongest man-made basis of the prosperity of each state. This consideration applies not only to energy riding in a coal car but equally to energy flowing over a wire, whether the burning of fuel or the falling of water was the source. Furthermore, really cheap power cannot be supplied to consumers unless the burning of coal and the flowing of water contribute their energy to a common reservoir for the common supply of industries, farms, homes and railroads. Such a system must transcend state lines and is likely to become nation-wide.

In the meantime, Massachusetts is planning to analyze the power needs of its growing industries, and the Associated Industries of Massachusetts have selected Charles T. Main, Past-President of The American Society of Mechanical Engineers, as chairman of a committee to determine the kinds and amounts of present powers, the cost of each, and the increase in that cost in the last ten years; the available new sources of power both within and without the borders of the state, the probable demand for such power, and the cost of supplying it to the industries and public utilities of the commonwealth of Massachusetts.

Business Cycles and Unemployment

Report of Committee Appointed by Secretary Hoover Suggests Methods for Preventing Widespread Unemployment During Periods of Depression

THE report of the committee appointed in September, 1921, by Secretary of Commerce, Herbert Hoover, to investigate the problem of unemployment as related to the fluctuations of the business cycle, has been made public. The committee, after stating the questions to be considered, discuss the nature and effects of the business cycle at some length, using the term to describe the series of changes in business conditions which are characterized by an upward movement toward a boom, followed by a downward movement into depression. As a result of their analysis of the problem the committee arrive at a number of conclusions which they embody in a series of recommendations relating both to the direct prevention of expansion and inflation and to the prevention of unemployment. The outstanding features of these recommendations are presented in the following extracts from the report.

Collection of Fundamental Data. In many industries the coöperation necessary to form a common pool of fundamental facts is made possible through trade associations, to which current figures are reported by their members. In other industries such figures, in whole or in part, are supplied directly to Government bureaus. In an endeavor to put in more available form the sum of information now current and to add to it Secretary Hoover has established in the Department of Commerce a monthly survey of current business which summarizes the data available from all sources that bear upon this major problem of business trends.

What is evidently needed is an increase in the resources of the Department of Commerce and a larger degree of coöperation with the department in coördinating and extending business information, so that business men and bankers may know promptly the facts about the rate of production measured in physical units, the stocks on hand and in transit, the trend of prices, the volume of sales, and the trend in money rates. There is great need also for recording data as to the speed of freight movements so as to show whether the output of farms and factories is being promptly distributed to the consumer or is being delayed in transit because of freight congestion.

Larger Statistical Service. The committee recommend the expansion and standardization of the statistics now collected by state and federal bureaus, the publication of employment statistics by the Federal Bureau of Labor Statistics, and the final summation and publication of all of these statistics by the Department of Commerce, in order that there may be promptly available a connected, uniform series of facts about the trend of business.

In collecting figures on stocks and production the following list of commodities has been suggested to the committee by experts as most significant in showing the trend of the business cycle:

1 Raw wool and woolen textiles
2 Raw cotton and cotton textiles
3 Hides and leather and shoes
4 Iron and steel and leading fabricated products, such as structural steel and standard tools
5 Zinc, lead, and copper and leading products of each
6 Bituminous coal.

Research. A primary necessity is the collection and dissemination of fundamental data. Following this, we need further development of special research into economic forces, into business currents, and into broad questions of economic method. Industries generally recognize the need of research in physical science. Laboratories have been equipped with large staffs of trained workers. A similar recognition of the importance of economic research and the interpretation of economic facts would be the beginning of better control of business conditions by business men.

The forecasting of probable business trends is difficult and can never be undertaken successfully by any kind of public institution, except in a limited field. Business men must themselves form their own fundamental judgments when adequate data are furnished. Research as to the effect of different trends and economic forces is, however, a different problem from forecasting. Such research should be carried on continuously by the Government bureaus, because the data available to these bureaus are more extensive than those available to other institutions, which must depend upon published summaries of Government data.

Control of Credit Expansion by Banks. The individual banker, like the individual business man, may properly be asked to assume some measure of responsibility. If only in his own interest, his policies should be determined by the general business situation as well as by the apparent soundness of the particular transactions his customers ask him to finance. One suggestion is that when prices are rising and business is expanding, bankers should ask borrowers to maintain an increasing ratio of quick assets to current liabilities.

Control of Inflation by the Federal Reserve System. The Federal reserve banks now hold, as a result of the World War, a much larger amount of gold than would suffice to support all of the credit which American industry and agriculture can possibly need on anything like present price levels. With the return of more prosperous conditions in Europe a considerable part of this gold will naturally leave us. Meanwhile this excess gold might become the basis of a disastrous inflation of our domestic credit, which would be followed by an even more disastrous collapse when the gold goes out. This is the problem which faces us in the development of the Federal reserve system to its maximum usefulness, and it is a problem worthy of most careful and thorough study by bankers and associations of bankers.

Control by Business Men of the Expansion of Their Own Industries. The committee have seen numerous instances in which the individual business man, by conducting his business with reference to the business cycle, has avoided dangerous overextension of inventories and fixed capital which in many other instances resulted in unemployment and business failure during the cycle just past.

Planning production in advance and with reference to the business cycle, laying out extensions of plant and equipment ahead of immediate requirements with the object of carrying them out in periods of depression and carrying through such construction plans during periods of low prices in conformity with the long-time trend, the accumulation of financial reserves in prosperity in order to mark down inventories at the peak, and the maintenance of a long view of business problems rather than a short view, will enable firms to make headway toward stabilization.

Control of Private and Public Construction at the Peak. One method by which periods of expansion might in part be controlled is through the cessation and postponement of construction by the Government, railroads, public utilities, and private owners in boom periods when prices are high. Reserves built up in periods of high earnings and expansion are then spent for construction during periods of depression. When this policy is more generally followed it will be of peculiar value, as it will tend to keep low the ratio of fixed investment to productive capacity, to the great advantage of industry.

Holding back public works and private construction for periods of depression not only gives employment to large numbers of workers when it is most needed, but creates a demand for raw materials for construction which in turn stimulates other industries to offer employment. It maintains the buying power of those directly or indirectly employed, it creates a market for goods, and enables the workers, directly or indirectly employed to buy the products of other industries. Finally, construction work in a period of industrial depression, when costs are lower, is economical.

The essential steps in any general program are to plan construction work, private or public, long in advance with reference to the cyclical movement of business, and in the case of public works to pass the necessary legislative appropriations when facts about the trend of business show that it is sound policy to spend money for such purposes.

Public Utilities. In the interest both of utilities and of the buying public it is obvious that the normal time to finance new construction or improvements in public utilities is in periods of depression, when interest charges are reasonable and costs of construction low. In so far as the managers of utilities and public-service commissioners can regulate construction in order to fill up the valleys and lower the peaks of the business cycle they will aid in alleviating the extremes of the cycle, and by means of their economies they will keep their capital investment from unnecessary expansion, to the advantage both of the utilities and of the public.

Unemployment Reserve Funds. Nothing is more demoralizing for wage earners than the feeling of insecurity of employment. Unemployment and the fear of unemployment are powerful causes of discontent. The idea of employer, employee, or both, contributing during periods of employment to a reserve fund under separate or joint control to help sustain the worker when unemployed in periods of depression and to equalize and stabilize his purchasing capacity merits consideration.

Employment Bureaus. We do not regard an employment service a having a direct and immediate effect upon the business cycle. We do believe that if such employment bureaus are organized throughout the country, their reports will show the demand for labor and the number of workers seeking positions and will therefore be another measure of business conditions. If employment bureaus are organized effectively enough to insure transfer from one position to another with the least possible loss of time, they will make labor more immediately available and thus prevent loss of production for the employer and loss of income for the wage earners, thus helping to maintain the level of purchasing power.

The personnel of the committee signing the report is as follows: Owen D. Young, chairman of the board, General Electric Co., chairman; Joseph H. Defrees, former president United States Chamber of Commerce; Mary Van Kleeck, Russell Sage Foundation; Matthew Woll, vice president, American Federation of Labor; Clarence M. Woolley, president American Radiator Co.; Edward Eyre Hunt, secretary of the President's Conference on Unemployment, secretary.

In its work, the committee received the assistance of appropriations toward its cost from the Carnegie Foundation and services contributed by the National Bureau of Economic Research, the Russell Sage Foundation, the Federated American Engineering Societies, the United States Chamber of Commerce, the American Federation of Labor, the American Statistical Association, the American Economic Association, the Bureau of Railway Economics, the Department of Commerce, and a number of other bodies.

Hydroelectric Power for the Metropolitan District

Availability, Cost, Service Requirements, Operating Difficulties, and Transmission Problems Discussed at Meeting of the New York Sections of National Engineering Societies

THE New York sections of the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, and the American Institute of Electrical Engineers held a joint meeting in the Engineering Societies Building, New York, on March 21, at which five speakers discussed the economical use of hydroelectric power for the New York-New Jersey Metropolitan district. The presiding officer was Calvert Townley, chairman of the New York Section A.I.E.E., who emphasized the vital need of an adequate future supply of power for this district and the importance of focusing on this need the attention of all engineering societies.

Coördinated Statement of the Problem

F. W. Scheidenhelm,[1] cited the principal obstacles to the use of hydroelectric power in the Metropolitan district as:

1. Limited information, or, more accurately, limited appreciation of the extent to which hydroelectric power could be made available and of the method of utilizing such power, especially in combination with steam-electric power
2. Uncertainty or disagreement as to the relative cost of delivered hydroelectric power compared with the cost of steam-electric power performing the same service
3. Doubt as to the quality of service on part of hydro plants and of connecting transmission lines
4. Legal difficulties, involving especially the means for acquiring necessary lands and rights, and
5. Lack of definite and continuing policy on part of the states concerned.

Colonel Scheidenhelm pointed out that the problem was essentially one of using hydroelectric power in combination with large sources of steam-electric power supply. He called attention to the fact that greater hydro capacity was installed under combined hydro and steam operation than if the same water power were to be developed to serve an independent market. He also pointed out that the utilization of hydro power would introduce financial economies because fixed charges on investment for steam development averaged from twenty to forty per cent more than for hydro. A greater use of water power would ease congestion on railroads.

For the combined systems, such as would obtain in the Metropolitan district, there would be the increased assurance of continuous service which resulted from diversity of sources of power supply. Thus the possible ill effects of labor difficulties at the coal mines, on the railroads, or in the steam-electric power plants themselves would be considerably mitigated as compared with systems relying entirely on steam-electric power.

Greater New York and Westchester County were separable from northeastern New Jersey only on political, not economic, grounds. The Hudson River was not a barrier in itself. It happened that on each side of the river the power market was such that it could independently utilize large quantities of hydro power, whether high-load-factor power from the Niagara and the St. Lawrence or low-load-factor power from an interior stream. Nevertheless, it was clear that in order to obtain the fullest benefits from the use of hydro power, state boundaries should not be allowed to become barriers to proper economic development.

Availability and Cost of Delivery

W. S. Murray[2] presented facts as to the availability of water power and cost of delivery. He referred to the Superpower Survey published in 1921 as a "formula of procedure" for unified development.

He considered three rivers as hydroelectric possibilities at or within two hundred miles from the metropolitan load centers—the Hudson, the Delaware, the Susquehanna. The maximum number of kilowatt-hours must be provided from these developments to reduce unit cost, and in this connection the impounding of waters of reservoirs was very important. The total capacity already developed in the Susquehanna was 83,500 kw. which should be increased in 1930 by approximately 100,000 kw. In an average year such a development would produce 1,230,000,000 kw-hr. In more distant years, using the total available head of 204 ft., a total capacity of 620,000 kw. would be justified. The Delaware River was fundamentally a storage river. As of 1930 it would appear to be economical to develop 350,000 kw., producing during an average year 1,250,000,000 kw-hr. at a cost at the river of slightly more than 6 mills. The Hudson also offered valuable storage opportunities which could be economically developed to 150,000 kw. as of 1930 with an average yearly capacity of 900,000,000 kw-hr. at a cost at the river of slightly under 6 mills.

Mr. Murray also stated that the low development costs on the Niagara and St. Lawrence made it possible to place electric energy within the Metropolitan load center at less cost than from the Hudson. In concluding, he stated the results of a recent intensive investigation that a combination of steam and hydroelectric energy could be developed within a radius of one hundred miles and delivered into the existing distribution systems at a cost not exceeding 7 mills, provided the load factor of the delivered power did not fall below 65 per cent. A bulk of 500,000 kw. could be made available in two years and increased to twice that amount if desired.

Service Requirements

George A. Orrok[3] outlined the service requirements which hydroelectric power must meet. He emphasized the importance of reliable service and outlined the severe operating conditions in the Metropolitan district. He estimated that in 1930 the output in the Metropolitan district would probably run between ten and twelve billion kilowatt-hours with a peak lying between two and one-half and three million kilowatts. In closing, Mr. Orrok discussed the price at which hydro powers were attractive as follows: Mr. Murray had mentioned 7 mills as the probable selling price of hydroelectric power delivered at the outskirts of the district. If there was added to this the connection cost of 2.5 mills, we could roughly approximate the condition under which this current might be utilizable by the power companies. With coal at \$8 a ton and a 60 per cent load factor, a price of 6 to 7 mills delivered at the district boundary seemed to be, roughly, about the point where the hydroelectric ceased to be attractive. With coal at a lower price or water which must of necessity be given a higher load factor, the limit of attractive price would be lower. Even at the figures given, the water seasonal variation must work in well with the district variation or there would be no economic advantage. The figures which he gave had been based on using as much water on the peak as possible, but even with this condition the night watch must waste water unless large diurnal storage was provided.

Factors Affecting Quality of Service

F. A. Allner,[4] from his experience in the operation of the Holtwood Plant on the Susquehanna River, told of the factors that affected quality of service. Ice trouble seemed to him the most important hydraulic trouble to guard against. This might be of three kinds, local, up-river, and frazil ice, the latter being the most dangerous. This could be eliminated by maintaining the highest possible temperature in the power house, by continuous movement of guide-vane mechanisms, and by steam or electric heating of submerged metal parts where the ice was inclined to stick. Mr. Allner compared the service troubles in the highly complicated steam plant with its complicated auxiliary apparatus with the hydro plant with its few sturdy and easily repaired parts. He also emphasized the ability of the hydroelectric plant to take on its load quickly. At the Holtwood plant a water-wheel unit was brought from standstill to full load in 21 sec.

[4] General superintendent, Pennsylvania Water and Power Co., Baltimore. Mem. A.S.M.E.

Lorin E. Imlay[5] discussed the reliability of long-distance transmission and pointed out that long-distance service was growing better from year to year, relating his experience in transmitting current from Niagara Falls over about 200 miles of overhead circuits.

In the discussion which followed, John P. Hogan[6] advanced the thought that not only should state boundaries be disregarded in water-power development, but perhaps national boundaries ought not to be considered. He stated that the only distant powers that might be economically used in the Metropolitan district were those that were practically continuous and could be delivered in the city at a relatively high load factor. He also emphasized the importance of considering each stream by itself and of a policy of uniform progressive development of that stream.

W. S. Finlay[7] summarized the problem of the Metropolitan district as the necessity of determining the character of the service it considered necessary to its welfare and comfort, recognizing the cost to be paid, and then bending every energy to the conservation of its resources and the development of such resources as affected its power service and supply.

Progress in Fatigue of Metals Investigation

DURING the year 1922, definite and important progress was made in the experimental work of the Fatigue of Metals Investigation at the Engineering Experiment Station of the University of Illinois. Engineering Foundation has continued its coöperation and the committee of the National Research Council has advised on program and report. A second report giving results and conclusions in detail is on the press as Bulletin No. 136, of the Experiment Station. This report, in slightly condensed form, will be printed also in the annual publication of Engineering Foundation, to be ready for distribution in May.

Interest in this investigation has spread and its practical value has come to be more widely appreciated. During 1922 outside funds for support of the project came wholly from the General Electric Company. Its officers have expressed high satisfaction with the work done.

Extension for two years is assured by the provision of additional funds to the amount of $30,000. The University of Illinois, the National Research Council and Engineering Foundation will continue to coöperate. The following industries will participate financially and in other ways: General Electric Company by a substantial addition to its preceding investment of $30,000; the Allis-Chalmers Manufacturing Company, the Copper and Brass Research Association, representing the most important producers and manufacturers of copper and its alloys, and the Western Electric Company. Several other companies are expected to join, in addition to a number mentioned in the first report (Bulletin No. 124, of the Engineering Experiment Station), which contributed materials and services of considerable value.

On the new part of the program are tests of steels at high temperatures, such as obtain in modern steam-engineering equipment and in internal-combustion engines, and a study of non-ferrous metals, particularly the copper alloys.

The investigation continues under the immediate charge of Prof. H. F. Moore and has the general supervision of Prof. Arthur N. Talbot, as the head of the Department of Theoretical and Applied Mechanics, in the Engineering College of the University of Illinois.

Small-Motored Planes

THE newspaper reports of the gliding competition in France on April 1 state that the winner made four flights in a glider fitted with a seven-horsepower auxiliary motor. One of the flights lasted a quarter of an hour and a speed of ninety kilometers per hour was attained—a unique performance. The accounts are not sufficiently explicit to enable a judgment to be formed as to the real value of the flights, but enough has been made known to emphasize the possibilities of planes driven by small motors as an economical and popular means of locomotion.

A.S.M.E. Meeting at Montreal to be Popular

MONTREAL, where the Spring Meeting of The American Society of Mechanical Engineers will be held, has the requisites needed to insure the success of the gathering: excellent hosts, a good technical program, and interesting excursions. The meeting will start on Monday, May 28, will continue for four days, and will be participated in by the members of the Engineering Institute of Canada. The technical sessions will be held at the Engineering Institute Building and at the Mt. Royal Hotel, the headquarters hotel of the meeting.

Two sessions will be devoted to Hydroelectric Power. There will also be sessions dealing with Management, Railroads, Port Development, Textiles, Fuels, and Machine Shop Practice. The afternoons will be set apart for visits to points of historic and scenic interest about Montreal, and on Tuesday and Wednesday evenings there will be novel entertainments. The Montreal Branch of the Engineering Institute of Canada is providing the entertainment for a smoking concert on Tuesday evening, and on Wednesday evening there will be a dinner dance at the Mt. Royal Hotel.

Plans are under way for an excursion by boat from Toronto to Kingston for those who come from points west and southwest of Buffalo, and an automobile trip is being arranged for those who care to drive from New York and the New England district. Following the meeting there will be excursions to Grand Mere, Shawinigan Falls, and Quebec. All indications point to a well-attended, enthusiastic meeting.

The details of the meeting to date have appeared in the *A.S.M.E. News* and complete particulars of the final program will be given in the issue of April 22.

"The Four C's Guide Post"

AT A RECENT meeting of the New York Railroad Club, E. K. Hall, vice-president of the American Telephone and Telegraph Company, spoke on the need for team play in our industrial organizations. Every man in the company must want to make the enterprise a success and be willing to do his share, whatever that may be, to attain that object. Mr. Hall did not believe that a successful formula had been found, but he did tell about what he called "The Four C's Guide Post" which may be explained in his own words, as follows:

"*Contact:* We start on the theory that one of the first things we have got to do is to get some contact between the management and the men. The men have been separated—separated geographically, and separated by an organization chart that starts with the president and, by the time it gets down to the man in the ranks, is way down in the depths. He could not go up that steep ladder if he was a steeple climber. We have got to find some means to get the people together—the management and the men.

"*Conference:* Getting them together is not enough. You get them acquainted, acquainted so they know each other. How do you get acquainted with a man? You do not get acquainted with him until you talk to him a little bit. He tells you what he thinks and you express an opinion and you size each other up, and that is the way you get acquainted. You are not acquainted when a man says, "Mr. A, meet Mr. B." That is contact, but not acquaintance. We say you have got to have something more than contact, you have got to have conference, you have got to talk things over. That is the second C.

"*Confidence:* Assuming you have a reasonably good bunch of people in the industry you are engaged in, if you talk together long enough and discuss things long enough and interpret yourselves to each other, that will inspire confidence. Then you are getting somewhere.

"*Coöperation:* The minute the men have confidence in the management and the management begins to have confidence in the men—and you cannot have one without the other, because the men are not going to have a whole lot of confidence in a manager who does not know them—it is very easy to coöperate, and that is the fourth C. That is team play. That is what we have got to have in the industry."

The Federated American Engineering Societies

Coal-Storage Survey

PROBABLY no decision reached by the Executive Board of American Engineering Council at its meeting in Cincinnati, Ohio, March 23 and 24, 1923, deserves higher commendation than that relating to a coal-storage survey. An authoritative statement covering the engineering, chemical, and economic factors involved in the storage of coal, and the influence of those factors on storage at the mine and by various classes of consumers, should be of prime importance in solving the complex coal situation. Many have contended that the widespread practice of storing coal by consumers would materially reduce the intermittent aspect of the coal industry; would result in an ample supply of coal at all times; would even up the demand for transportation facilities; would enable a larger resort to water transportation; would reduce operating and transportation expenses, and therefore would lead to a reduction in the cost of coal to the consumer. The compilation and analysis of complete data on all of the important factors involved should form a report as valuable as that on the Elimination of Waste in Industry.

In forming the committee to undertake the work the F.A.E.S. proposes that each of the following groups shall be represented: Bituminous and anthracite coal mining, transportation, public utilities, Bureau of Mines, equipment, chemical engineering, and any others that may be able to contribute scientific and fundamental information. W. L. Abbott, chief operating engineer, Commonwealth Edison Co., Chicago, has been chosen as chairman of the committee, which will develop its own plans, direct the investigation, employing the necessary assistance, and prepare the report.

The plan has the full endorsement of Secretary Hoover, Dr. George Otis Smith, vice-chairman of the U. S. Coal Commission, Mr. Wadleigh, U. S. fuel administrator, and Dr. H. Foster Bain, director of the Bureau of Mines. The work of the Department of Commerce and the Coal Commission, which are studying other features of the coal industry, and that of the F.A.E.S. committee will be so coördinated as to avoid duplication, confusion, and conflict. It is hoped that the report may be completed not later than November 1, 1923.

Storrs Plan of Domestic Coal Storage

EARLY in March, in a conversation with the Executive Secretary of the F.A.E.S., John Hays Hammond, chairman of the U. S. Coal Commission, voiced the desire of the commission for the coöperation and assistance of the engineers of the nation in its work and suggested a line of specific activity. Mr. Hammond emphasized the importance of coal storage and stated that it is a more difficult task to secure the storage of domestic coal than that of coal purchased by large users. He proposed a movement for a larger storage of domestic coal and urged that the engineers of the country lend their support to such a movement.

If engineers will point out to their clients and employers the advantages, accruing both to the public and to the coal industry, which can be secured if coal is stored during the summer, it is believed that they will be willing to arrange for the domestic coal purchases of their employees.

The plan which he advocated, one which has particularly impressed the Coal Commission, was devised by L. S. Storrs, of the Connecticut Company, New Haven, Conn. Under that plan the employee submits to his employer, prior to April 1, an estimate of his winter fuel needs. Delivery is to be made at the option of the retail dealer during the six months following. Full payment for the coal will be made by the company at the time of delivery. The company is reimbursed by deducting the cost of the coal from the employee's salary in monthly instalments over the six months' period.

Under this plan the employer purchases the coal at the best possible price and secures delivery early in the season. The employees, many of whom are accustomed to buying coal in very small lots during the period of highest prices and distribution difficulties, can make substantial savings and be assured of a sufficient quantity of coal.

Mr. Hammond's suggestion was transmitted immediately to the liaison officers of the member societies and, while at the time of writing reports of action taken are not available, a large number of inquiries from individual engineers and from companies as to details of the Storrs plan have been received at F.A.E.S. headquarters. Several large companies propose to adopt the Storrs plan or some similar method. Officials of the Department of Commerce, the Coal Commission, and the Bureau of Mines interested in the problem of coal storage have all expressed approval of the plan, and in many quarters it has been enthusiastically received. It is hoped that engineers will lend their fullest support to the movement.

Cincinnati Meeting of the Executive Board

IN ADDITION to the coal-storage decision, the Executive Board took action on a number of important matters at its Cincinnati meeting, and a number of interesting progress reports were presented. The Committee on Transportation, authorized at a meeting of the Committee on Procedure in February, had made a preliminary survey of the problem of transportation and advocated coöperation with a number of national organizations which have been working on it for some time. The Executive Board approved that policy. Max Toltz, of St. Paul, is chairman of the committee.

The Board voted to assist in the movement to bring about uniform safety legislation. In a statement on this subject issued recently by the F.A.E.S., both state and national legislation are recommended. Congress is asked to enact safety laws providing for the safe construction and equipment of buildings, regular inspecton of conditions, and the training of employees to observe proper precautions against accidents. The statement points out that "although the U. S. Employees' Compensation Commission is now expending approximately $3,000,000 per annum to alleviate the results of industrial accidents, it has no authority to take action of a preventive nature which might obviate the necessity for this expenditure and the loss of life and limb which it connotes." The F.A.E.S. also recommends the adoption by the several states of uniform legislation, and will support the plan of the National Safety Council for Conservation Week.

Concerning the registration of engineers it was resolved that "American Engineering Council should continue to collect and keep up to date a record of the Engineers' Registration and Licensing Laws that may be proposed or passed, together with decisions thereunder, for the use of the constituent societies of the F.A.E.S. and others, but that it assumes no control over the actions of such constituent societies in regard thereto."

The Board also voted to study the question of constituting the American Engineering Council a clearing house on elimination of waste, to endorse the plan for Government reorganization, to broaden the program of its Reforestation Committee, and to further American participation in the proposed world power conference in London in 1924.

Report of the Secretary

Secretary Wallace presented a detailed report, an interesting feature of which was a résumé of services rendered by the F.A.E.S. to various engineering societies, groups of engineers, organizations, and individuals during recent weeks. It has supplied information on the formation of engineering organizations, secured speakers for different groups, suggested men for important engineering positions, and provided full information on registration of engineers, uniform traffic regulation, provisions for housing workers, and other matters of importance.

He announced that the report on the Elimination of Waste in Industry is to be published in German by the Masaryk Academy of Czechslovakia, which is a government agency, and circulated in Czechoslovakia, Austria, and Germany, and quoted the president of the Academy as stating that the report is "one of those very few real contributions toward reconstruction of the postwar world."

Engineering and Industrial Standardization

Voluntary Adoption of Standards of Quality[1]

AMONG numerous topics of interest to the manufacturers and merchants of the United States contained in the Annual Report of Secretary of Commerce Hoover for the year 1922, there is one to which I particularly desire to invite your attention. Under the heading Voluntary Establishment of Grades and Qualities, Secretary Hoover has the following to say:

Agitation has been current for many years for the extension of the Federal laws to the establishment of grades and qualities of different commodities. The lack of such established grades and standards of quality adds very largely to the cost of distribution because of the necessity of buying and selling upon sample or otherwise, and because of the risk of fraud and misrepresentation, and consequently the larger margins in trading. It was considered by the department, however, that it would be infinitely better if such grades and qualities could be established voluntarily in the trades themselves instead of by legislation, and policed by trade associations as in the case in several old-established trades. To this end a number of conferences have been held in different branches of the lumber, textile, paper and other trades. The service of the department has been to bring the different branches of the trade, the manufacturers, wholesalers, retailers, and representatives of larger consumers' associations together and to develop committees of different branches of trades. The plan has been generally welcomed and applications have been received from many trades for such assistance. The expert services of the Bureau of Standards, Bureau of Foreign and Domestic Commerce, and the other bureaus of the department have been brought into service for technical advice in these matters, and results of important bearing upon the improvement of business ethics and cheapening of distribution have been attained.

This topic of voluntary action of business men to establish definite grades for various lines of merchandise should be of especial interest to the organization members of the National Chamber. Shoe manufacturers, textile manufacturers, and others have been worried by snap-judgment proposals to set up so-called "pure shoe" and "pure fabric," etc., standards by Government action. Of course, the reputable American business man is not afraid or unwilling to sell his goods on reasonably drawn specifications or to stand back of the quality of his product to a reasonable extent. There is nobody better qualified to pass on what is and what is not reasonable as a standard of quality or performance than those who are in the trade itself. Here, as Secretary Hoover points out, is undoubtedly a field for voluntary action on the part of producers, manufacturers, and merchants in establishing grades and setting standards of quality or performance, with which the consumers will be sympathetic.

Business is facilitated and the ground for commercial disputes between buyer and seller is narrowed down if sales are made on the basis of standard grades of merchandise, perfectly familiar to both buyer and seller. In a good many foreign countries there has been loss of good will for particular American dealers as well as some lingering prejudice to the good name of American business generally, which can be traced to the lack of understanding and agreement between buyer and seller as to the qualities entering into transactions, or to the absence of standards of quality and performance. When such standards exist, backed up by the moral force of a trade association or trade group in the United States, the promotion of the sale of American merchandise of a given kind and the building of good will toward American trade abroad are made easier, and rest upon a sound foundation.

Standardization, and the setting up of systems of inspection and certification in some cases, have made most progress among lines of raw material and foodstuffs sold in bulk and moved in large amounts. The full possibilities of doing business on standards of quality have not yet been realized, even in many such lines of merchandise. It is, of course, not only in the foreign trade, but in the whole wide range of domestic trade that the use of clear standards, easily checked up, may be developed. The American Society for Testing Materials, and many other organizations represented in the American Engineering Standards Committee are making great progress in setting up and improving national standards on engineering products. The applicability of the same principles to numerous lines of manufactured specialties is well worthy of consideration by trade associations and chambers of commerce.

Some commercial and trade associations not only set up standards but go further and provide rules and facilities for inspection and certification of merchandise. Costs must be kept down. With all due recognition of this fact, however, where actual inspection and certification of individual shipments do not add disproportionately to the costs of merchandise, and do serve a useful purpose, associations may well consider the possible desirability of making some arrangements, either with existing bureaus, laboratories, or other agencies doing commercial work of sampling, inspecting, testing, and certifying, or of actually setting up such accommodations if they do not exist adequately for the needs of the particular industries as those needs grow.

Our department managers in the different departments of the staff of the Chamber of Commerce of the United States are desirous of coöperating with any organization undertaking or extending this class of work. We have been in touch with some of the organizations that have gone far in this direction. The book of rules for trading in all sorts of oil products, adopted by the Interstate Cotton Seed Crushers Association may be cited as an example of association work on definitions of grade and quality, sampling, testing, fixing variation, performance of contract, etc., which would probably be a revelation to those not in the trade. We want more information concerning the extent to which other associations have gone to date in the adoption of voluntary standards and the enforcement of those standards. And, further, we want an indication from our members as to the ways in which our Natural Resources Production Department, our Fabricated Production Department, our Domestic Distribution Department, our Foreign Commerce Department, or the departments dealing with insurance, finance, and transportation can be of assistance in furthering this movement. We are in touch with the Government bureaus chiefly concerned and are working directly with some national organizations in getting their standards known in foreign countries.

[1] From an open letter to American business men by Julius H. Barnes, President, Chamber of Commerce of the U. S.

Report of the Director, Bureau of Standards

THE 1922 Report of the Director of the Bureau of Standards which has been recently made available in pamphlet form ($5^3/_4$ by 9 in., 282 pages) contains much of interest to engineers whether they are engaged in manufacturing, sales, or pure engineering. The following paragraphs taken from the early pages of the report will serve to emphasize the important service which the Bureau of Standards is able and anxious to render to the public and to industry.

The bureau compares with its own standards of measurement the standards and measuring instruments of states, cities, scientific laboratories, educational institutions, and the public. In this way the standards of the National Government are made available to every one in the country. For these comparisons a nominal fee is charged, except in the case of national and state government institutions. The bureau is at all times glad to assist these institutions in matters concerning these standards or their use, whether it be in connection with the enactment of laws, regulations, or ordinances concerning the weights and measures of every-day trade or in connection with precision standards used in scientific work.

It must not be inferred from the above that the bureau's activities are devoted principally to the interests of the user or consumer. The fundamental facts regarding standards of measurement, quality, or performance are the very things which most deeply concern manufacturers; they are fundamentally concerned, either directly or indirectly, with the improvement of methods of production or the quality of the output. It may be said that the bureau occupies somewhat the same position with respect to the manufacturing interests of this country that the bureaus of the Department of Agriculture do to the agricultural interests. Many industries realize the importance of scientific investigation which, in practically every case, involve some kind of precision measurement.

During the past year the bureau has continued its close coöperation with American industries. It has continued to act as a clearing house for fundamental, scientific, and technical information, and manufacturers are coming to realize more and more that they can often secure from the bureau general and sometimes even specific advice concerning improvements in their particular industrial processes. The solution of many difficult problems in the industries cannot be reached in commercial plants, but requires the work of a specially equipped research laboratory, working always in close coöperation with manufacturers who are the best judges of the practical aspects of the problem.

One of the greatest services which the bureau performs for the industries is the training of men for scientific and technical research work. Many young men receive what is, in some respects, better than a postgraduate

course by working in some of the minor scientific positions at the bureau during the years immediately following the completion of their college course. These men then go into the industries with a better conception of the problems of research work.

National Conference Votes for Safety Code on Walkway Surfaces

A CONFERENCE attended by sixty-three representatives of trade associations, technical societies, safety organizations, and Government departments, held in New York recently, declared by unanimous vote that "It is desirable to have a nationally uniform safety code on walkway surfaces" and that the development of this code should be carried out under the procedure of the American Engineering Standards Committee.

The conference voted to include in the code elevator floors, elevator landings, corridor floors, ramps, runway floors, stair treads and landings, fire-escape treads and landings, floors around machinery and at door thresholds, and sidewalk hazards such as coal-hole covers and sidewalk doors. It was recommended that the sectional committee consider the question of platforms in front of electrical apparatus, especially switchboards and floors around machinery in motion, as to insulation and non-slip qualities. This new code will apply to apartment houses, factories, and other working places, office buildings, hospitals, hotels, and restaurants, railway cars, railway stations and train platforms, schools and theaters.

At a meeting of the Main Committee of the A.E.S.C. held since this conference the American Institute of Architects and the American Society of Safety Engineers were designated as joint sponsors for this project. These sponsors will organize the sectional committee which will draft the code. This sectional committee as usual will be composed of official representatives of all organizations concerned with the subject of safe walkway surfaces, either as producers, consumers, casualty underwriters, or governmental officials representing the general public.

Protection of Heads and Eyes

A SECOND edition of the National Safety Code for the Protection of the Heads and Eyes of Industrial Workers has been issued in pamphlet form. The arrangement of the code is such as to first present the general requirements, including a classification of the occupations which require eye protection. Then follow the detailed requirements for each group of occupations, operating rules, and finally the specifications for tests which must be met to insure that protectors will adequately fulfil their purpose.

Following is a discussion of the rules intended to assist the reader in understanding the reasons for the rules and in interpreting the rules, and to give suggestions for the best means of carrying them out.

E.I.C. Elects Successor to President St. Laurent, Who Recently Died

WALTER J. FRANCIS, consulting engineer of Montreal and senior vice-president of the Engineering Institute of Canada, has been elected president to fill the unexpired term of Arthur St. Laurent, who died early in March. Mr. St. Laurent, who assumed office in January, was born in Rimouski, Quebec, in 1859. He was graduated from Montreal University, and in 1888 entered the service of the Public Works Department of Canada, remaining in government service all his life and rising to the position of chief engineer of the department. Among the operations over which he had charge was the construction of the dam at St. Andrews Rapids on the Red River; the building of a traffic bridge across the North Saskatchewan River at Edmonton, where he introduced concrete in bridge construction; the lengthening of the dry dock at Levis, Quebec; and the construction of the Laurier bridge at Ottawa and the grain elevator No. 1 at Montreal Harbor.

Mr. St. Laurent's successor is a graduate of the University of Toronto. He was engineer for the royal commission of inquiry into the Quebec bridge disaster and reported on the wreck, developing in detail the theory for the collapse. His consulting work has included designs and reports on many hydroelectric and steam power plants, investigations and reports on buildings, especially foundations, and municipal investigations.

Facts Favoring Railway Electrification

MANY articles have been written comparing steam and electric motive power for railroads. Generally they state that electric power permits more rapid acceleration, that stand-by losses are reduced or eliminated, large overloads can be handled for short periods, smoke is eliminated, coal and water stations are not needed, locomotive coal need not be hauled, less coal is used, etc. On the other hand it is shown that when steam power is used, intricate and interdependent power-distribution facilities are not required, capital expenditures are reduced, no trouble is caused by inductive interference or electrolysis, and so on. All these statements are generally accepted as facts, but it is unfortunate that most of them of necessity are qualitative rather than quantitative. For example, it is variously estimated that electric operation will save all the way from 10 to 70 per cent of the annual coal bill. Actual figures in one case indicate the saving to be 28 per cent, but even these figures are open to criticism. It is for this reason that we welcome such facts as the following: Electric locomotives on the Chicago, Milwaukee & St. Paul are used to haul trains on continuous runs of 440 miles except for station stops; switching locomotives on the New York, New Haven & Hartford are kept in continuous service 24 hours a day for more than 70 per cent of the total time without being shopped for even minor repairs, while road engines frequently make 500 miles a day and average 33,000 miles per locomotive failure; multiple-unit cars on the Pennsylvania operate with an average of over 48,000 car-miles per detention. A recently issued statement also announces that several of the 41 passenger locomotives which have been in service for 16 years have now been run more than 1,000,000 miles. Facts like these do two things; establish the dependability of electric equipment and make easier the decision of the road wishing to determine whether or not it should adopt electric operation. (*Railway Age*, Mar. 24, 1923, p. 795)

Civil Engineers Vote Against Joining Federation

A BALLOT of the membership of the American Society of Civil Engineers on joining The Federated American Engineering Societies, canvassed on April 6, 1923, showed a total vote of 5753, of which 3641 were opposed to joining the Federation. The results of the ballot, tabulated by districts, are as follows:

	District	Yes	No
1	Foreign	25	84
	Territory within 50 mi of N. Y. Postoffice	166	688
2	New England, New Brunswick, and Nova Scotia	84	331
3	New York (except as included in District 1) and Quebec	107	221
4	Eastern Pennsylvania, New Jersey (except as included in District 1), and Delaware	143	292
5	District of Columbia, Maryland, and Virginia	134	254
6	Western Pennsylvania, West Virginia, and Ontario	87	214
7	Michigan, Wisconsin, Iowa, Minnesota, Manitoba, North and South Dakota	276	144
8	Illinois	167	186
9	Indiana, Kentucky, and Ohio	184	154
10	Alabama, Florida, Georgia, Mississippi, North and South Carolina, and Tennessee	109	203
11	Colorado, New Mexico, Arizona, Southern California, Utah, and Wyoming	191	189
12	Idaho, Montana, Washington, Oregon, Alaska, Alberta, British Columbia, Saskatchewan, and Yukon Territory	102	124
13	Northern California and Nevada	84	209
14	Missouri, Arkansas, and Louisiana	108	158
15	Nebraska, Kansas, Oklahoma, Texas, and Mexico	145	200
		2112	3641

The Efficiency of The Scotch Marine Boiler

THE captions for Figs. 7 and 8 in Mr. Jefferson's paper on The Efficiency of the Scotch Marine Boiler, published in the April issue of MECHANICAL ENGINEERING, were, through error, interchanged. The higher-efficiency curve is for the forced-draft test, while the lower values are for the induced-draft test. Photographs of all the burners used in the test were submitted with the original article. The selection of illustrations was made by the Editor.

Meetings of Other Societies

American Railway Engineering Association

Standardization and labor economics were leading topics under discussion at the twenty-fourth annual meeting of the American Railway Engineering Association held in Chicago, March 13–15, 1923. J. L. Campbell, of the El Paso & Southwestern Ry., in his address as retiring president of the association, spoke at some length upon the problem of labor economics, and in regard to standardization emphasized the need of a wider use of adopted standards of design and practice. Both he and R. H. Aishton, president of the American Railway Association, called attention to the large amount of standardization work essential in railway engineering. The Committee on Standardization recommended close coöperation with the work of the American Engineering Standards Committee. The matter was discussed by many of those present but no definite action was taken. The Association is at present represented on the A.E.S.C. by one member, through the American Railway Association.

The Committee on Economics of Labor considered the problems of obtaining and retaining labor, and organizing labor for efficient and economical work. This committee is considering methods of organizing forces for maintenance work and submitted a report of preliminary studies outlining methods of renewing rails and ties.

The Rail Committee presented statistics of rail failures, revealing a deterioration of quality of rail in the 1916 and 1917 rollings. The number of failures per 100 track-miles during five years' service ranged above 200 for the rails rolled about 1910, while subsequent improvement of quality brought the failures of 1914 rail down to 74. The latter figure increased to 105 for 1916 rail. Preliminary service indications for the rollings of 1918 and subsequent years indicate renewed improvements.

Final specifications for the erection of railway bridges were presented and adopted, and highway-bridge specifications for bridges less than 300 ft. span were presented.

Following a discussion of the need for participation by engineers in the revision of the Interstate Commerce Commission's schedule of accounts for railways, it was voted that the association, in connection with the American Railway Association, take prompt action to bring the engineering requirements of an accounts schedule to the attention of the commission.

The Committee on Water Service discussed the relative merits of cast iron, steel, wood, and other materials for pipe lines, the Committee on Yards and Terminals presented a comprehensive study of the principles affecting the design of passenger stations for main-line traffic, and other committees gave reports on additional phases of railway engineering.

Edward H. Lee, president and chief engineer, Chicago & Western Indiana R. R., was elected president for 1923–1924. E. H. Fritch was reëlected secretary.

American Management Association

A conference of nearly two hundred executives, representing industrial and commercial enterprises in all parts of the country, was held in New York on March 14, 1923, to organize the American Management Association. This new organization takes the place of the National Personnel Association, which was formed last year through the merger of the National Association of Corporation Training and the Industrial Relations Association of America. It will be devoted exclusively to the consideration of the human factor in commerce and industry.

Among the speakers at the meeting were Charles R. Hook, vice-president and general manager of the American Rolling Mill Co., Middletown, Ohio, and Howard Coonley, President of the Walworth Manufacturing Co. Mr. Hook stressed the necessity of close and friendly coöperation between the heads of industrial enterprises and the workers in order that better conditions, social and economic, may be brought about. He stated that the problem of industrial America is not just more production, but more units of production per man per day. One part of the problem, he continued, deals with improved machinery to reduce the number of men needed per unit of product and the other affects individual efficiency and reward. Mr. Coonley discussed the correlation of sales and production.

The officers of the new association are: President, W. W. Kincaid, president of the Spirella Co., Niagara Falls, N. Y.; Vice-Presidents; Sam A. Lewisohn, New York, vice-president of the Miami Copper Company, John A. Stevenson, vice-president of the Equitable Life Assurance Society of the United States, New York, and Fred W. Tasney, vice-president of the Prudential Insurance Company of America, Newark, N. J. Mr. Lewisohn, who presided at the business meeting, issued a statement in behalf of the officers and directors of the association, as follows:

> Personnel work is an integral, inseparable part of management interwoven into all of the efforts and activities of the production and sales departments and of the office. It cannot be segregated as an isolated function, and all efforts to bring about such a separation are foredoomed to failure. There is ample experience to prove this sweeping statement.
>
> This meeting was designed to present to executives two important phases of the problem in which the Association is interested. It is believed that the consideration of the human side of management as an integral part of the whole will lead to a more permanent acceptance of the idea. Incidentally it will provide greater opportunity for the personnel man and an increasingly complete interpretation of the management problem with adequate recognition to the most important factor—the human factor—in commerce and industry.

American Boiler Manufacturers' Association

The American Boiler Manufacturers' Association held its winter meeting in New York on Feb. 12, 1923. Following an address by the president, A. G. Pratt, vice-president of the Babcock & Wilcox Co., E. R. Fish, representative of the association on the A.S.M.E. Boiler Code Committee, reported progress in the work of that committee, and a letter from Charles E. Gorton, chairman of the Uniform Boiler Law Society, reporting the progress of boiler legislation in several states, was read.

Papers on Budgeting, by G. S. Barnum, of the Bigelow Co., and on the Standardization of Bolt, Nut, and Rivet Proportions, by F. G. Cox, weer presented. Mr. Barnum's paper emphasized the value of an accurate method of cost accounting to the manufacturer.

W. C. Connelly presented the report of the Committee on Related Industries, and summarized the replies to a questionnaire on boiler rating which had been sent out to the entire membership of the association. About 45 replies were received; of these 7 preferred to rate the boilers by horsepower, 24 by square feet of heating surface, and 11 by both heating surface and horsepower. The manufacturers of water-tube boilers were the only ones to present a unity of opinion on the use of 10 sq. ft. per hp.; the others varied from 7.5 to 12, the greatest difference being in the small sizes of locomotive and vertical-type boilers. On the question of including integral economizer surface as part of the boiler heating surface, 19 firms favored treating this as a separate item, while 4 considered that it should be treated as boiler heating surface.

Reports on a conference with the Department of Commerce on Standardization and Simplification, and on the work of the National Board of Boiler and Pressure Vessel Inspectors were also presented.

American Chemical Society

The 65th meeting of the American Chemical Society was held at New Haven, Conn., during the week of April 2, 1923. Sessions were held by all the divisions and sections except the leather and fertilizer divisions. The papers presented numbered over 350, and covered such subjects as agricultural and food chemistry; petroleum, gas, and fuel chemistry; motor fuels; industrial and engineering chemistry; cellulose chemistry; rubber chemistry; chemical education; history of chemistry; biological chemistry; sugar chemistry; physical, inorganic, organic, and dye chemistry; water, sewage and sanitation; and the chemistry of medicinal products.

Historical, educational, and industrial exhibits were given, and inspection trips made to a number of manufacturing plants in New Haven and neighboring cities, and to various laboratories at Yale University. One day was devoted to the dedication of the Sterling Chemistry Laboratory.

Speakers at general meetings included James R. Angell, president of Yale, Brigadier General Amos A. Fries, Chemical Warfare Service, U. S. War Department, Arthur D. Little, Boston, Mass., Francis P. Garvan, president of the Chemical Foundation, and Sir J. J. Thomson, F.R.S.

LIBRARY NOTES AND BOOK REVIEWS

Accurate Tool Work. By C. L. Goodrich and F. A. Stanley. Second edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 300 pp., illus., diagrams, $3.

A collection of articles written by the authors or selected from the *American Machinist*, which discuss practically, methods and devices for producing accurate, interchangeable machine parts.

Briquetting. By Albert L. Stillman. Chemical Publishing Co., Easton, Pa., 1923. Cloth, 6 × 9 in., 466 pp., illus., $6.

This is the first American work on the subject of briquetting, and is based, the author states, on many years' experience. The book opens with an account of the raw materials, which is followed by a chapter on briquet presses. Succeeding chapters describe the methods for briquetting various materials, such as steel swarf and turnings, cast-iron borings, non-ferrous metals, wood waste, peat, lignite, coals, flue dusts and ores. Binders are also discussed. Bibliographies and lists of patents on each subject are given.

Car Builders' Cyclopedia. 1922. Tenth edition. Locomotive Cyclopedia. 1922. Sixth edition. Simmons-Boardman Publishing Co., New York, 1922. Cloth, 9 × 12 in., nearly 1200 pp. a vol., illus., diagrams, $8 per vol.

These two works have long been valued for the definite, thorough description of current American practice in the construction and repair of railroad rolling stock which they present. Each opens with a dictionary of the terms used, following this by a series of chapters which present drawings and photographs of contemporary equipment of all kinds, with brief descriptive articles on development and present practice. Specifications of the American Railway Association, Government regulations and safety rules are given.

The present editions offer the text in a new arrangement, by which the information on each broad topic is collected in one chapter instead of being scattered through the book under specific headings as in previous editions. The new arrangement will, it is thought, facilitate reference to the books.

Design of Machine Elements. By James A. Mease and George F. Nordenholt. First edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 237 pp., diagrams, tables, $2.50.

Most textbooks on this subject are too comprehensive, in the opinion of the authors of this one, to be suitable for an elementary course. To overcome this difficulty they present the present text which makes no claim to originality of subject-matter except in the methods of computing gear pitches, but which is new in scope and in its manner of presentation. The book is the outgrowth of notes originally prepared by Prof. P. B. de Schweinitz for use at Lehigh University.

Design of Steam Boilers and Pressure Vessels. By George B. Haven and George W. Swett. Second edition. John Wiley & Sons, New York; Chapman & Hall, London, 1923. Cloth, 6 × 9 in., 435 pp., illus., diagrams, charts, tables, $4.

This book is intended primarily to teach rational methods of boiler design, while at the same time it is intended to be an introduction to the study of machine design, a purpose for which the authors believe an analysis of the stresses existing in boilers and other pressure vessels has many advantages.

In general, the results here presented have been obtained by rational rather than empirical methods, the usages of current boiler-making practice having been kept constantly in view. Many graphs and tables are given which enable numerical results to be obtained without using formulas. The principles are illustrated by their application to the complete practical design of boilers and tanks of six different types.

Dictionary of Applied Physics. Vol. 3, Meteorology, Metrology and Measuring Apparatus. By Sir Richard Glazebrook. Macmillan & Co., New York and London, 1923. Cloth, 6 × 9 in., 839 pp., illus., 63s.

The third volume of this dictionary maintains the high standard of excellence shown in the first two volumes. It should be of interest to engineers in all branches of the profession, as it contains accurate scientific data and precise theoretical information on measuring instruments and methods of measurement. Among the important articles are: Surveying Tapes and Wires, by Sidney W. Attwell; Preparation of Quartz Fibers, by Charles V. Boys; Nomography, by Selig Brodetsky; Physics of the Atmosphere, by David Brunt; Measurement of Solar Radiation, by William W. Coblentz; Watches and Chronometers, by E. G. Constable; Design of Scientific Instruments, by Horace Darwin and Cecil C. Mason; Balances, by F. A. Gould; Meters, by Edgar A. Griffiths; Calculating Machines, by Ellice M. Horsburgh; Comparators and Line Standards of Length, by W. H. Johnson; Combination of Observations, by H. L. Jolly; Mechanical Means of Integration, by Hyman Levy; Weighing Machines, by George A. Owen; Gauges, by Frederick H. Rolt; Clocks and Time-keeping, by Ralph A. Sampson; Metrology, by John E. Sears, Jr.; Humidity, by Sydney Skinner; Draughting Devices, by Alma Turner; Micrometers, by H. H. Turner; and Atmospheric Electricity, by C. T. R. Wilson. Ample cross-references and a good index are provided, and there are numerous references to other literature on many subjects.

Dimensional Analysis. By P. W. Bridgman. Yale University Press, New Haven, 1922. Cloth, 6 × 9 in., 112 pp., $5.

The substance of this book was given as a series of lectures to the Graduate Conference in Physics of Harvard University in 1920. The growing use of the methods of dimensional analysis in technical physics, as well as the importance of the method in theoretical physics, make it desirable that every physicist should have it at his command. Professor Bridgman's statement of principles is accompanied by many illustrations of their applications, especially chosen to emphasize the points concerning which there is the most common misunderstanding. Some of these deal with important questions of electrical theory, aeronautics, and other subjects of interest to engineers.

Drop Forging and Drop Stamping. By Henry Hayes. Isaac Pitman & Sons, New York and London, 1923. (Pitman's Technical Primers.) Cloth, 4 × 6 in., 108 pp., illus., $0.85.

In previous books on drop forging, attention has generally been concentrated upon a description of the plant used. A broader treatment has been attempted in this volume, particularly with a view to relating the mechanical with the metallurgical problems. The aim has been to provide an introduction to the equipment and methods of the drop-forge shop, to the principles underlying drop forging and to the heat treatment and hammer treatment of forgings. The question of dies is also discussed.

Electricity in Agriculture. By Arthur H. Allen. Isaac Pitman & Sons, London and New York, 1922. (Pitman's Technical Primers.) Cloth, 4 × 6 in., 117 pp., illus , tables, $0.85.

A small book indicating briefly the various ways in which electricity can be used by the farmer for light and power purposes and for electroculture, and the methods by which he can avail himself of electricity. The book also calls to the attention of central-station managers the possibilities of the farmer as a customer. Written for British farmers, it treats the questions in the light of British conditions.

Eleménts de Mécanique, A L'Usage des Ingénieurs; Statique Cinématique. By Robert d'Adhémar. Gauthier-Villars et Cie, Paris, 1923. Paper, 6 × 10 in., 254 pp., 16 fr.

This textbook reproduces the course of instruction given by the author at the Institut Industriel du Nord de la France. It contains the elements of kinematics and dynamics, and an elementary development of statics.

Engineering Economics. By John C. L. Fish. Second edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 311 pp., tables, $3.

This book treats of the principles which underlie economic judgment in the business side of engineering. The present edition, which is practically a new text, assumes choice of investment to

be the fundamental problem of engineering economics and proceeds to the analysis of this problem in a way that will give the student a working knowledge of the principles involved.

Engineering of Excavation. By George B. Massey. John Wiley & Sons, New York; Chapman & Hall, London, 1923. Cloth, 6 × 9 in., 376 pp., illus., diagrams, tables, $6.

The writer of this treatise, after spending practically all of his time since 1899 in the study of excavating problems and the application of machinery to them, has brought together the fruits of his experience. The book describes present methods of excavating and the machines and other equipment used in excavating and transporting both on land and under water. Capacities are given and the machines which are best suited for various kinds of work are indicated.

Gasmaschinen und Ölmaschinen. Vol. 1. By Alfred Kirschke. Vereinigung Wissenschaftlicher Verleger (Walter de Gruyter & Co.), Berlin and Leipzig. 1922. Boards, 4 × 6 in., 133 pp., illus., diagrams, $0.30.

This is the first of two small volumes, adapted to the pocket, in which are given a concise account of the origin and development of the internal-combustion engine. The present volume treats of small gas and oil engines. Chapters are devoted to gas as a source of power, early gas engines, cycles, general design and construction, valve gears, ignition and regulation, oil and spirit engines, automobile, airship and boat engines, gas producers, cost of operation, and gas and steam engines.

Hendricks' Commercial Register. 1923. S. E. Hendricks Co., Inc., New York, 1922. Cloth, 8 × 11 in., 2320 pp., $15.

Hendricks' Commercial Register endeavors to list all producers, manufacturers, dealers, and consumers connected with the engineering, chemical, metallurgical, railroad, contracting, and allied industries. It provides a ready directory to the manufacturers of an article and to the location of any firm. It also furnishes an index to trade names, enabling the manufacturer of any named article to be found. Over eighty thousand firms are listed in the 1923 edition.

Labor and Democracy. By William L. Huggins. Macmillan Co., New York, 1922. Cloth, 5 × 8 in , 213 pp., $1 25.

This volume, by the presiding judge of the Kansas Court of Industrial Relations, is a discussion of the relations between government and modern industrial conditions. The author endeavors to point out some of the dangers to democratic institutions inherent in the labor movement of today, to appraise the rights of labor, of capital, and of the public, to suggest legal principles upon which remedial legislation may be based, and to give the first results of the Kansas experiment in adjudicating industrial disputes.

Lehrbuch der Eisen- und Stahlgiesserei. By Bernhard Osann. Fifth edition. Wilhelm Engelmann, Leipzig, 1922. Cloth, 7 × 10 in., 693 pp., illus., diagrams, 24 mks.

This textbook of foundry is intended for beginners in the industry and also as a reference work for those engaged in iron and steel founding.

A concise but comprehensive account of the methods and appliances used is given, which is supplemented by numerous references to the literature and drawings. Special attention is given to molding methods, materials and machines. Chapters on steel and malleable castings are included. The volume concludes with a chapter on the metallography of cast iron.

Les Marées et leur Utilisation Industrielle. By E. Fichot. Gauthier-Villars et Cie., Paris, 1923. (Science et Civilisation.) Paper, 5 × 8 in., 254 pp., 9 fr.

The work of a chief hydrographic engineer of the French navy, this volume is a study of the possibility of using the energy of waves, on a large scale, as a source of industrial power. The author describes the action of the heavenly bodies on the waters of the ocean, the undulatory movements of the ocean, and the formation and propagation of waves. This study of the theory of waves is followed by an exposition of the projects intended to utilize the waves as a source of power. The book is intended not only for specialists, but also for legislators and others interested in economic problems.

Meaning of Relativity. By Albert Einstein. Princeton University Press, Princeton, 1923. Cloth, 5 × 7 in., 123 pp., $2.

This volume presents, in a translation by Prof. Edwin Plimpton Adams, four lectures delivered by Doctor Einstein at Princeton University, during May, 1921. The first lecture is upon space and time in pre-relativity physics; the second upon the theory of special relativity; and the remaining two upon the general theory of Relativity.

Machine Tools and Their Operation. By Fred H. Colvin and Frank A. Stanley. McGraw-Hill Book Co., New York and London, 1922. Cloth, 6 × 9 in., 2 vols., illus., diagrams, tables, $8.

This textbook is intended to give the mechanic an understanding of the principles involved in the operation of the ordinary machine tools, and thus enable him to adapt them to the various jobs that occur in the shop. Special attention is given to such subjects as cutting speed, clearance, angles, chip clearance, lubrication, speed and feed, and tool supports. The language is clear, simple and non-mathematical.

Metals and Their Alloys. By Charles Vickers. Henry Carey Baird & Co., New York, 1923. Cloth, 6 × 9 in., 767 pp., illus., tables, $7.50.

This work is based on Brannt's well-known work, Metallic Alloys, but the text has been so enlarged and so thoroughly revised that a new book has resulted. The book is intended to furnish modern, practical information on the composition and properties of industrial metals and their alloys, and on their manufacture, casting and working. The needs of the foundryman have been kept especially in view.

Modern Motor Car Practice. Edited by W. H. Berry. Henry Frowde & Hodder & Stoughton, London, 1921. (Oxford technical publications.) Cloth, 6 × 9 in., 582 pp., illus., $10.50.

This work, the result of the collaboration of a number of prominent English authorities on automobile engineering, is a valuable record of contemporary motor-car practice. An account is given of present methods of design and construction of each part of the automobile, with some review of the way in which present forms have developed, of the advantages and disadvantages of various designs, and of the trend of future change. Written in an interesting style and well illustrated, the book should prove of use to designers and manufacturers, and also to owners.

Practical Factory Administration. By Matthew Porosky. First edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 5 × 8 in., 244 pp., diagrams, $2.50.

The purpose of this book is to present the accepted principles of modern factory administration and to show how they may be effectively applied to actual operating conditions. It is addressed to executives, salesmen, cost accountants, and students of industrial administration. The principles, practices, and forms that it gives are presented from the point of view of the average rather than the exceptionally large establishment.

Principles of Electric Spark Ignition in Internal Combustion Engines. By J. D. Morgan. Crosby Lockwood & Son, London; D. Van Nostrand Co., New York, 1922. Cloth, 6 × 9 in., 94 pp., diagrams, $2.25.

In this little book an account is given of the scientific basis of electric spark ignition. During recent years much research has been undertaken on ignition problems, the main results of which, so far as they are of direct value to designers and students of gasoline engines, are here brought together. The design and constructional details of ignition apparatus have been excluded from this discussion.

Principle of Relativity with Applications to Physical Science. By A. N. Whitehead. University Press, Cambridge, 1922. Cloth, 6 × 9 in., 190 pp., 10s. 6d.

This book is not an attempt to expound Einstein's theory, but to set forth an alternative theory of relativity and to show the results deducible from the application of the formulas assumed for the gravitational and electromagnetic fields. Dr. Whitehead believes that our experience requires and exhibits a basis of uniformity, and that in the case of nature this basis exhibits itself as the uniformity of spatio-temporal relations; a conclusion that entirely

cuts away the casual heterogeneity of these relations which is the essential of Einstein's later theory. This uniformity is essential to the outlook of the author. He finally arrives at metrical formulas identical with those of Einstein's earlier theory, but with entirely different meanings ascribed to the algebraic symbols.

Problems in Machine Design. By O. A. Leutwiler. First edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 133 pp., diagrams, tables, $1.50.

A series of isolated problems covering the various parts of the subject of machine design, intended to supplement those given in textbooks on that subject, and thus to give the student greater familiarity with the application of theory and a better working knowledge of the subject. Almost all the problems have been taken directly from existing machines, so that the student works with actual engineering information.

Seagoing and Other Concrete Ships. By N. K. Fougner. Henry Frowde and Hodder & Stoughton, London, 1922. (Oxford technical publications.) Cloth, 6 × 10 in., 216 pp., illus., diagrams, 10. $7.

The aim of the author is to present a true record of the principal seagoing concrete ships actually built up to the present, and to analyze the merits of these ships in comparison with ships built of wood and steel. The main part of this book is based on personal experience gained in the construction of about thirty vessels of concrete during the past five years. Information about ships built by others has been obtained partly through correspondence with the designers, builders or owners, and partly from the engineering press.

Standard Inventory Manual. By Frederic W. Kilduff. First edition. Accounting Standards Corporation, Chicago, 1922. Cloth, 6×9 in., 227 pp., charts, tables.

A reference book for managers of industrial enterprises, based on the practice of well known firms. Intended to assist him to prepare an inventory manual for his own firm which will contain complete, detailed rules for planning, preparing, taking, pricing and tabulating inventories with the least possible expense and loss of time.

Steam-Turbine Principles and Practice. By Terrell Croft. First edition. McGraw-Hill Book Co., New York aud London, 1923. (Power Plant Series.) Cloth, 6 × 8 in., 347 pp., illus., $3.

Intended to provide the operating engineer and the plant superintendent with information reqnired in every-day work. The topics treated are (1) those with which he must be familiar to insure the successful, economical operation of turbines, and (2) those which he must know in order to choose the proper turbines for any class of work. Design is not treated. The book is a clearly written account of steam turbines, written for the user, not for the designer or maker.

Structural Drafting and the Design of Details. By Carlton Thomas Bishop. Second edition. John Wiley & Sons, New York, 1922. Cloth 8 × 11 in., 352 pp., diagrams, tables. $5.

This book for students and structural draftsmen corresponds in scope to the duties of the structural steel draftsman, and therefore covers not only the preparation of the detailed workings drawing for steel structures, but also the design of the details of construction. It is a textbook in structural drafting and may be used as a textbook in elementary structural design. The new edition has been prepared to meet the extensive changes in the standards of the Association of American Steel Manufacturers. At the same time other changes and corrections have been made.

Tables Annuelles de Constantes et Données Numeriques de Chimie, de Physique et de Technologie. Vol. 4, 1913–1916. Two parts. Gauthier-Villars et Cie, Paris; Cambridge University Press, Cambridge, Eng.; University of Chicago Press, Chicago, 1922. Cloth, 9 × 11 in., 1377 pp., $13.57.

The annual tables of chemical, physical and technical constants and numerical data are prepared under the direction of the International Research Council and the International Union of Pure and Applied Chemistry, by an international committee. The aim of its editors is to summarize and present in convenient form for reference the data in its field which appear in the important periodicals and treatises of each year, and thus supply investigators with the latest results of research.

Volumes 1 to 3, issued in 1912, 1913 and 1914, covered the literature of 1910–1912. Volume 4, just published, covers that from 1913 to 1916 inclusive. Full references to sources of data are given.

Tool Engineering, Fixtures for Turning, Boring and Grinding. By Albert A. Dowd and F. W. Curtis. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 340 pp., diagrams, $3.50.

The first volume of this series dealt with the design of jigs and fixtures. The present volume discusses the factors that affect the design of tools and fixtures for turning, boring, and grinding. Fundamental points in design are treated and the reasons why certain things are done are explained in detail.

Technische Schwingungslehre. By Wilhelm Hort. Second edition. Julius Springer, Berlin, 1922. Cloth, 5×8 in., 828 pp., illus., diagrams, $4.80.

The author has undertaken to collect and present in systematic fashion our knowledge concerning vibratory phenomena of technical importance. The book covers the mechanics of rigid, elastic, liquid and gaseous bodies and the field of electricity. Methods for investigating these phenomena are given, with examples taken from practice. An extensive bibliography is included.

Telephony. By Samuel G. McMeen and Kempster B. Miller. American Technical Society, Chicago, 1922. Fabrikoid, 6 × 9 in., 943 pp., illus., diagram, $5.50.

A descriptive, non-mathematical work covering the entire field of telephone engineering in one volume of reasonable size. Describes the customary types of subscribers' apparatus, line systems, switchboards, automatic systems, line construction, central offices, etc. Based on American practice.

Theory of Relativity and its Influence on Scientific Thought. By Arthur S. Eddington. Clarendon Press, Oxford, 1922. (Romanes Lecture, 1922.) Paper, 6×9 in., 32 pp., $0.70.

In this pamphlet containing the Romanes Lecture for 1922, Professor Eddington gives a clear, concise account, in non-mathematical terms, of the evolution of the theory of relativity.

Treatise on Weighing Machines. By George A. Owen. Charles Griffin & Co., London, 1922. Cloth, 6 × 9 in , 202 pp., illus., diagrams, charts. $3

This book, the first English treatise on its subject, explains in simple language the principles underlying the construction of weighing machines. It is intended as a guide to the proper types for various purposes and to methods of maintaining accuracy. The basic principles of all weighing machines are included in one or another of the types described.

20th Century Guide for Diesel Operators. By Julius Rosbloom and Orville R. Sawley. Western Technical Book Co., Seattle, 1922. Cloth, 6×9 in., 637 pp., portraits, illus., diagrams, $2.50.

The authors have attempted to furnish in compact form a summary of present-day knowledge of Diesel engines and their auxiliary machinery. The information given is presented in a form suited to the needs of those in charge of power plants and covers hath land and sea operation. Many commercial types of engines are described. One chapter is devoted to low compression or "semi-Diesel" engines.

Wechselstromerzeuger. By Franz Sallinger. Vereinigung Wissenschaftlicher Verleger. Walter de Gruyter & Co., Berlin and Leipzig, 1922. Boards, 4 × 6 in., 127 pp., diagrams, $0.25.

This booklet is intended, on the one hand, as an introduction to the subject of alternating-current generators, and on the other, to give engineers without special electrical training, who are connected with the construction or operation of these machines, an understanding of their essential characteristics. A special effort has therefore been made to explain these characteristics simply and to derive the most-used formulas and diagrams.

The windings are first explained, in connection with the generation and calculation of the electromotive force and the armature fields. After the vector diagrams have been derived, the experimental proving and the method of operation are treated. In conclusion data are given on the design, calculation and construction of alternators, with examples of actual machines which show how the formulas and diagrams are used.

Monel Metal Refinery and Rolling Mill

(*Continued from page 288*)

is standard throughout, except that the housings are very heavy, weighing 12 tons each. The arrangement permits an addition of four mills on the other end of the motor drive. As there is very little fluctuation in the power required on this type of mill no flywheel has been furnished, but a motor with large starting torque is provided.

The Merchant Mills

It will be noted from Fig. 4 that in the building with the 24-in. merchant mill there are other merchant mills used for furnishing the greatly varied product in tonnages that, from a rolling-mill point of view, are small. This equipment consists of the 24-in. mill referred to previously, which not only makes sheet bar but also the various sizes of billets required, a 20-in. mill, a 14-in. mill, a 10-in. mill, and a 14-in. Belgian rougher; and the wire mill, which consists of two separate mills in line with each other, 9 in. pitch diameter, one being a five-stand roughing mill and the other a four-stand finishing mill. These mills are equipped with gears and direct motor drive and all have a flywheel on the motor-shaft speed except the 9-in. roughing mill, which due to construction difficulties has the flywheel on the mill-shaft speed. The 9-in. finishing mill drives direct without any flywheel or gear reduction.

All mills are driven by fixed-speed motors except the 10-in. mill, requiring a variation from 120 r.p.m. to about 80 r.p.m. to accommodate the varied size of material, and the 9-in. mill, the intermediate mill between the 14-in. roughing and 9-in. finishing mill, which will have a speed variation of 257 r.p.m. to 384 r.p.m., arranged in 17 intermediate steps, to accommodate the delivery speeds of the 14-in. mill.

The whole of the south side of this building is arranged with lifting doors, so that it is easy to adapt the temperature of this end to either summer or winter conditions, the same type of doors being arranged at intervals on the furnace lean-to side.

The dimensions and arrangements of the buildings are shown in Fig. 2. All of the buildings, with the exception of the office, laboratory, oil and grease house, and the electric substation, are of steel construction, the average weight per square foot of projected area being specified as 25 lb., although in some cases this is exceeded.

Wide monitors one-half the building width were adopted for the main building roof; the sawtooth roof was used for the lean-tos. These features give excellent ventilation and lighting. To assure the best working conditions during the warmer months, the prevailing winds were studied and the buildings placed accordingly.

Steel lifting doors are continuous on the sides of the refinery, hammer-shop, merchant-mill, and sheet-mill buildings. For truck or railroad entrances to buildings, rolling steel doors are provided.

The roofing and sheeting is of corrugated black sheets; the windows have wooden sash, which take up any variation in the steelwork and eliminate warping of frames which otherwise might occur. There is in all about 160,000 sq. ft. of these windows used in the entire plant. The buildings were given two coats of a noncorrosive paint and a finishing coat of battleship gray color, which gives a pleasing appearance and aids the inside lighting.

The Oil Venturi Meter

(*Continued from page 298*)

in the kinetic head and the friction loss the coefficient was computed and expressed by the formula—

$$C = 1/\sqrt{1 + (1.67/R)}$$

These coefficients were plotted on Fig. 1. This calibration applies equally well to any other size of venturi tube of the same shape. It shows that the coefficient decreases indefinitely as the slope of the lower part of the line becomes the constant 0.5. The general agreement with the experimental data for the glass model, which was of slightly different shape, shows that the assumption made in this computation was justified for low values of the turbulence but is not sufficient as the critical turbulence is approached. This is indicated by the dropping of the experimental line below the computed, and is probably due to the increased internal losses in the fluid with the higher readjustments of velocity in the cone. At low values of the turbulence the venturi tube acts merely as a resistance and is exactly as useful for the measurement of rate of flow as a piece of straight pipe with similar piezometer connections would be.

The data presented in Fig. 2 for the Simplex Standard venturi tubes are accurate to within 0.5 per cent for all values in the turbulent-flow region. This calibration is for all meters of 2:1 ratio of diameters for all sizes of tubes from 1 in. to 48 in. in diameter.

As liquids are usually transported at a much lower velocity (s) than the velocity (c) of sound in the liquid, the effect of the compressibility is negligible. The effect upon the venturi or pipeline friction-loss coefficient due to the compressibility of the liquid flowing is found to be a function of s/c by the method of dimensions. When, as is frequently the case, gases and vapors are handled at the acoustic velocity (c) or higher, the coefficients must be considered as functions of s/c as well as of Qg/du. Experimental data compiled on a graph according to this method would provide a rational calibration of venturi, orifice, and pitot meters for use with steam and high-pressure gas or air. This same method might similarly be applied to show the performance of steam-turbine nozzles and jet pumps.

The thin-plate orifice and fixed pitot-tube meters may be calibrated by the use of this same method of dimensions. The fixed pitot tube is very sensitive to irregularities of flow in the viscous-flow region, especially with heated oils; however, experimental data are necessary to determine its value and range of usefulness.

The accuracy of measurements by the venturi or thin-plate orifice meters in the viscous-flow region may be considerably affected by heated oil or by valves and fittings near the venturi tube or orifice plate, especially when the fittings are located on the upstream side. The amount of error due to these causes can only be determined by experiment.

The thin-plate orifice meter is less affected by the viscosity than the venturi meter at the lowest turbulences that are ordinarily used in practice; consequently the orifice is more suitable for use with fairly viscous liquids than is the venturi meter.

Aluminum Bronze

(*Continued from page 284*)

shapes. This alloy can also be heat treated to some extent, in a manner similar to steel. By heating and quenching, its physical properties are improved to some extent, depending upon the exact composition of the material. It has been found that an addition of iron up to about 3 per cent in 8, 9, and 10 per cent aluminum bronzes improves their physical properties, workability, resistance to corrosion, etc.

The author's experience with a large variety of alloys from the manufacturing and the engineering viewpoint confirms his belief that the aluminum bronzes as a class are valuable additions to our list of engineering materials, and if he has pointed out some of the salient points, sufficient to arouse the interest of the engineer to investigate their merits further, the purpose of this paper will have been accomplished.

[In connection with the foregoing it is interesting to glance over Thomas D. West's paper on Casting Aluminum Bronze and Other Strong Metals in Vol. 8 (1887) of A.S.M.E. Transactions and one by Leonard Waldo on Aluminum Bronze Seamless Tubing in Vol. 18 (1897), both pioneer papers in presenting facts regarding this adaptable alloy.—Editor]

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 117-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AIRPLANE ENGINES

Navy Developments. Recent Developments in Aircraft Engines in the Navy, B. G. Leighton. Soc. Automotive Engrs.—Jl., vol. 12, no. 4, Apr. 1923, pp. 325–334, 12 figs. Former and present tests; progress made in development: reduction in weight; air-cooled vs. water-cooled engine; influence of power-plant weight on transportation costs.

AIRPLANE PROPELLERS

Reed One-Piece. Air Reactions to Objects Moving at Rates above the Velocity of Sound with Application to the Air Propeller, S. Albert Reed. Aerial Age, vol. 16, no. 4, Apr. 1923, pp. 182–185, 6 figs. Results of tests with Reed one-piece solid metal semi-flexible propeller.

AIRPLANES

Fokker. Fokker F5 Commercial Transport Airplane. Aviation, vol. 14, no. 14, Apr. 2, 1923, pp. 367–369, 4 figs. Convertible wing feature permits of speed and load variation for different services.

Wright All-Metal Pursuit. The Wright All-Metal Pursuit Airplane. Aviation, vol. 14, no. 14, Apr. 2, 1923, pp. 364–366, 2 figs. Duralumin cantilever monoplane characterized by excellent performance and military adaptability. Built by Dornier Co. in Switzerland, to fill American requirements.

AIRSHIPS

Goodyear Army TCl. Trials of New Goodyear Army Airship TCl. Aviation, vol. 14, no. 14, Apr. 2, 1923, p. 371, 1 fig. Novel features of non-rigid airship of 200,600 cu. ft. gas capacity; fitted with two 150-hp. Hispano-Suiza engines.

U. S. ZR3. Characteristics of U. S. Naval Airship ZR3. Aviation, vol. 14, no. 14, Apr. 2, 1923, p. 366, 1 fig. Capacity, 68,000 cu. m.; overall length, 206 m.; diam., 27.9 m.; max. breadth, 28 m.; max. height, 31 m.; power plant, five 400-hp.; max. speed, 79.3 mi. per hr.; cabin accommodations with sleeping quarters, 30 passengers.

AUTOMOBILE FUELS

Volatility. Motor-Transport Performance with Varied Fuel-Volatility, C. T. Coleman. Soc. Automotive Engrs.—Jl., vol. 12, no. 4, Apr. 1923, pp. 343–350, 9 figs. Data obtained regarding economic operation of motor vehicles with fuels of varied volatility, under service conditions.

AUTOMOBILES

Steering Systems. A Critical Study of Modern Automotive-Vehicle Steering-Systems, Herbert Chase Soc. Automotive Engrs.—Jl., vol. 12, no. 4, Apr. 1923, pp. 377–388 and (discussion) 388–397, 33 figs. Discussion of steering-gear faults.

BOILER PLANTS

Reconstruction. Rebuilding Boiler Plant Reduces Coal Consumption over One-Half. Power, vol. 57, no. 15, Apr. 10, 1923, pp. 546–552, 11 figs. Modern plant containing 6 water-tube boilers varying in size from 4000 to 5000 sq. ft. of heating surface, was built on site of old overload plant containing 15 boilers, without interruption to service.

BOILERS

A.S.M.E. Code. Comments on A.S.M.E. Revised Code for Testing Stationary Boilers, David Brownlie. Power, vol. 57, no. 15, Apr. 10, 1923. pp. 575–577, 1 fig. Criticism and suggestions for further revision, and necessity of international code.

CARBURETORS

Cadillac. Cadillac Makes Detail Changes in Carbureter Design. Automotive Industries, vol. 48, no. 13, Mar. 29, 1923, pp. 724–725, 1 fig. Double thermostat now used to govern relief of pressure on carbureter bowl; float valve redesigned.

CASE HARDENING

Method. New Method of Case Hardening, Frank Hodson. Forging & Heat Treating, vol. 9, no. 3, Mar. 1923, p. 160. Process introduced and patented by Assar Gronwall of Sweden consists of converting carbonic acid as formed to carbon monoxide.

CENTRAL STATIONS

Economic Operation. Effects 35 Per Cent Reduction in Generating Cost, D. E. Druen. Power, vol. 57, no. 13, Mar. 27, 1923, pp. 470–474, 5 figs. Changes in operating practices and building up of efficient personnel have resulted in average saving of $1000 per day in 50,000-kw. station of Kansas City Railways.

COST ACCOUNTING

Shop Office. Shop Office Accounting, Norman G. Meade. Indus. Management (N. Y.), vol. 65, no. 4, Apr. 1923, pp. 216–220, 14 figs. How three large corporations keep track of materials and stock.

COSTS

Graphic Analysis. Solving Cost and Economy Problems by Graphs, James A. Brown. Management Eng., vol. 4, no. 4, Apr. 1923, pp. 251–254, 3 figs. Management questions mathematically analyzed.

CUPOLAS

Charging System. Devise Flexible Charging System. Foundry, vol. 51, no. 7, Apr. 1, 1923, pp. 276–279, 7 figs. Describes layout adopted by Muncie Foundry & Machine Co., Ind., for handling materials from railway car to yard and from yard to cupola.

DIE CASTING

Methods. Die-Sinking Under a Drop-Hammer, Fred H. Colvin. Am. Mach., vol. 58, no. 12, Mar. 22, 1923, pp. 449–450, 4 figs. Method which saves time and money and helps to reduce cost of die castings; adaptation of silverware methods to another field.

ECONOMIZERS

Foster. New Foster Economizer. Power, vol. 57, no. 13, Mar. 27, 1923, pp. 485–486, 2 figs. Differs widely from those in general use, namely, in size of tubes used, placing them in horizontal position, use of cast-iron gilled rings on outside of steel tubes, and employment of water for cleaning tubes in place of scraper or steam blowers.

ELECTRIC WELDING, ARC

Cyc-Arc. A Development of the Cyc-Arc Welding Process. Engineer, vol. 135, no. 3508, Mar. 23, 1923, pp. 306–309, 9 figs. With present machine it is said to be possible not only to weld dissimilar metals and alloys together, but also identical metals.

Flash. Flash Welding, A. L. De Leeuw. Am. Mach., vol. 58, no. 12, Mar. 22, 1923, pp. 433–436, 5 figs. Advantages over slow butt welding; current consumption and pressures required; limitations; welding non-ferrous metals.

EMPLOYEES

Rating Scales. Are Rating Scales Justified? Eugene J. Benge. Indus. Management (N. Y.), vol. 65, no. 4, Apr. 1923, pp. 199–202, 4 figs. Results of investigation conducted by author on group of 51 men in attempt to analyze criticisms of rating-scale validity.

FORGE SHOPS

Germany. Famous German Forging and Machine Plant, Godfrey L. Garden. Iron Age, vol. 111, no. 13, Mar 29, 1923, pp. 886–887, 3 figs. Describes plant of Haniel & Lueg at Düsseldorf for manufacture of steam-hydraulic presses, blowing and gas engines, pumps and rolling mills.

FORGING

Hydraulic Presses. Observations on the Construction and Installation of Hydraulic Forging Presses, W. R. Ward. Forging & Heat Treating, vol. 9, no. 3, Mar. 1923, pp. 143–146. Outline of manufacture of forging presses; various operations and materials; foundations; installation and testing.

FOUNDRIES

Labor-Saving Machinery. Eliminating Skilled Foundry Labor, F. L. Prentiss. Iron Age, vol. 111, no. 14, Apr. 5, 1923, pp. 949–954, 10 figs. Special machines and conveyors result in producing 500 Chevrolet 4-cylinder castings per day with only 17 semi-skilled men and 28 flasks.

GAGES

Measuring Machine. The Wickman Gauge Measuring Machine. Engineer, vol. 135, no. 3506, Mar. 9, 1923, pp. 266–268, 8 figs. Machine for verification of workshop gages, to be carried out quickly and accurately.

GEARS

Burnishing. Burnishing the Teeth of Gears, Ellsworth Sheldon. Am. Mach., vol. 58, no. 9, Mar. 1, 1923, pp. 325–326, 1 fig. Corrects minor errors of contour, smooths and densifies tooth surface; analogous to cold hammering; forestalls effects of distortion in hardening

INDUSTRIAL MANAGEMENT

Methods and Principles. Management Methods and Principles of Frank B. Gilbreth, Inc., K. H. Condit. Am. Mach., vol. 58, nos. 1, 8 and 12, Jan. 4, Feb. 22 and Mar. 22, 1923, pp. 33–35, 293–295 and 443–447, 14 figs. Jan. 4: Principles of application of psychology to management. Feb. 22: Plant survey; use of stereoscopic camera; collecting blank forms, written orders and blueprints; disposition of useless material; process charts. Mar. 22: Principles upon which process chart is constructed and tools used; functions of organization chart; route models and their use.

Statistics of Industry. Signals for Business Conditions, Ernest F. DuBrul. Management Eng., vol. 4, no. 4, Apr. 1923, pp. 259–264, 5 figs. Statistical flags of industry show what to do and when to do it. Points out that study of industry's statistics of orders and prices enables one to lay out proper division of its cycle into various sectors.

LOCOMOTIVES

Exhaust-Steam Utilization. Condensing and Utilisation of Exhaust Steam in Locomotives. Engineer, vol. 135, nos. 3507 and 3508, Mar. 16 and 23, 1923, pp. 279–281 and 303–304, 7 figs. Consideration under two heads: (1) locomotives which condense comparatively small volume of exhaust, generally for purpose of feedwater heating; (2) locomotives which condense whole of exhaust in order to expand steam down to lowest pratical possible pressure below that of atmosphere.

MOLDING METHODS

Green-Sand Cores. Foundryman Develops New Practice, H. E. Diller. Foundry, vol. 51, no. 7, 1923, pp. 252–256, 9 figs. Describes method developed by Edwin Jory of handling green-sand cores in mold. Molding operations and devices in gray iron and steel shop.

OFFICE MANAGEMENT

Routine Charts. The Use of Routine Charts, G. Charter Harrison. Management Eng., vol. 4, no. 4, Apr. 1923, pp. 223–228, 2 figs. Improving and systematizing office procedure. Author shows by example how to analyze procedure by arranging various forms on chart.

RAILWAY SHOPS

Production Methods. Production Methods in a Railroad Shop, L. S. Love. Iron Age, vol. 111, no. 13, Mar. 29, 1923, pp. 881–885, 25 figs. Improvements in fixtures and tools effect savings in cost of work; parts machined in multiple fixtures; waste material reduced.

Scrap Reclamation. Railroad Salvage and Other Shop Work, S. Ashton Hand. Am. Mach., vol. 58, no. 13, Mar. 29, 1923, pp. 469–472, 14 figs. Reclamation of materials; substitute for turntable; milling teeth in spherical cutter. Practice at Emerson Shops of Atlantic Coast Line R. R., South Rocky Mount, N. C.

STEAM-ELECTRIC PLANTS

Oil-Burning. High Efficiency Oil-Burning Station, C. H. Delany. Elec. World, vol. 81, no. 13, Mar. 31, 1923, pp. 735–738, 7 figs. Installation of 12,500-kw. horizontal turbine, operating at 1800 r.p.m. directly connected to 3-phase, 60-cycle, 12,000-volt generator; boilers are provided with steam-atomizing oil burners; use of graphic meters.

STEEL MANUFACTURE

Electric-Furnace. Electrically Melted Ferro-Manganese Improves Converter and Open Hearth Practice, Frank Hodson. Blast Furnace & Steel Plant, vol. 11, no. 4, Apr. 1923, p. 243, 1 fig. Points out with proper metallurgical manipulation of ferro-manganese, it is desirable to use electric furnace with large open bath rather than restricted channel.

Figuring Alloys. Short Method for Figuring Alloys, J. M. Quinn. Blast Furnace & Steel Plant, vol. 11, no. 4, Apr. 1923, pp. 232–238. Comprehensive system of tables and proportions used by practical steel makers.

STOKERS

Low-Grade Fuel. Stokes Anthracite Culm and Gas-house Tar, Joseph Harrington. Power, vol. 57, no. 14, Apr. 3, 1923, pp. 523–524, 3 figs. Mixture of anthracite dust and liquid tar from gas producers is burned successfully on forced-draft chain-grate stokers with no modification of furnaces at plant of Consolidated Gas & Elec. Co., Long Branch, N. J.

Pluto. The Pluto Mechanical Stoker. Engineering, vol. 115, no. 2985, Mar. 16, 1923, pp. 325–328, 25 figs. Arrangement and details of stokers developed by N. V. Maatschappig Pluto, of Nijmegen, Holland, which are in successful use in large power station at Amsterdam and elsewhere on Continent.

WAGES

Merit System. A Merit System for Establishing Wage Rates, K. H. Crumbine. Am. Mach., vol. 58, no. 8, Feb. 22, 1923, pp. 301–302. Describes universal plan based only on merit, claimed to be just to all employees.

WATER POWER

New York. Availability and Economics of Hydro-Electric Power for New York. Power, vol. 57, no. 14, Apr. 3, 1923, pp. 508–514. Abstracts of following papers: Coördinated Statement of Problem, F. W. Scheidenhelm; Available Water Power and Cost of Delivery, W. S. Murray; Requirements of Service for Hydro-Electric Power, George A. Orrok; Factors Affecting Quality of Hydro-Electric Service, F. A. Allner; Reliability of Long-Distance Transmission, Lorin E. Imlay. Discussion.

New York State's Water Power, Guy E. Tripp. Elec. World, vol. 81, no. 12, Mar. 24, 1923, pp. 685–686, 1 fig. Reasons why it must not be isolated or developed individually; advantages of interstate transmission and superpower systems which embrace steam-driven as well as water-power stations.

WOODWORKING MACHINES

Planing and Molding. High-Speed Wood Planing and Moulding Machines. Engineering, vol. 115, no. 2986, Mar. 23, 1923, pp. 365–366, 6 figs. partly on supp. plate. One machine is capable of producing tongued-and-grooved flooring and matchboarding at speed of 250 ft. per min., and other of shaping boards to various moldings at 80 ft. per min.

Contributors and Contributions

U. S. Navy Crane Ship No. 1

The vital part that high-grade engineering plays in the defense of the country is reëmphasized by the article in this issue describing the largest floating crane in the world—and the only sea-going one—into which the old battleship *Kearsarge* has recently been converted. The difficult nature of the engineering problems involved in rebuilding the hull and in constructing the crane will be readily apparent, and their solution reflects great credit upon American engineers, in particular those of the U. S. Navy and of the Wellman-Seaver-Morgan Company who were charged with the responsibility for the achievement.

Orifice Coefficients

Jacob M. Spitzglass, vice-president and consulting engineer of the Republic Flow Meters Company, Chicago, Ill., presents a paper discussing the results of extended experimental work conducted at the research laboratory of his company on the use of orifice plates for measuring the flow of fluids in pipes.

Mr. Spitzglass was born in Russia in 1869. After unsuccessful attempts to obtain a technical education there and in Western Europe he came to America and in 1909 was graduated from the Armour Institute of Technology with the degree of B.S. in mechanical engineering. Four years later he received his M. E.

His first position after graduation was with the Northwestern Gas Light and Coke Company. Then for a year he tested steam engines for the Armour Glue Works and experimented in measuring the flow of steam to the various lines of the concern. He later was engaged to do experimental work for the People's Gas Light and Coke Company and won recognition for his work relating to the flow of fluids through pipes. He improved and developed the Gebhardt steam meter. This meter is now being manufactured by the Republic Flow Meters Company. Mr. Spitzglass has received the Longstreth Medal for his work in developing and correcting the defects of the steam meter.

Recent Developments in Balancing Machines

With the increased speed and capacity of motors the necessity for satisfactory balancing equipment has been keenly felt, especially for the balancing of small high-speed motors for domestic use. A machine which makes it possible to manufacture quietly running motors is described by Carl R. Söderberg in this issue.

Mr. Söderberg is a native of Sweden, where he was born in February, 1895. He was graduated from the Technical Preparatory School at Härnösand in 1914, served two years as an apprentice in the shipbuilding industry, and then entered Chalmer's Institute of Technology, Gothenburg, from which he was graduated in 1919. With a scholarship from the American-Scandinavian Foundation for study of the shipbuilding industry in America, he came to this country and pursued post-graduate work at the Massachusetts Institute of Technology and the University of Michigan until June, 1920. Since then he has been employed successively by the New York Shipbuilding Corporation at Camden, and the Westinghouse Electric and Manufacturing Company at East Pittsburgh, where he has specialized on vibration problems.

Steel-Car Construction

The first box car having its entire frame built of steel was originated by the Canadian Pacific Railway nearly fifteen years ago. In this issue H. R. Naylor, assistant works manager of the Angus Shops of the Canadian Pacific, at Montreal, Canada, describes the shop specially erected to fabricate the steelwork for these cars, giving particulars regarding its layout, crane facilities, machine equipment, etc. He presents the various machining operations and the jig method of car assembly now employed and the method used in the final erection and finishing of the cars.

Mr. Naylor was born in England in 1885 and served his apprenticeship in railway engineering in that country. He entered the service of the Canadian Pacific Railway Company in 1907 as patternmaker and has served that company in various capacities since that time, assuming his present position about three years ago.

Industrial Safety Codes

The brief paper on the development of industrial safety codes appearing in this issue was presented by M. G. Lloyd, chief of the Safety Section of the U. S. Bureau of Standards, and vice-president of the American Society of Safety Engineers, at a joint session of that society and the A.S.M.E. Safety Codes Committee at the A.S.M.E. Annual Meeting in December, 1922.

Mr. Lloyd is a graduate of the University of Pennsylvania, which has conferred upon him the degrees of Bachelor of Science, Doctor of Philosophy, and Electrical Engineer. After serving as instructor of physics at this university he became connected with the Bureau of Standards and was engaged for several years in electric and magnetic testing and research. From 1910 to 1917 he was technical editor of the *Electrical Review and Western Electrician*. He returned to the Bureau in 1917.

Code for Care of Power Boilers

The Proposed Code for the Care of Power Boilers, formulated by a Sub-Committee of the Boiler Code Committee and containing rules for the care of steam boilers and other pressure vessels in service, is now presented for public discussion. A hearing on this report is on the program of the A.S.M.E. Spring Meeting at Montreal. When revisions are completed this report will form a part of the A.S.M.E. Code.

A.S.M.E. Spring Meeting

The Montreal Meeting of The American Society of Mechanical Engineers is in progress as this issue of MECHANICAL ENGINEERING is being mailed. An account of the technical sessions will appear in the July issue.

The A.S.M.E. News for June 7 will tell of the excursions and of the social events.

U. S. Navy Crane Ship No. 1: An Achievement

Details of the Conversion of the Battleship "Kearsarge" into a Titanic Seagoing Crane for Handling Loads of 250 Tons—The Engineering Problems Encountered in Dealing with Stresses of Unprecedented Magnitude and How They Were Solved

When in an engineering structure the size exceeds certain well-tested limits, the difficulties of design and construction multiply at a very rapid rate. There have been many instances of this character. Steel bridges have been built for many years, but when it came to an enormous structure like the Quebec Bridge it was found that our knowledge of stresses of the magnitude involved was insufficient. The same type of difficulty was encountered and overcome in converting the battleship *Kearsarge* into a seagoing crane ship capable of handling and transporting two modern three-gun turrets complete with their guns.

"U. S. Navy Crane Ship No. 1" as it is known officially but called the "*Kearsarge* Crane," is the only large seagoing crane ever constructed and the largest floating crane in existence. Big floating cranes have been built in the past, but only for harbor work and not for navigation in rough water or in heavy seas. The *Kearsarge* bears a 250-ton revolving crane of the luffing-jib type so designed that the jib may be lowered into a cradle and secured firmly for sea service. Built to handle loads of 250 tons under normal conditions, she has actually lifted 312 tons. Such loads on a floating structure impose stresses of an unprecedented character, both on the crane and the foundation, which means that all parts have to be designed with unusual care, generous factors of safety, and with particular regard to the selection of materials in order that there shall be no weakening of any part due to overstressing. To meet these conditions interesting expedients and methods of design were resorted to, both by the Navy Department, in whose hands was the reconditioning of the hull, and by the Wellman-Seaver-Morgan Co., of Cleveland, Ohio, the builders of the crane itself. Among these may be mentioned a new method of combined welding and riveting ship plates, the novel track arrangement for the crane, the rotating mechanism—provided with wheels of a new type, the methods of cradling the crane at sea, etc.

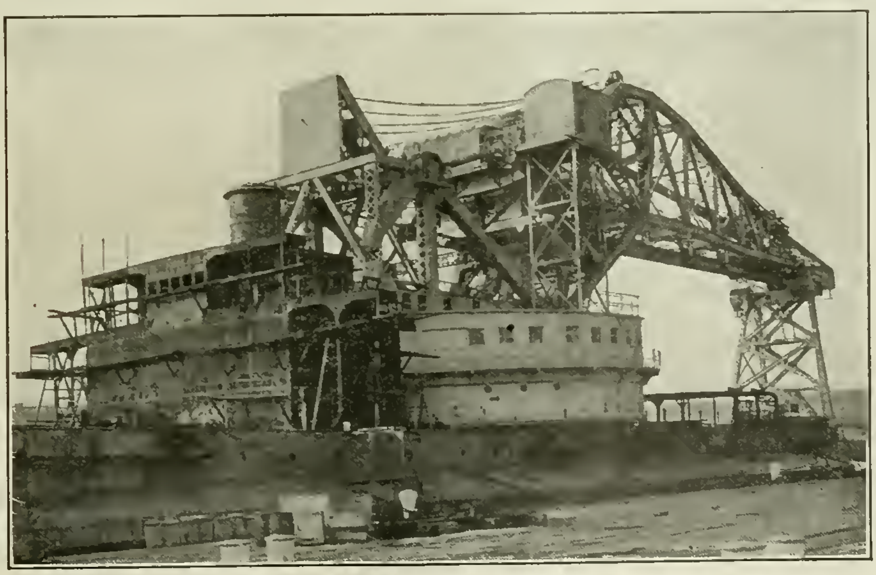

Fig. 1 When Ready for Sea, the Jib Rests in a Cradle at the Stern of the Crane Ship

Special Usefulness of the Large Seagoing Crane

Cranes of this type are expected to prove useful in many ways. For fitting-out purposes, handling guns, turrets, boilers, etc., they are beyond comparison with any other type as they can be easily moved to any point where their service is required. This is a very decided advantage as it permits the use of a crane not only at different places in the same base but also extends the scope of operations to yards which would otherwise be unable to command such facilities. The utility of a seagoing crane, however, is not limited to work around navy yards and piers. Its value in salvage operations cannot be overestimated. With the extreme facility of movement possessed by the *Kearsarge* crane, it is quite possible that a sunken submarine might be salvaged if the work were undertaken before the conditions became too unfavorable. In fact, a sunken tug was salvaged during the war by a 150-ton pontoon crane.

The name "Kearsarge"—that of a mountain in Merrimac County, New Hampshire—is one with a long and honorable record in the annals of the United States Navy. The first vessel to bear it was a gunboat hastily built in the early days of the Civil War. Immediately upon completion it was dispatched to European waters to protect United States shipping from the depredations of Confederate privateers. It achieved fame by sinking the *Alabama*, one of the South's speediest and most successful ships. A quaint insight into the knightly attitude of the two American navies is given in the report of Capt. John A. Winslow, of the *Kearsarge*, dated June 19, 1864, from Cherbourg, France, to Secretary of the Navy Gideon Welles in reference to the battle with the *Alabama*. "I have the honor to inform the Department," wrote Captain Winslow, "that the day subsequent to the arrival of the *Kearsarge* off this port I received a note from Captain Semmes [of the *Alabama*] begging that the *Kearsarge* would not depart, as he intended to fight her and would delay her but a day or two." There was no such exchange of notes with the enemy in the recent war. The old *Kearsarge* was wrecked on February 2, 1894, on Roncador Reef in Central American waters, and the construction of a new one was authorized by act of Congress of March 2, 1895. This vessel was built at the Newport News Shipbuilding and Drydock Co. yards, Newport News, Va., and was launched on March 24, 1898.

Old or new, the *Kearsarge* embodied novel features. The original vessel, together with her sister ship the *Kentucky*, was selected for an experiment in the installation of superposed turrets, an 8-in. turret being rigged on top of a 13-in. The later *Kearsarge* and the *Kentucky* (now to be scrapped as a result of the Washington Conference) were the first to be completely equipped with electric auxiliaries such as turret-operating machinery, deck winches, ventilating fans, etc.

Beginning the Work of Conversion

After the World War the need of a mobile crane for the use of

the Navy became apparent, and the conversion of the *Kearsarge* into a crane ship was decided upon largely because the hull of the vessel was in an excellent state of preservation and suitable for the purpose in view.

At the beginning of the conversion the guns, turrets, much of the armor, the upper works of the vessel, and a number of the boilers were removed. Little was done to the hull, but it was found necessary to widen the beam by the construction of large bulges on the outside of the hull for the purpose of increasing its transverse stability. These bulges are divided into a number of watertight compartments.

Reinforcing the Hull

In order to carry the immense load and stresses imposed by the presence of the crane and possible loads of the upper decks, the whole ship structure had to be materially reinforced. Just to show the magnitude of these loads, it may be stated that a preliminary calculation showed that the presence of the crane would impose a tangential load of the order of 460,000 lb. acting with a lever arm of 42 ft. 8 in. from the top of the roller path of the crane. So great were these loads that for a while it appeared to be doubtful whether the hull of the ship would be strong enough to withstand their terrible tearing action. The entire structure was accordingly reinforced by an ingenious and liberal use of columns, gusset plates, etc.

In this work some interesting expedients were adopted. Thus, the entire main deck consisting of triple plates was, in addition to the usual riveting, electrically butt-welded in such a manner that the top plate is now practically a single piece from end to end.

In the matter of carrying the main deck loads by the vertical partitions, it was found difficult to select a design of angle which would have sufficient metal left after the necessary rivets had been driven in. It was one of the cases familiar in bridge construction of either enough rivets and not enough metal left in the plate, or enough plate and not enough rivets. The problem was solved after preliminary tests in the ingenious way shown in Fig. 3. Here the vertical wall does not quite reach to the horizontal plate, and the angle in addition to being riveted is welded to the vertical plate all along its lower edge. The result is that much of the shear stress is taken off the rivets and transferred to the welded edge, which under these conditions is capable of carrying safely quite a considerable load.

This is but one instance of the care in design exercised by the engineers of the Navy Department in the reconstruction of the hull. Another is that all doors in the inner walls of the hull are made oval shaped and reinforced by heavy plate frames.

The duty of the Navy Department in reconstructing the hull for the reception of the crane ended with the preparation of the main deck carrying frame for the crane. This latter represented substantially a ring roughly 60 ft. in diameter the upper surface of which had to be level within very close tolerances. This was made possible by increasing the rigidity of the hull structure by the means referred to above. A rather interesting water level which was rigged up permitted the testing of any number of points on the circular track simultaneously.

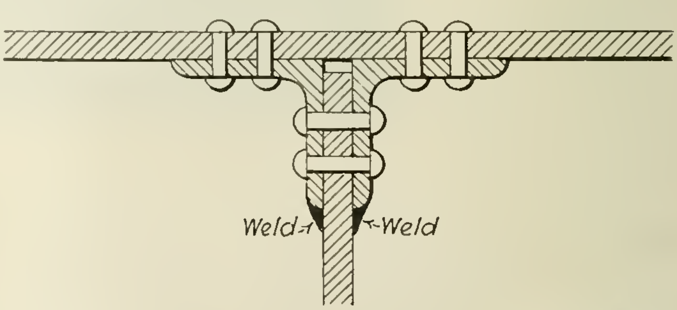

Fig. 3 Method Used in Attaching Vertical Wall to Deck Plate

Nature of the Engineering Problems Involved

The engineering problems encountered by the Navy were, however, only a small part of those involved in the construction of the crane proper, this latter having been carried out under contract by the Wellman-Seaver-Morgan Company, of Cleveland, Ohio. Stationary cranes had been built in sizes much larger than the *Kearsarge* unit and floating cranes of a type much smaller, but never before had it been attempted to complete a floating crane of this size. Such construction involved difficulties of a nature never before encountered. In the first place, the designer had to deal with stresses of an unprecedented magnitude and little-known character.

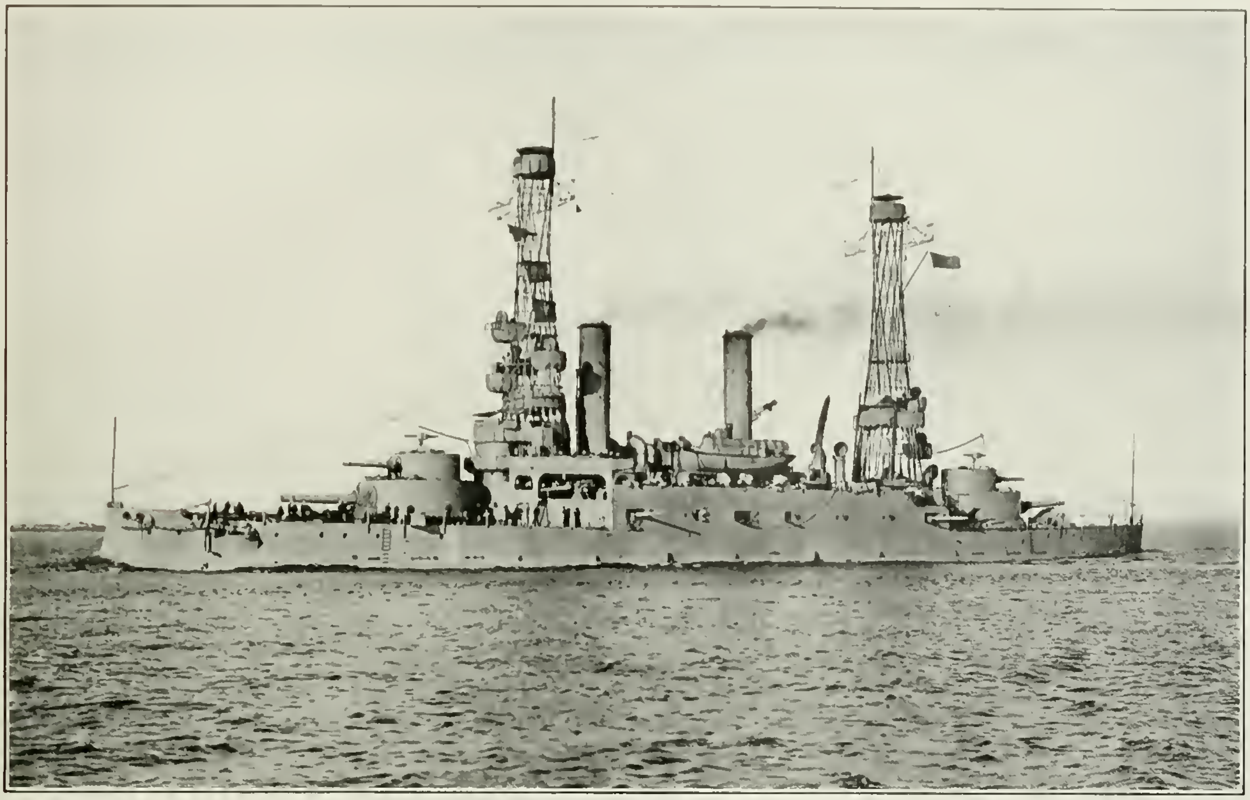

Fig. 4

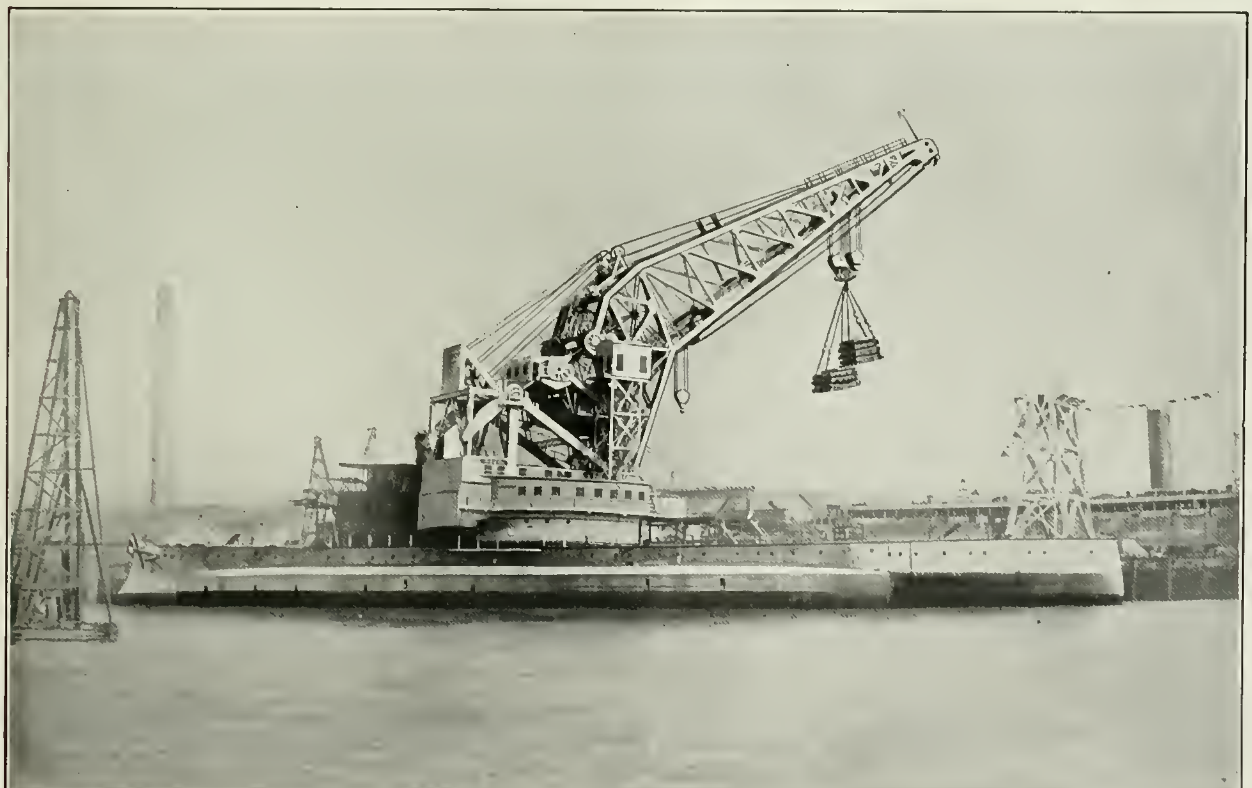

Fig. 5

In Its Naval Career the "Kearsarge" Has Played Two Rôles

Fig. 4 shows the *Kearsarge* as a battleship in active service. Fig. 5: Rebuilt into U. S. Navy Crane Ship No. 1 mounting a 250-ton revolving crane the *Kearsarge* is handling a full load under test. Note the cradle at the stern of the ship in which the jib is held while at sea, and the bulge to increase the ship's beam. The auxiliary hoist appears at the lower end of its trolley on the jib.

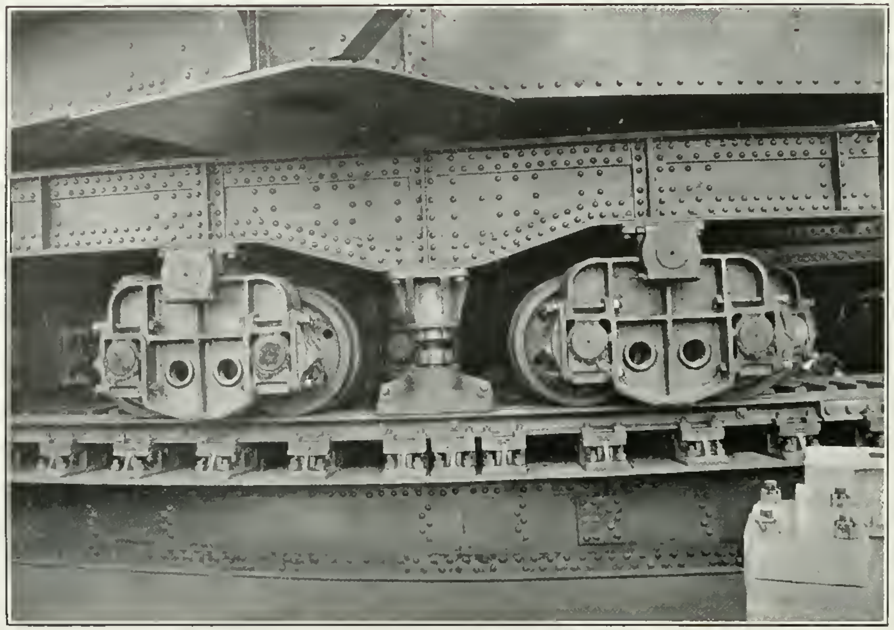

Fig. 6

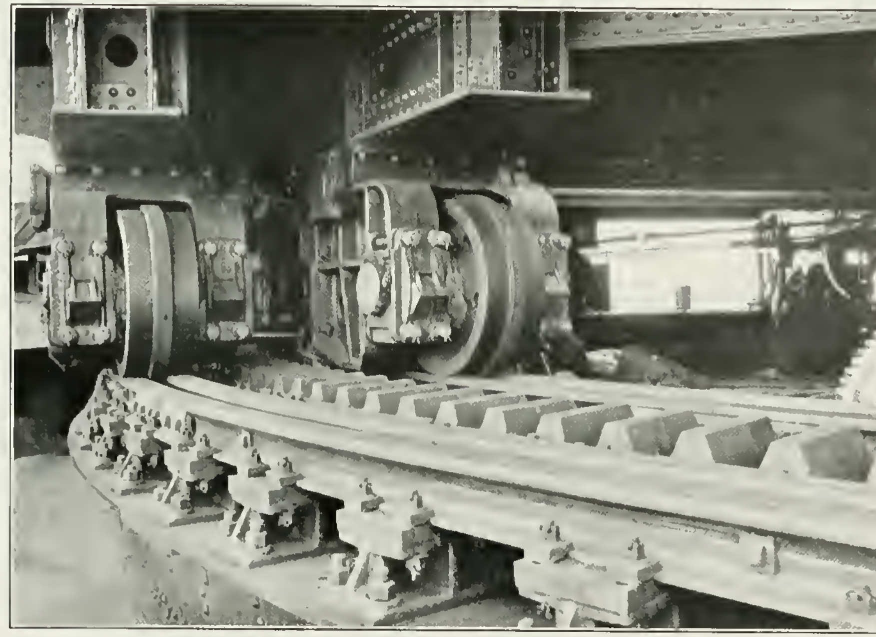

Fig. 7

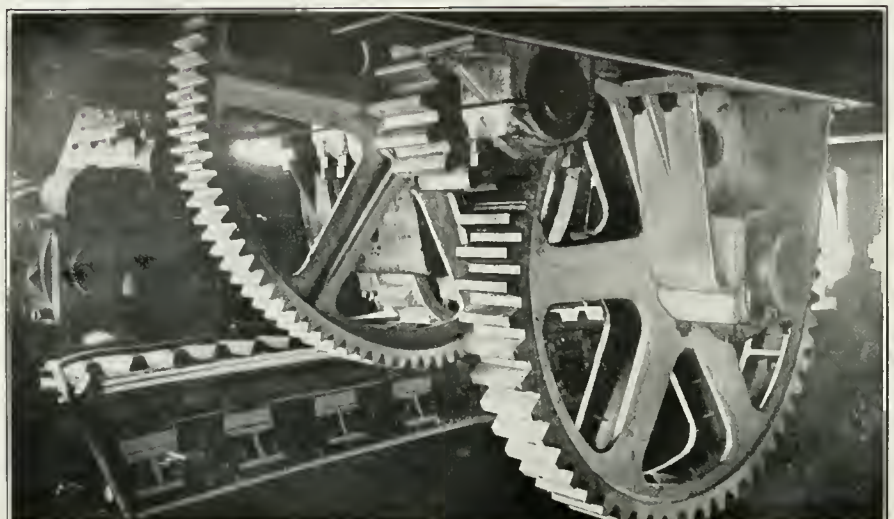

Fig. 8

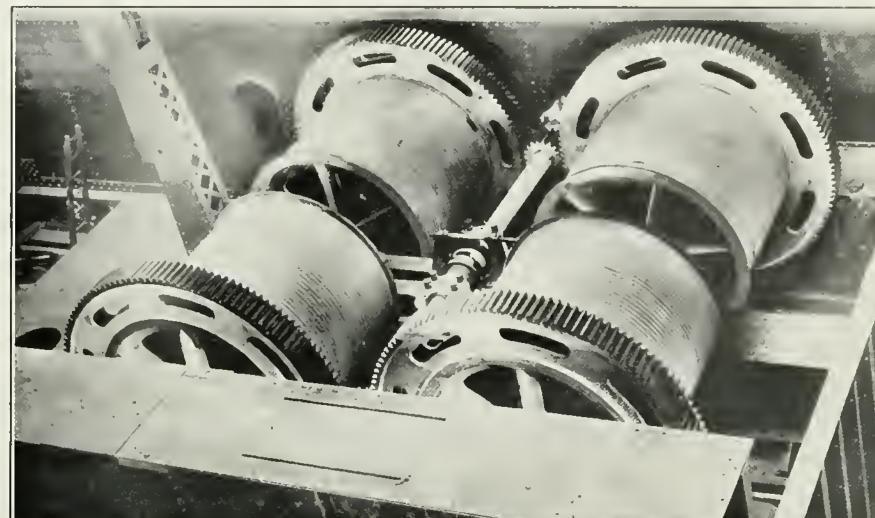

Fig. 9

Details of Design Are Rugged

Figs. 6 and 7 show the interesting method of supporting the crane superstructure. Fig. 6 makes especially clear the equalizing action of the supports which enables the crane superstructure to conform to any deflection in the track. The important lifting jack for use when jib is cradled is also shown between the two trucks. In Fig. 7 the conical rollers are displayed as is the rack through which the rotating mechanism operates. The gear train and part of the rotating mechanism are shown in Fig. 8 while in Fig. 9 the large hoisting drums may be seen.

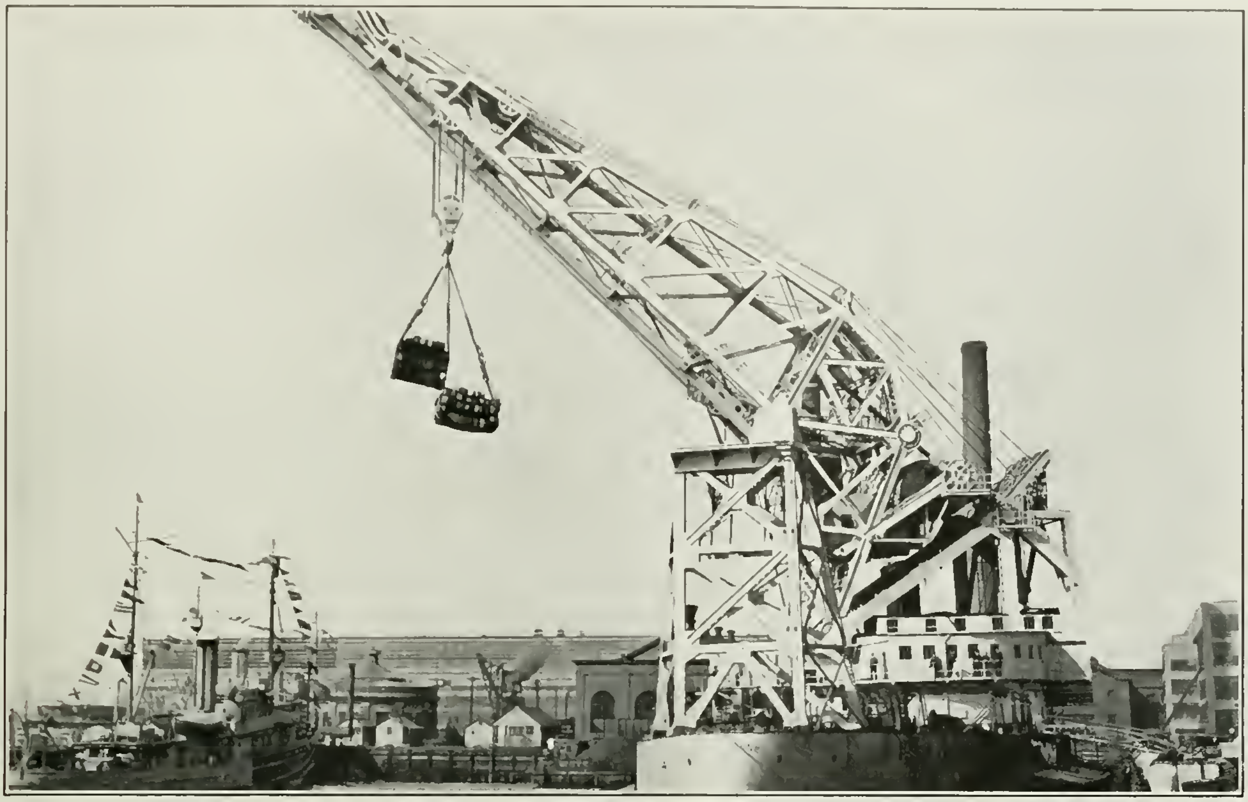

Fig. 10

Fig. 11

The Crane Ship Operates Under Widely Varying Conditions

The crane ship can handle 250 tons at 101 ft. radius from the center of rotation. Fig. 10 shows this with the ship on even keel. Using the auxiliary hoist the crane can handle 50 tons at 173 ft. radius with the hoist at the extreme end of the trolley. Fig. 11 shows this and also the two main hoists of 125 tons each, which can be used together to handle 250 tons. Fig. 10 shows the jib nearly at its highest position, while in Fig. 11 the jib is nearly horizontal.

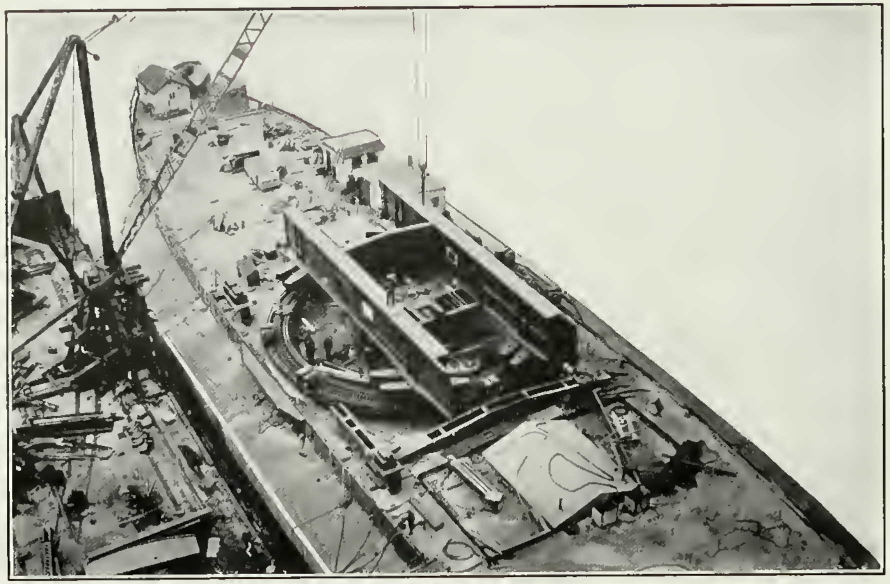

Fig. 12

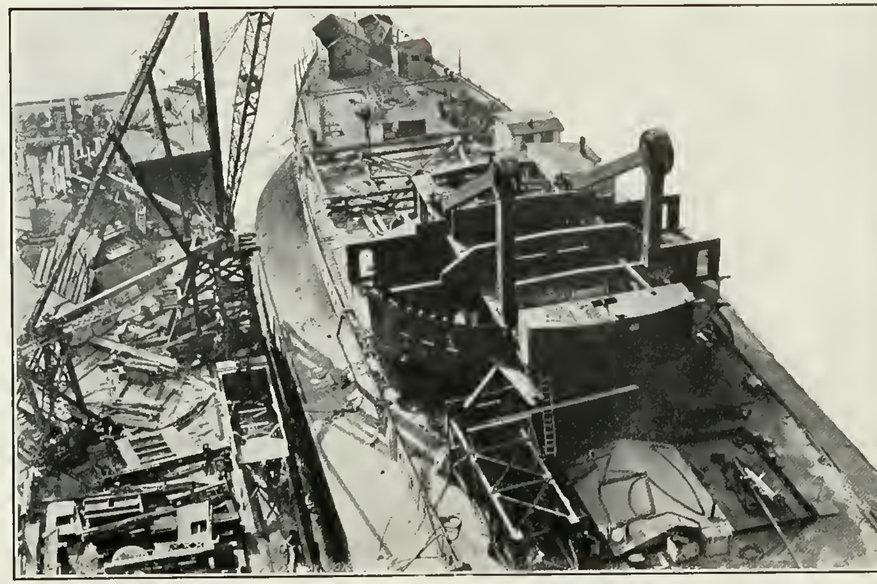

Fig. 13

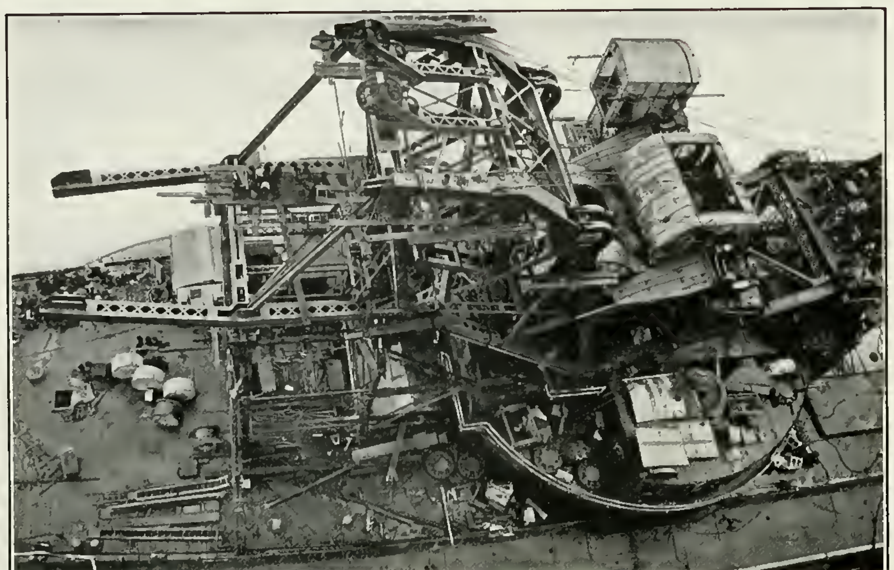

Fig. 14

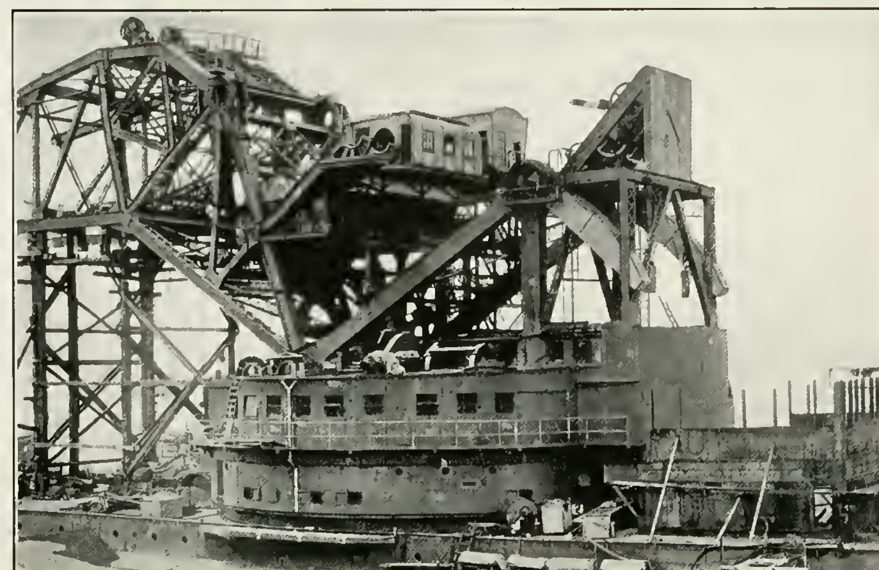

Fig. 15

Erection Pictures Show Fundamentals of Design

Fig. 12 (January 3, 1922) The foundation frame of the superstructure is built of two girders, each resting on four equalizing girders, a pair under each end. Details of the latter are shown in Figs. 6 and 7. Fig. 12 also shows two trucks placed on the outer circular track on each side of the main frame. These four trucks are for support of the outrigger girders shown at right angles to the foundation girders in Fig. 13 (January 23, 1922). Note the widening effect of the hull bulges in these two figures. Figs 14 (March 31) and 15 (May 31) show the construction of the jib well under way. The hoisting machinery is being used to bring the jib members into position.

The Navy specifications demanded that the crane should be capable of withstanding the roll of a ship of the order of 25 deg. complete in 3 sec., which imposed on every part of the structure an enormous strain. Furthermore, this was to be a seagoing unit, which meant that it might have to encounter rough weather. Every part, therefore, had to be cradled in such a manner that when the vessel was traveling in the open sea there would be no pounding—not an easy proposition with a structure in excess of 40 ft. high above the deck level and weighing millions of pounds. Finally, the crane had to operate on a circular track of 60 ft. mean diameter in a floating structure, that is, one inevitably subject to distortions, and yet remain under perfect control. The whole structure was so large that the manufacture of parts which otherwise would have been merely a matter of routine became a serious engineering problem in itself.

To give but one instance, luffing screws had to be made in sizes 15 in. in diameter and 28 ft. long, while the nuts for them were 5 ft. long, 26 in. in diameter, and about 5000 lb. each in weight. It was a man-sized job to handle parts of this character, and it is a high testimonial to American engineering that every detail of the crane was designed and manufactured in the United States—not because there were any restrictions imposed as to the procurement of parts abroad, but because facilities were available here to do everything to the complete satisfaction of the parties involved, and with excellent success as the tests have shown.

Design and Construction of the Crane

The *Kearsarge* crane is of the luffing-jib type and is so designed that the jib may be lowered to rest in a cradle at the stern of the ship. (Fig. 1.) In view of the great weight of the crane and the fact that it was to be installed on a seagoing vessel, it was very important to arrange it so that it would be in a perfectly steady position while the ship was under way. To provide for this the crane when not in use is supported at three points. In the first place, it is securely held in the cradle just referred to, which is a substantially built tower. Next, it is held by the center pin about which it rotates; and finally in the rear, back of the rotating track and under the counterweight, there is a heavy pin held in a rigidly constructed frame. The whole structure is such that the jib cannot move notwithstanding the rolling of the ship. The crane is provided with four hooks, two of 125 tons lifting capacity each, one 250-ton compensator-type hook, and a light 40-ton hook on a special trolley for emergency work. Special cradles are provided for these hooks so that when the ship is under way there are no swinging parts.

The operating equipment of the crane consists of two main hoists of 125 gross tons capacity each, operated by separate motors and so arranged that they may be coupled together when handling the maximum load of 250 tons. For this purpose an equalizer is provided which carries a 250-ton hook and is connected by heavy pins to the hooks of the 125-ton blocks. (Fig. 16.) In actual tests 312 tons were lifted, equivalent, roughly, to the weight of 4500 persons. These blocks are suspended by ropes passing over sheaves located at the fixed point of the jib, the reach being varied by luffing the jib.

The Foundation

The crane foundation is formed by a circular box girder having concentric web plates spaced 4 ft. apart with a mean diameter of 60 ft. This girder is securely built into the hull of the ship and a top flange projects about 2 ft. above the deck and is provided with a heavy cover plate forming a plane surface upon which the crane runway is mounted. This runway consists of four rings of 150-lb. rails spaced in pairs over the webs of the foundation girder. The rails are supported on cast-steel radial chairs secured to the girder and provided with wedges so that the elevation of the rails may be properly adjusted. In order to permit the rotation of the crane about its center pin without undue friction, the rails are so elevated that the centers of their heads are located on the elements of two cones having their apex at the center of rotation.

The usual method of operating cranes of this type is by rollers. In this case, however, the diameter of the runway was so large and the loads carried so great that it would have been impossible to retain the rigidity of the track necessary for roller operation. Because of this, a novel construction was evolved, the crane rotating on double-tread cast-steel wheels approximately 30 in. in diameter with treads finished to diameters corresponding to the rolling cones, one side of the cone being, of course, somewhat higher than the other, with a corresponding variation in the elevation of the treads on the track. This may be seen from Figs. 6 and 7 which show the wheels. The wheels are arranged in pairs with each pair carried in a cast-steel equalizing-truck frame forming a truck unit. Between the trucks are provided powerful jacks capable of supporting the weight of the entire structure. When the crane is in operation the jacks are, of course, lifted off the track. When the ship is under way at sea and the crane is cradled the jacks support the weight of the structure and thus

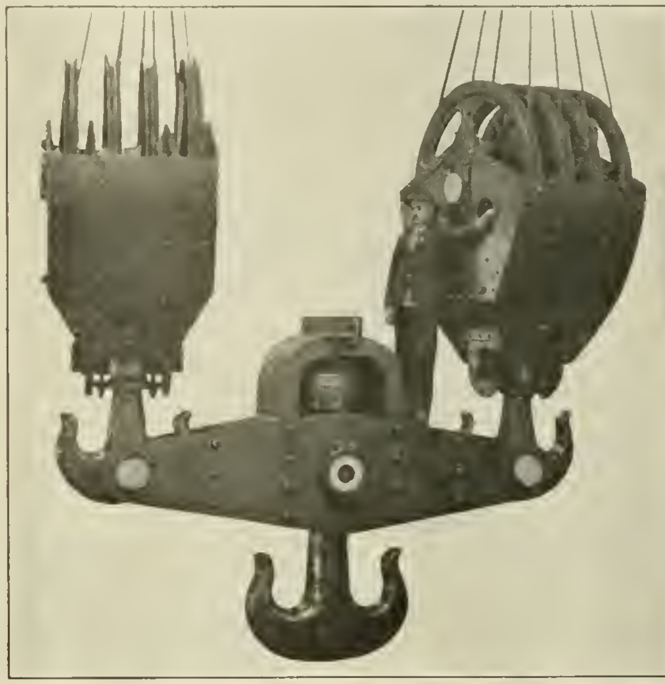

Fig. 16 With an Equalizer, the Main Hoists Handle 250 Tons

relieve the wheels from possible pounding in a rough sea, which result in the production of flats.

The main structure of the crane is built upon two box girders which are 10 ft. deep and 75 ft. long, and have webs spaced 30 in. apart. These girders are supported by the main carrying trucks, four fully equalized units being located under each end of the girders. Intermediate between the main trucks are spring-mounted truck units which are adjusted to take a part of the maximum truck load. Outrigger girders normal to the sides of the main girders are supported over four truck units for the purpose of securing side stability. The center-pin girder is built between the main girders and extends to within 2 ft. of the deck. The center pin is secured in this girder and turns in a bearing mounted in a companion girder built into the ship's hull. The center pin is hollow and the electric conductors supplying power for crane operation pass up through it to rings on the contact column above, from which the current is taken off by brushes.

The counterweight compartment is built between the main girders at the back and contains about 1,000,000 lb. of armor plate secured in place by concrete. This counterweight is proportioned so that the reverse movement with the light jib in its high position is approximately the same as the forward movement with maximum load at full reach. Back stays are built at the rear of the main girders for the purpose of supporting the back luffing nuts. These stays also serve as a support for the hoist-rope sheaves.

All the machinery for hoisting and rotating is carried by the main and outrigger girders and is completely enclosed by a circular machinery house which extends below the top of the crane foundation to form a skirt so constructed as to prevent the seas from washing over the trucks or foundation.

The Luffing Mechanism and Its Operation

From its lowest position when resting in the cradle to its highest working position the jib revolves about its hinge pins through an angle of nearly 60 deg. This movement is accomplished by large luffing screws operating through the upper and rear nuts previously mentioned. The screws are made of chrome-nickel steel and are 15 in. in diameter and 28 ft. long. Two of these screws are coupled together at the center, one having right-hand and the other left-hand threads so that their rotation tends to increase or diminish the distance between the nuts according to the direction in which they are turned. The threads of the screw are of the buttress type, 4 in. pitch, and the maximum load carried on each screw is 500 tons, which occurs with the load at maximum reach.

The design of these luffing screws was anything but an easy problem. The screws are exposed to such enormous stresses that very great strength had to be put into them and at the same time their size had to be held down as much as possible in order to reduce the weight of the screw and the size of the luffing nuts, of which more will be said later. Furthermore, the forging of a piece 28 ft. long was a difficult proposition in itself, and any increase in diameter would have materially increased the difficulty of forging. After certain tests chrome-nickel steel was selected and its use made it possible to keep the diameter of the screw down to 15 in.

Special manganese bronze is used for the luffing nuts which are about 5 ft. long, 26 in. in diameter, and weigh about 5000 lb. each. Each nut is enclosed in a cast-steel housing with trunnions turning in bearings attached to the boom and the back stay, and the design is such that when the jib is at rest on the cradle the lower nut trunnion may be slacked off, relieving the load on the screws and avoiding the possibility of excessive tension which might be produced by the deflection of the ship in a seaway. The selection of the material for these nuts was not easy, as, for obvious reasons, steel could not be used. We are informed that the bronze finally chosen has the following physical characteristics:

Ultimate strength	100,000 lb.
Yield point	60,000 lb.
Elongation	24 per cent
Brinell hardness	165

Operation of the luffing screws is controlled by a cross-shaft geared to the screw couplings by bevel gears. This shaft is turned by a spur-gear reduction to the intermediate shaft, which in turn is connected to the motor by herringbone gears. This mechanism is mounted on a machinery floor carried by a luffing strut which is pivoted to the jib midway between the jib hinge and upper luffing nut. (Fig. 17.) This strut also pivots on a large housing which encloses the screw coupling and the bevel gears midway between the upper and lower nuts.

The strut thus located forms a bisector of two legs of the triangle formed by lines joining the luffing nuts and the jib hinge, and it always maintains the same angle with the horizontal in all positions of the jib; this condition lends itself to the arrangement of the luffing mechanism as the floor of this machinery house is thus maintained horizontal at all times. This fact is also true of the auxiliary trolley mechanism, which is supported by the strut. However, on account of the fact that the relative positions of the strut and the jib are constantly varying, it is necessary to locate the trolley drum on the center of the lower pivot of the strut, which is of course a point common to both. In this location no change in length of the trolley ropes results as the jib traverses its entire range.

The maintenance of the floor of the machinery house at all times in a horizontal position as referred to above is secured in the following manner: The luffing strut at its upper end is provided with a bearing engaging trunnions on the bevel-gear housing in which the coupling for the upper and lower screws is located. This coupling is used for connecting the upper and lower screws, right and left hand, respectively, and the nuts through which the screws turn are located at equal distances on either side of the housing trunnions.

The screws are revolved to luff the jib and it is evident that any revolution of the screws through the nuts increases or diminishes the center distance. At the same time the coupling retains its position midway between the nuts. The lower end of the luffing strut is secured by pins to the jib at a point midway between the forward and upper luffing nut and the jib hinge. On account of the fact that the two points of support of the strut are always midway between the points which vary in the course of the luffing function, the strut always remains parallel to the third side of the triangle which is formed by these points, the third side in this case being the backstay. It is therefore evident that any structure forming a part of the strut or built into the strut will maintain a constant angle with the backstay or any portion of the stationary part, and thus will be maintained in a permanent angular relation to the deck.

All the functions of the crane are controlled by one operator, the various levers for this purpose being located in an elevated cab at one side of the jib.

U. S. Crane Ship No. 1—General Data

	Battleship	Crane Ship
Length	368 ft.	368 ft.
Beam	72 ft. $2^1/_2$ in.	92 ft.
Draft	23 ft. 6 in.	19 ft. 7 in.
Displacement	11,520 tons	10,350 tons
Speed	16 knots	11 knots
No. of vertical triple-expansion engines	2	1

Speeds of Hoists

Main hoist loaded	6 ft. per min.
Main hoist empty	16 ft. per min.
Auxiliary hoist loaded	15 ft. per min.
Auxiliary hoist empty	30 ft. per min.
Auxiliary trolley	50 ft. per min.
Luffing from high to low position	25 min.
Rotating one revolution	9 min.

Ranges of Operation

Main Hoists:

Radius: Between 72 ft. and 101 ft. from center of rotation.

Vertical Range: From 103 ft above to 40 ft. below rails on which crane revolves.

Auxiliary Hoist:

At 114 ft. radius the auxiliary hook has a vertical range from 135 ft. above the rails to 40 ft. below. With the jib in its highest position the upper vertical range of the auxiliary hoist is increased to 147 ft. at 91 ft. radius, and the maximum reach with the jibs in a horizontal position is approximately 173 ft. from the center of rotation. The maximum range of the auxiliary hoist is 175 ft.

Prevention of Accidents Due to Rolling of Ship

One of the important problems in the design of this crane was to so proportion its members that they would not only sustain the working load but would withstand the strain and impacts resulting from the rolling and pitching of the ship when at sea, and elaborate means are provided to protect the machine from any damage arising from this cause.

Heavy jackscrews are provided between the truck units. These jacks may be set to relieve the wheel loads and prevent pounding which might result in flat wheels. Each side of the crane has large turnbuckles for securing the crane structure to the hull, and the rear of the crane is provided with a socket into which a forged-steel locking pin is inserted to prevent the rotation of the structure as the ship rolls from side to side. The cradle in which the jib rests is fitted with heavy steel shoes and provided with clamps for holding the jib in position. A cradle is also provided for receiving the hoist blocks and equalizer when not in use.

The Hoisting Machinery

The main hoist machinery consists of two units, each having a capacity of 125 gross tons. The drums (Fig. 9) forming a part of this mechanism are 86 in. in diameter and 8 ft. 4 in. long arranged in tandem, each drum being provided with a driving gear meshing with a common pinion carried on a shaft between the drums.

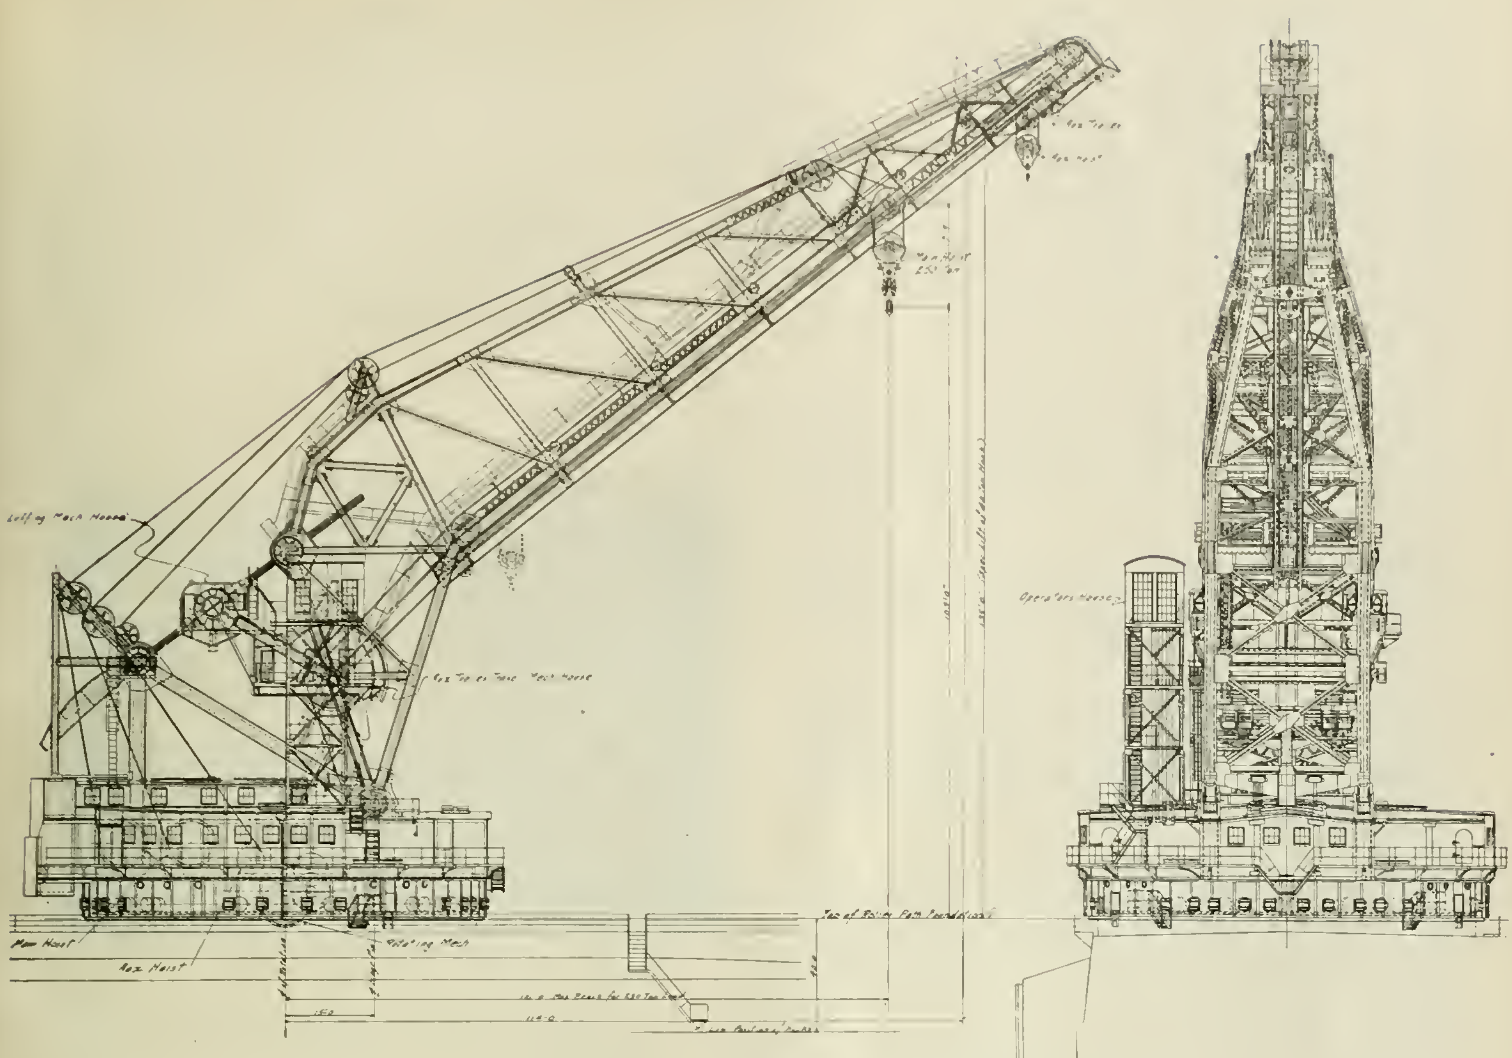

Fig. 17 The Crane Design Involves Severe Problems

Severe mechanical and structural problems were involved in the design of a crane to handle over three hundred tons on the main hoist and fifty tons on the auxiliary hoist between the limits shown in Fig. 17. Note particularly the isosceles triangle with the jib post as one of the equal sides, the inclined foundation member as the other, and the luffing screws as the base. The connection between the middle point of the jib post and the luffing nuts is always parallel to the inclined foundation member, and the floor of the luffing-mechanism house is always horizontal.

The drums and driving gears of these units are located between the main gears of the crane. The drums stand on their supporting shafts which are carried in bearings secured to a common bed plate. This bed plate is in turn carried by a substantial structural foundation built into the crane structure.

The pinion shafts of the two hoist units are in accurate alignment and a jaw clutch is provided at the center to connect the two units when handling the 250 tons on the equalizer.

Midway between the curved rails upon which the trucks travel is a bevel-gear rack used for rotating the crane. (Fig. 7.) The pitch diameter of this rack is 61 ft. The teeth are 20 deg. involute in form and have a pitch of about 9 in. The rack is made in sections which are bolted to the rail chairs.

Meshing with the rack are two pinions located diametrically opposite at each side of the revolving structure. (Fig. 8.) These pinions have 12 teeth 20 deg. involute in form and are half-shrouded. They are keyed to separate shafts which are driven through two reductions of spur gears and a motor train of cut herringbone gears by a 110-hp. General Electric motor. The motor and first intermediate shaft are mounted on a cast-steel bed plate in the machinery house, while the second and third shafts are below the floor girders. Each motor pinion is fitted with a magnetic disk brake and connected to the motor by a flexible coupling. Double-acting equalized post brakes are provided on each unit operated by a single lever in the cab. There is no mechanical connection between the two rotating units, as the series characteristics of the motors equalizes the load on the two pinions.

Although the motor brakes when set will normally resist any tendency to rotate, as an additional precaution a heavy locking pin is provided which is inserted by a hand-operated mechanism into a socket in the under side of the counterweight compartment at the rear of the structure. This pin is of forged steel 14 in. by 12 in. and is operated by a screw-toggle arrangement and a handwheel. The mechanism is located in the transverse girder attached to the deck of the ship, and of such a height that the rotating structure just clears in passing.

Four 4-in. turnbuckles are provided at the outer ends of outrigger girder. When the crane is not working or preparing for a sea voyage, these turnbuckles are secured to socket castings attached to the crane foundation to prevent any movement when the ship is rolling.

The luffing mechanism is located in a house built into the upper end of the luffing strut between the screws. The upper end of the strut is provided with heavy strap castings which surround trunnions on the bevel-gear housings. These housings are made in halves and enclose the bevel gears and pinions which turn the luffing screws. The bevel gears are bolted to flanges of nickel-steel couplings, used to connect the upper and lower luffing screws, which are tightly fitted into sockets in the ends of the couplings and secured by wedged keys. The screws are 15 in. in diameter and have a 4-in. pitch thread. One right-hand and one left-hand screw are used on each side of the crane for luffing the jib. The combined length of the two screws and their coupling is 83 ft., and their weight about 45,000 lb. The lower base of the housing forms a thrust bearing against a shoulder on the coupling to maintain the luffing strut in position.

The bevel pinions driving the coupling gears are keyed to opposite

Orifice Coefficients—Data and Results of Tests

By JACOB M. SPITZGLASS,[1] CHICAGO, ILL.

This paper discusses the results of experimental work conducted at the Research Laboratory of the Republic Flow Meters Co., of Chicago, on the use of orifice plates for measuring the flow of fluids in pipes.

Extensive tests were carried on for a period of several years to determine the effect of the varying factors such as the orifice ratio, the size of the pipe, and the distance of the upstream and downstream connections upon the pressure difference across the orifice plate. The tests were conducted on seven sizes of pipes, from 2-in. to 12-in. standard. Fourteen orifice ratios were used in each size and twelve connections were tested on each side of the orifice plate.

The tests were made on the flow of atmospheric air, supplied by a Sturtevant blower driven by a 15-hp. motor and having a maximum capacity of 6000 cu. ft. per min., at a pressure of 10 in. of water. To vary the velocity of flow, an adjustable air gate was attached to regulate the intake to the blower. The air passing through the orifice was measured by five calibrated impact tubes ranging from 1 in. to 4 in. in internal diameter.

The theoretical relations of the functions are given briefly, preceded by definitions of the terms involved. The paper includes a number of tables and a collection of characteristic curves that may be employed for determining the flow through orifice plates in a given size of pipe.

IT HAS been long established in the literature of mechanical engineering, and especially in the various textbooks on hydraulics, that a stream of fluid issuing from a rounded aperture in the wall of a large vessel can be gaged accurately by the difference in static pressure between the inside and the outside of the vessel containing that fluid.

The relation between the pressure difference and the velocity of the jet issuing from the aperture has been derived theoretically for jets flowing into the open atmosphere and also for jets submerged under a lower head of the same fluid. It has been established by numerous experiments that upon leaving the vessel the cross-section of the stream is gradually reduced in area until, at a point known as the vena contracta, it is only about 60 per cent of the actual area of the aperture in the wall of the vessel. This contrivance used as a device for measuring the flow of fluids has been termed the "frictionless" or "thin-plate" orifice.

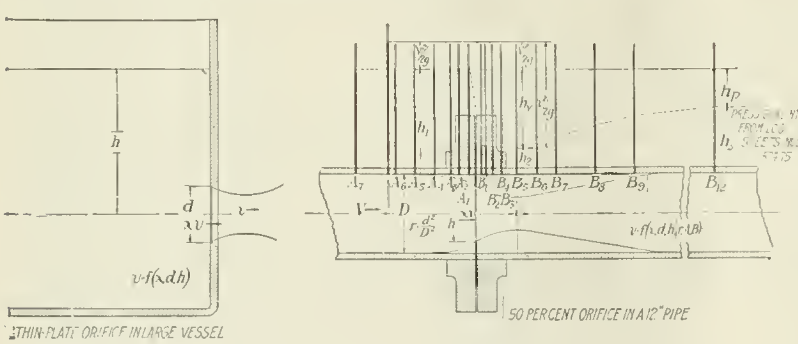

Fig. 1 Thin-Plate Orifice—Jet Contraction and Pressure Gradient

Recently the principle of the thin-plate orifice has been successfully applied to measuring the flow of fluids in pipes by the drop of pressure through the restricted area of an orifice plate placed between two flanges of the given pipe. At first the practice was limited entirely to cases where the area of the opening was much smaller than the cross-section of pipe, so that they could be considered as being similar to the submerged aperture in the wall of a large vessel. Further developments in this application have necessitated the use of larger-ratio orifices, which obviously differ from the case of the jet issuing from the large vessel, and therefore cannot be treated in the same manner. A comparison of the two cases with reference to Fig. 1 brings out the following points of difference:

First, in the case of the thin-plate orifice in the large vessel, the velocity of the jet issuing from the wall represents the equivalent of the hydrostatic head or pressure above the center of the opening, since the fluid in the vessel may be considered to be at rest. In the case of the pipe orifice it is the increase in velocity over the velocity of approach that is equivalent to the differential head across the orifice. This item may be termed the effect of initial velocity in the pipe.

Second, in the case of the pipe orifice the formation of the stream may be greatly affected by the proximity of the walls of the pipe both on entering and on leaving the orifice. In the case of the large vessel this effect is eliminated on either side of the orifice and the stream of the fluid can be freely formed into the natural contraction of the issuing jet. This item may be termed the effect of the size of the pipe or of the proximity of the walls.

Fig. 2 Interior of Research Laboratory

Third, in the case of the large vessel the pressure difference affecting the flow of the fluid is fixed by the difference between the pressure inside and outside the vessel. In the case of the pipe orifice it is necessary to obtain the pressure difference between a point ahead of the orifice where the current is parallel to the walls of the pipe and a point beyond it where the jet has been fully contracted, in order to have the true equivalent of the increased velocity pressure of the jet. This may be termed the effect of shifting the pressure taps on either side of the orifice.

These given points of difference are demonstrated graphically in Fig. 1 to show their relations to the dimensional quantities involved. Thus, the effect of initial velocity is a function of the relation between the velocity V of the fluid in the pipe and the velocity v of the jet at the point of greatest contraction, or of the ratio d^2 D^2 between the cross-sections, which, in its turn, is a function of the jet contraction x and of the ratio between the cross-section of the orifice and the cross-section of the pipe. The effect of restriction or the proximity of the walls is a function of the distance between the wall of the pipe and the edge of the opening, which, in its turn, is a function of the diameter D of the pipe for any given orifice ratio. The effect of shifting the pressure taps is necessarily a function of the location of the taps on the A and B sides of the orifice plane.

The experimental work described in the complete paper was undertaken with the object of obtaining the necessary data for this analysis: namely, to determine by actual tests the effect produced in the pipe orifice, used as a flow-measuring device, by the variation of the orifice ratio, by changing the size of the pipe, and by shifting the pressure taps on either side of the orifice plate.

[1] Vice-president and consulting engineer, Republic Flow Meters Co. Mem. A.S.M.E.

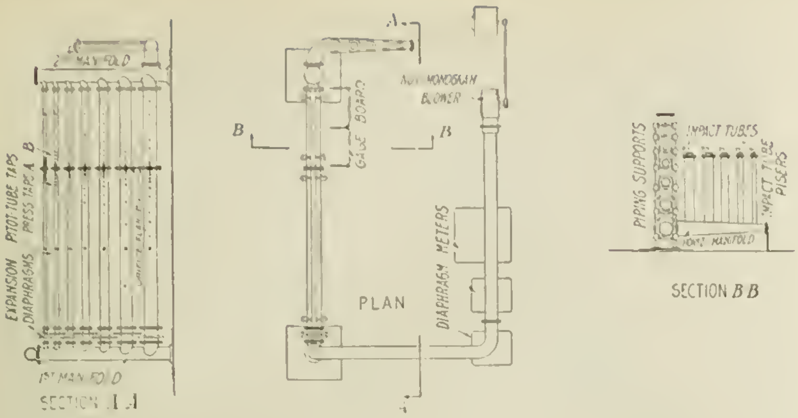

Fig. 3 General Layout of Research Laboratory Equipment

The Tests

In the early part of 1919 the engineering department of the Republic Flow Meters Company began its first series of orifice tests on several sizes of pipes. On the removal of the company to its new headquarters in 1920, a research laboratory was established on the second floor of the factory building for the purpose of furthering the experimental work on orifice coefficients. Fig. 2 is a view of this laboratory and Fig. 3 shows the general arrangement of apparatus as originally installed.

Extensive tests were carried on to determine the effect of the varying factors such as the orifice ratio, the size of the pipe, and the distance of the up-stream and down-stream connections upon the pressure difference across the orifice plate. The tests were conducted on seven sizes of pipes, from 2-in. to 12-in. standard. Fourteen orifice ratios were used in each size and twelve connections were tested on each side of the orifice plate.

The tests were made on the flow of atmospheric air, supplied by a Sturtevant blower having a maximum capacity of 6000 cu. ft. per min. at a pressure of 10 in. of water. The air passing through the orifice was measured by five calibrated impact tubes ranging from 1 in. to 4 in. in internal diameter. A detailed account of the calibration of the impact tubes is given in the complete paper, as well as curves showing the coefficient as a function of the impact head through the tube. The arrangement of the installation for the final tests is also described and illustrated in detail, and an account is given of the method of testing the various orifices.

Theoretical Relations of Functions

The following notation is adopted with reference to Fig. 1, in which most of the quantities and dimensions are demonstrated diagrammatically.

- d = diameter of the thin-plate orifice, either in the restricted pipe or in the wall of the large vessel
- D = diameter of pipe
- x = percentage of jet contraction at the smallest cross-section or the vena contracta of stream
- r = ratio of orifice cross-section to pipe cross-section, or d^2/D^2; xr = ratio of vena contracta to cross-section of pipe
- ρ = $1/r$ = ratio of pipe cross-section to orifice cross-section or D^2/d^2; ρ/x = ratio of pipe cross-section to the vena contracta of stream
- A = distance from plane of orifice to upstream pressure taps
- B = distance from plane of orifice to downstream pressure taps
- h_1 = static pressure at section of normal flow ahead of orifice
- h_2 = static pressure at section of vena contracta
- h_3 = static pressure at section of normal flow beyond orifice
- h = differential head between any two points on opposite sides of the orifice
- h_v = differential head between the two points designated as h_1 and h_2. This quantity represents the pressure drop across the orifice corresponding to the increased velocity of the flow
- h_p = differential head between the two points designated as h_1 and h_3. This quantity measures the total loss of pressure caused by the sudden contraction and expansion of the flow through the orifice
- Z = ratio of h_p to h_v
- V = velocity of fluid at section of normal flow in pipe
- v = velocity of fluid at vena contracta of stream
- xv = velocity of fluid at section of orifice
- Q = rate of flow or amount of fluid passing through the orifice in a given unit of time
- C = coefficient of discharge defined by

$$Q = C\frac{\pi}{4}\frac{d^2}{\sqrt{1-r^2}}\sqrt{2gh} = C\frac{\pi}{4}\frac{D^2}{\sqrt{\rho^2-1}}\sqrt{2gh} \qquad [1]$$

C' = velocity coefficient of orifice defined by—

$$v = C'\sqrt{2gh}, \text{ and } C' = f(A)f(B)\sqrt{\frac{1}{1-x^2r^2}} \qquad [2]$$

(xC') = orifice coefficient defined by—

$$Q = (xC')\frac{\pi}{4}d^2\sqrt{2gh} \qquad [3]$$

C'' = orifice coefficient defined by—

$$Q = C''\frac{\pi}{4}D^2\sqrt{2gh}, \text{ or } C'' = (xC')r \qquad [4]$$

Derivations of Equations [1] to [4] defining C, C', and C'' are given in the complete paper. Subscript v, with reference to the given terms, applies to the condition of pressure tap A at normal flow ahead of the orifice plane and pressure tap B at the vena contracta. Subscript p applies to the condition of pressure tap A at normal flow ahead of the orifice plane, and pressure tap B at normal flow after the orifice plane.

The quantity C in Equation [1] is the coefficient of discharge for the orifice as compared with the coefficient of discharge for the venturi tube. In using this coefficient it is always necessary when solving Equation [1] to compute the radical $\sqrt{1-r^2}$ for the given orifice ratio. This is especially troublesome when a solution is sought for the size of the orifice necessary for a given differential and amount of flow, as it involves two unknown quantities C and

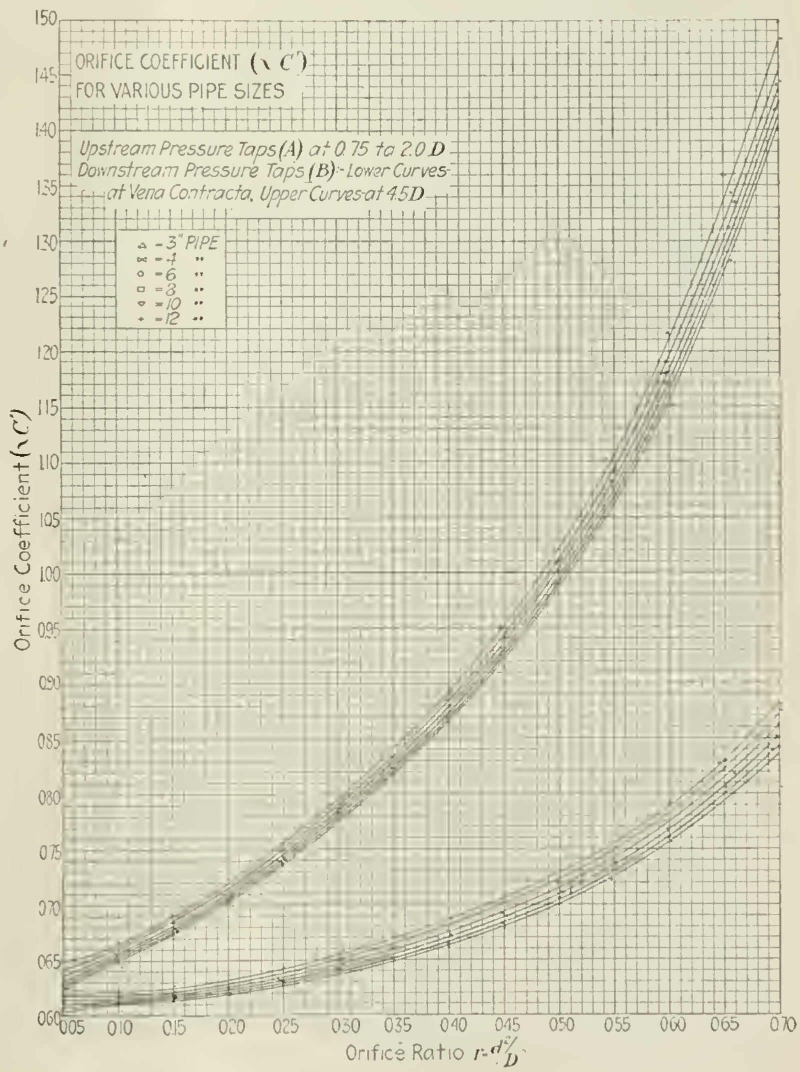

Fig. 4 Orifice Coefficients for Various Pipe Sizes

r. To overcome this difficulty, a modification of Equation [3] is employed with reference to the cross-section of the pipe. Since $d^2 = D^2r$, we can write—

$$Q = (xC')r\,\frac{\pi}{4}\,D^2\sqrt{2gh}$$

or—

$$Q = C''\,\frac{\pi}{4}\,D^2\sqrt{2gh}$$

This equation in combination with a C''-r curve gives a direct solution for the size of orifice necessary for a given flow.

The pressures h_1, h_2, and h_3 at the three main sections of the orifice region are significant for the fact that they indicate the relation between the drop of pressure h_v equivalent to the increase in velocity and the pressure loss h_p caused by the sudden contraction and expansion of the flow. From the above equations, we can write—

$$C_p\sqrt{h_p} = C_v\sqrt{h_v}$$

from which—

$$\text{Fraction of loss } Z = \frac{h_p}{h_v} = \left(\frac{C_v}{C_p}\right)^2 \ldots\ldots [5]$$

$$\text{and fraction of pressure restoration} = 1 - Z = 1 - \frac{h_p}{h_p} = 1 - \left(\frac{C_v}{C_p}\right)^2.$$

The same applies to any of the experimental coefficients determined for the two sections corresponding to h_2 and h_3, respectively.

Computation of Results

The method adopted was to compute the rate of flow in pounds per minute for the calibrated impact nozzles used as a standard,

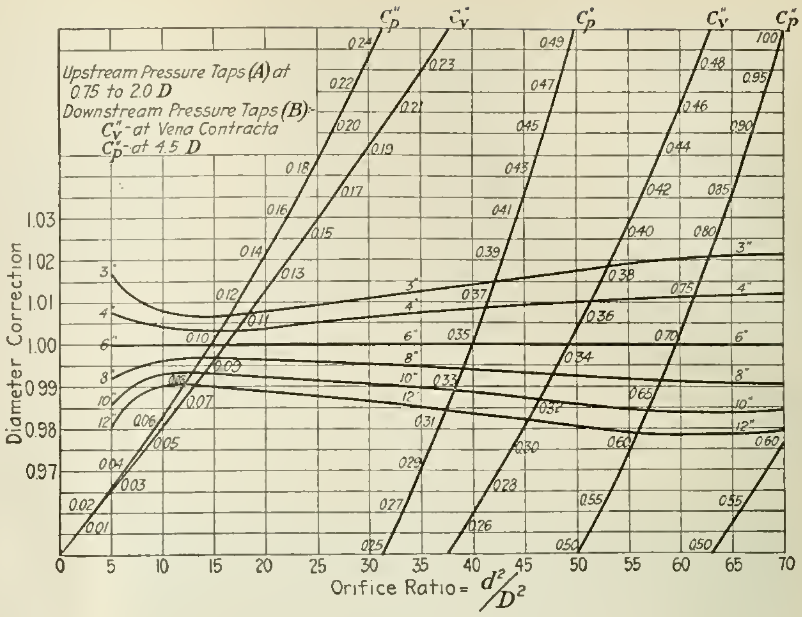

Fig. 6 Orifice Coefficient C'' for 6-in. Pipe and Correction Factors for Other Sizes

and the rate in pounds per minute derived theoretically for the given orifice plate, assuming xC' to be equal to unity. The actual value of the coefficient xC' for the given orifice is necessarily the ratio of the former to the latter. The method of procedure is demonstrated on the sample log sheets in the complete paper which contain the data of one A-run and one B-run on the 12-in. pipe.

The data of the final tests are recorded on 1625 log sheets filed in chronological order and cross-indexed under the various headings of impact tube, pipe size, and orifice ratio. A log sheet of the impact-tube tests contains a run on a given tube either varying the velocity head at constant setting or the setting at constant velocity. A log sheet of the orifice tests contains a run on a given-ratio orifice at constant velocity either varying the upstream A-taps with the downstream constant, or the downstream B-taps with the upstream constant. A complete test for a given orifice ratio comprises four velocity tests and from five to twelve log sheets for each velocity, part of them with A constant and B varying, and part with B constant and A varying. Each pipe size was tested for fourteen orifice ratios with the exception of the 2-in. pipe, on which the lower-ratio orifices were not completed at the writing of this paper.

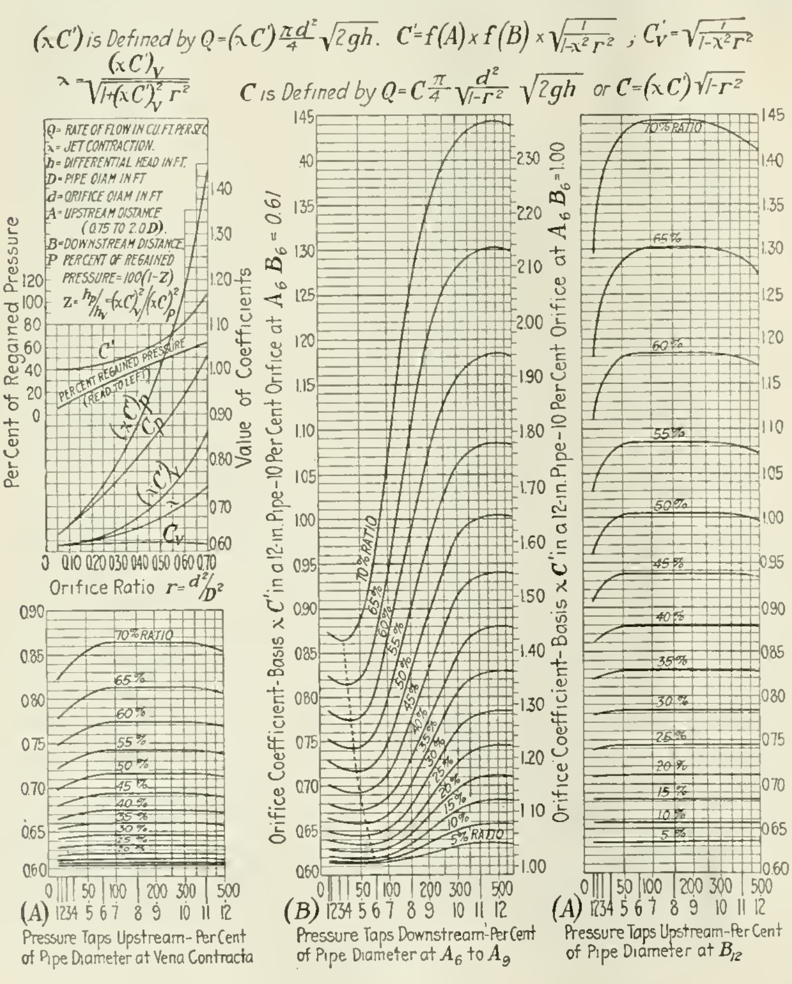

Fig. 5 Characteristic Curves for Orifice Plates

Characteristic Curves of Orifice Plates

At the completion of a test for a number of orifice plates in a given size of pipe the values of the coefficient xC' were plotted in three sections on large sheets ruled in logarithmic coördinates. The first section represented the so-called A-curves plotted as a function of the upstream distances from the A-runs of the test with the downstream connection at the vena contracta. The second section represented the B-curves plotted as a function of the down-stream distances from the B-runs of the test. The third section consisted of A-curves plotted as a function of the upstream distances with the downstream connection at four and one-half diameters of the pipe or the point of complete restoration of pressure.

These curves, not given in the paper, represented in substance the form similar to the three main sets of the final curve, shown in Fig. 5 for the 10-in. pipe, except that in the original curves each orifice ratio was represented by a group of lines adjoining the test points of the several velocities for a given ratio. Also in those curves the actual orifice ratios were used, which differed somewhat from the equal divisions of the final curves in Fig. 5. With small exceptions the lines of each group did not

deviate much from each other, so that in each case a single line was drawn which represented the average value of the coefficient for the given ratio.

From these average lines the points of minimum and maximum were plotted on Fig. 4 as a function of the orifice ratio for the various sizes of pipe, the lower set for the coefficient $(xC')_v$ at the vena contracta, and the upper set for the coefficient $(xC')_p$ at four and one-half diameters from the orifice plate. After the points of the two sets on Fig. 4 were joined by smooth lines for the given sizes of pipes, the corrected values were obtained for the even ratios in multiples of five and the points transferred to the original curves and compared with the average lines of the nearest ratio. A new line was drawn parallel to the old one to pass through the corrected points for the even ratio. In this manner the effects of possible errors of observation were reduced, first, by comparison with the similar tests of the same ratio, second, by comparison with the similar tests of various ratios of the same size of pipe, and third, by comparison with the similar tests of the various sizes of pipes.

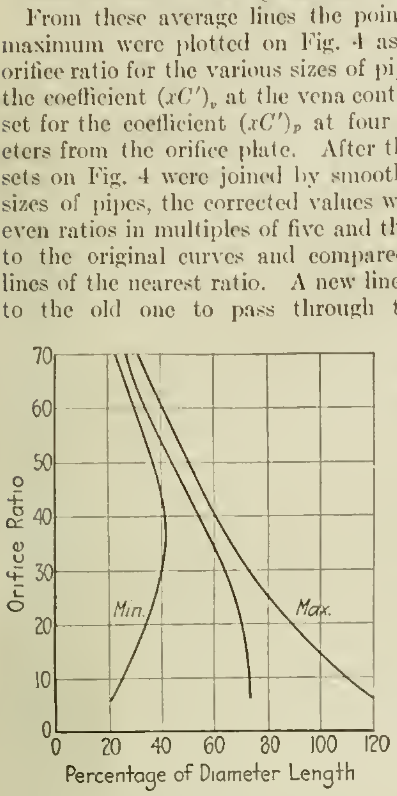

Fig. 7 Spacing of Taps at Vena Contracta

The final curves for the even ratios of the 6-in. pipe are shown in the three main sections of Fig. 5. These three sections give a generalization of the complete work for the given size of pipe. They point out forcibly the great importance that must be attached to the proper spacing of the orifice connections. In fact, they would seem to indicate that an excessive precision is necessary in determining these points, since a very small change in the tap distance along the steeper parts of the curves might cause a change of several per cent in the value of the coefficient.

To eliminate possibility of large errors in the practical application of the orifice, it is best, therefore, to select only those points for use at which a slight change in the position of the tap would not appreciably affect the coefficient. This condition is obviously fulfilled at the minimum and maximum points, since these points occur at the flat portion of the curve.

The A-curves given are restricted to as study of conditions at these two points. These two sets can be used in a similar manner to select the proper points at which to place the upstream pressure taps. Thus, since the flat parts of the curve occur between points A_6 and A_9, the upstream pressure taps should always be located between these points for the practical application of the orifice.

The curves in the upper left-hand section of Fig. 5 fulfil both of these conditions selected for good practice, that is, the upstream connections are always between 0.75 D and 2.00 D, and the downstream connections are at the vena contracta or at four and one-half diameters of the pipe. In this section are plotted as a function of the orifice ratio the values of xC', x, C', C and also the percentages of pressure restoration in the pipe. The values of these coefficients are given in Tables 1 to 6 for the various sizes of pipe.

The selection of the upstream and downstream distances to be used in general practice must not be taken as a limitation on the use of the orifice to these few points. With the proper care in spacing the pressure taps the coefficient corresponding to the exact distance can be easily and precisely obtained from the characteristic curve for the given pipe size.

In an earlier paragraph the orifice coefficient C'' was mentioned as affecting the simplest solution of orifice problems since it relates directly to the known section of the pipe D^2. Accordingly, Fig. 6 was prepared in a convenient form for ordinary use, giving values of C''_v and C''_p as a function of the ratio. To eliminate the necessity of repeating the curves for each size, only those for the 6-in. pipe were prepared, and additional lines were drawn to scale giving correction factors to be used in obtaining the coefficient for the other pipe sizes.

Fig. 7 shows the spacing of pressure taps at the vena contracta in percentage of the diameter length corresponding to the given orifice ratio. The center line is a duplicate of the one passing through the minimum points of the characteristic B-curves in Fig. 5. The two outside curves, marked "min." and "max.," show the limits to which the tap may be shifted without varying the coefficients more than 0.25 per cent either way. The actual spacing

should be made as nearly as possible to that given by the center curve, since it is drawn to indicate the exact position of the vena contracta.

Conclusion

The scope of this paper will not permit of going into the particular details of each individual test. Its main object is to present the results obtained in the research laboratory in such a form that they can be applied conveniently.

A few remarks may be in order about the most salient points brought out by this investigation.

The orifice plate used as a measuring device for the flow of fluids in pipes has a relative accuracy well within the limit of 2 per cent. If reasonable care is applied in the selection of the location, the proper spacing of the pressure taps, and the proper centering of the orifice between the flanges in the pipe, the possible deviation may be reduced to less than 1 per cent. The maximum variation from the average in any single test seldom exceeded 1 per cent when the differential pressure was above 1 in. of water.

The loss of head through the entire region affected by the orifice, which is the differential to the point of complete restoration, is an accurate function of the velocity squared—the same as that of the drop of pressure to the vena contracta. This means that the coefficient C_p is just as reliable as the coefficient C_v. In cases where the pressure difference has an appreciable value it is even better to use the point of restoration, as the curve is much flatter at that point, in the case of large-ratio orifices, and a deviation from the proper section will not result in any appreciable error.

The coefficient of discharge C_v is shown to be very nearly constant for orifices of all ratios. This would mean that the orifice can be treated as a venturi, using the same value of C_v and correcting for initial velocity of approach the same as is done in the venturi tube.

The jet issuing from the orifice does not contract to the same extent in the smaller sizes of pipes. This is probably due to the fact that the portion of the flow which is restricted by the orifice has a proportionately lower velocity due to the increased skin friction in smaller sizes of pipes.

The variation of velocity pressure from 100 to 300 per cent does not affect the value of the coefficient. This seems to indicate that the name "frictionless orifice" is not misleading. For this reason it is best to use very thin material for the orifice plate to eliminate the friction at the sides of the opening. If the material has to be heavier, it is advisable to bevel the *downstream* side of the opening.

The regained head increases very rapidly with the increase of orifice ratio, making the larger-ratio orifice more applicable to cases where the loss of pressure is an important item.

Reference is made to the fact that the characteristic curves given in this paper are based upon the assumption that the coefficient of discharge for a 10 per cent orifice in a 12-in. pipe is equal to 0.61. This assumption, however, is borne out by the results of previous experiments by many authorities and can be further substantiated by additional volumetric tests at this point. The experiments, as demonstrated in this work, have shown that the orifice plate is relatively accurate for measuring the flow of fluids for the varying sizes of pipes and the various ratios of orifices at the proper spacing of the pressure taps. The characteristics curves given in the paper have a complementary scale with the basic value of 0.61 as unity, so that if further experiments should prove that the 10 per cent orifice in a 12-in. pipe has a value somewhat different from the one given, these curves can be applied in the same manner to the new value of the standard.

Discussion[1]

R. J. S. Pigott[2] wrote that the paper was especially interesting in that the values obtained and the characteristics of the stream, when taken in conjunction with the dimensional analysis given in the Fluid Meters Report, afforded a means of coördination of practically all of the experimental work on disk orifices. Heretofore these experiments had been thought to show considerable variation from each other, but when allowance was made for the difference of location in upstream and downstream taps, the ratio of orifice sizes, pipe sizes, and the location of vena contracta, it was found that nearly all the experiments gave coefficients substantially in agreement. Allowing for the difference of view of the various experimenters, it was very encouraging that this should

[1] These extracts from the discussion deal more particularly with those portions of the paper appearing in the preceding abridgment. The table and figure numbers are those used in the abridgment.

[2] Mechanical Engineer, Stevens & Wood, New York, N. Y. Mem. A.S.M.E.

be the case, and it was curious that the mathematical analysis of this flow prepared by Dr. Buckingham of the Bureau of Standards for the report should have predicted the characteristics of the orifice as found by Mr. Spitzglass, each working entirely without knowledge of the other's results. It was unfortunate that nearly every experimenter on both venturi tubes and the disk orifices should have used a different system of plotting and comparison; but possibly by trying all the different ways the best method would be adopted by the public who had to use them.

J. W. Hogg,[3] in a written discussion, said that it would be well to know whether the coefficient of the basic orifice, as well as the results derived from its use as a means of calibration, were applicable to steam and water, and possibly to other fluids heavier or lighter than water but possessing a different viscosity.

Fig. 7 showed that a good location for the low-pressure fitting was one-half of a pipe diameter behind the plate for ratios up to 50 per cent, therefore if the flow could be measured between this range without excessive differential head, a distance of one-half pipe diameter behind the orifice might be taken as a fixed location for the low-pressure connection.

It would be noted on Fig. 4 that the coefficient of discharge for a given ratio of areas decreased as the pipe size increased. The author stated in one of his concluding paragraphs that the jet issuing from the orifice did not contract to the same extent in the smaller size of pipe as it did in the larger, and further that this was probably due to the fact that the portion of the flow which was restricted by the orifice had proportionally lower velocity due to the increased skin friction in the small pipes. It then appeared that the ratio of the perimeter of the pipe to the area of the pipe or some other similar function could be incorporated in a equation to be used in figuring the coefficients for sizes of pipe which were entirely too large to be erected in a laboratory for experimental purposes. After this equation was determined the coefficient of discharge for these large pipes, such as 18-, 24-, and 30-in., could be easily interpolated.

It would also be noted in Fig. 4 that the two sets of coefficients depending upon whether the vena contracta or the point of restoration were used as the location of the low-pressure fitting were widely different in value, and the set of coefficients at the vena contracta might be termed low coefficients, while the set at the point of restoration might be termed high coefficients. It appeared from all the data taken in this test that sufficient was on hand to determine a set of coefficients with intermediate values with respect to the other two sets, and this set could be obtained by locating the high-pressure fitting at the point of restoration and the low-pressure fitting at the vena contracta.

A. F. Spitzglass[4] wrote that it seemed best for practical work in calculating orifices that separate curves be used for each size of pipe. The values for determining these curves could be obtained from Tables 1 to 6 by multiplying the values given in the first column for $(xC'')_v$ by the orifice ratio r.

Since the completion of the tests the objection had been raised that the Ellison gages could not be relied on to give results within the limits of accuracy necessary for laboratory work, unless calibrated individually against some absolute standard. Lest this cause reflection to be cast upon the value of the data given, it seemed necessary to explain the methods adopted to overcome this difficulty.

Each test was essentially a comparison of two similar functions of the pressure head at two different points in the stream. Neglecting the corrections applied, the coefficient varied as the square root of the ratio of the orifice differential to the head on the impact nozzle. Thus, only a relative accuracy between the two devices used for determining the pressures was necessary to give the required precision. With this in mind, tests were made on a large number of gages, checking them against each other over the complete range of their scales. Of these, three were finally selected that gave practically identical readings along the entire scale. One of these was used for obtaining the orifice differential and the other two for obtaining the head on the impact nozzle. To retain this precision it was necessary, therefore, to choose a nozzle of such a cross-section that the two gages would read on the same part of the scale. Furthermore, in averaging the results of any of the tests, most weight was given to those runs in which the two pressures were nearly identical.

George S. Hendrickson[5] wrote that the calibration curves for the impact nozzles showed that the coefficient changed when the velocity changed, due to the friction. As he understood it, the coefficient of the venturi tube was given as a constant irrespective of the velocity, and the conclusion he drew was that both could not be correct. He would ask whether coefficients of the venturi tube had shown a variation at different velocities.

All the tests had been made for a given pipe size in the same pipe by varying the orifice ratio. In commercial pipe it was safe to assume that the inside surface of different pipes would not have the same characteristics. One piece might be very smooth and another quite rough. He believed that this might affect the orifice coefficient, especially on the larger ratios and higher velocities.

C. A. Dawley[6] wrote that the arrangement of flow nozzles on manifolds as shown in Fig. 3, was unfortunate from the fact that the air flow had to make three right-angle turns within a short distance, thereby creating violent disturbances or eddies in the flow stream. This piping would naturally produce swirling or helical flow in the vertical pipes leading to the flow nozzles, and would certainly give a higher velocity on one half of the opening of the nozzle than on the other half. The net result of both of these irregularities would be to give a low, and perhaps a variable, coefficient for the nozzles. The fact that the coefficients found did not increase systematically with the diameter and that they were uncertain or variable in some instances, supported the belief that they were influenced by the conditions of installation. It would be of value if the author would explore, with a search tube, the whole area of the nozzle outlets as installed, finding the velocity across two diameters at different radii compared with that at the center, and then that the 3- and 4-in. nozzles should be installed in turn directly at the end of the 12-in. pipe in which the disk orifice was located and a further determination made on the relative coefficients.

The most important point settled by the paper was the location of the vena contracta and the point of maximum restoration of pressure beyond the disk orifice. For the range of heads covered by the author's tests, these results should stand regardless of any minor inaccuracy in the coefficients of the impact flow nozzles as found.

E. G. Bailey[7] wrote that it was unfortunate that the author had deemed it best to present the data in such form that they could not well be correlated or compared with other data previously presented to the Society on a similar subject. It was also very unfortunate that he did not have a standard or basic measurement upon which to start the comparison. The flow nozzles were calibrated on an assumed coefficient of one orifice, then the orifices were recalibrated on the basis of the flow nozzles. The same flow nozzle could not be used for all the different sizes of pipe, so that the final results were rather far from a definite absolute basis. Mr. Bailey believed the results as a whole gave coefficients too high; also that the paper showed more difference between the coefficients of different sizes of pipe than actually existed. While most of the data might be within 2 or 3 per cent of correct absolute value, he thought in the present state of the art greater accuracy was expected of the meter manufacturer. It was to be hoped that some subsequent tests could be made to substantiate or modify these absolute values as mentioned in the last sentence of the paper.

It would be interesting to know why Mr. Spitzglass had limited his test to a 70 per cent ratio orifice which was equivalent to 83.70 diameter ratio.

The use of circular concentric orifices gave no latitude as to the location of the vena contracta. This was rather annoying when high hub flanges were encountered; also when a pipe was tapped for an orifice of one capacity and later an orifice of a different capacity was to be installed. This might require retapping the connections at a comparatively short distance away, so that it could not

be accomplished without going to another position on the circumference of the pipe. He had found it very advantageous in such conditions to use eccentric and segmental orifices.

John L. Hodgson[8] wrote that the author had repeated work which he had briefly summarized in Fig. 18 of his paper on the Commercial Metering of Air, Gas and Steam, read before the Institute of Civil Engineers in April, 1917.

Commenting on Mr. Spitzglass's paper, he would say that the contour of the impact nozzles used in the tests was unsuitable for low-pressure work, as the effect of viscosity, which was most marked at low flows, altered the shape of the stream lines, and hence the distribution of velocity across the section. A nozzle contour which was suitable for Mr. De Baufre's purpose was entirely unsuitable for that of Mr. Spitzglass, where it was essential to work at values of p_2/p_1 which were very nearly unity.

The proposal to use pressure holes further downstream rather than the vena contracta for flow-measurement purposes was, according to Mr. Hodgson's tests, suitable only for the most approximate measurements (unless the orifice had been calibrated in its own pipe line) as variations in the roughness and—in the case of large orifice ratios—the diameter of the pipe caused very considerable variations in the flow coefficient.

It was unsatisfactory to use circular orifices for area ratios greater than 50 per cent, as small errors in centering or in the diameter of the pipe upstream or downstream of the orifice caused considerable errors in the measurement.

For many reasons the most reliable position for the pressure holes was in the plane of the orifice as he had shown in his paper above referred to. It was a matter for regret that Mr. Spitzglass had determined no pressures at these particular points.

Author's Closure

The author, in closing the discussion, said that in regard to Mr. Hogg's question as to whether the coefficient 0.61 for the 10 per cent orifice in a 12-in. pipe was applicable for water and steam as well as for air, the dimensional analysis given in the Fluid Meter Report showed that the values of the coefficient depended on the kinematic viscosity of the fluid, but from all experimental data available water, steam and the common gases showed no difference in the coefficient of the orifice.

As to adopting a distance of one-half diameter for the low-pressure connection of the orifice, he would say that this method had been used by many experimenters, but there was no advantage in adopting it for general practice. In a high-ratio orifice it was very important to place the connection at the proper point and it was best to adhere to this practice. If at any time the orifice was to be changed it would not be necessary to change the connection, as the difference in the factor could be easily obtained from the curves in the paper.

Mr. Hogg had asked whether an equation could be derived to determine the effect of pipe size upon the coefficient of the orifice from the relation of the mean hydraulic radius as pertaining to the friction drop of pressure. The dimensional equation referred to was supposed to correlate the results of tests so that the data of one size of pipe would apply to other sizes by following the law of dynamical similarity in the construction of the orifices.

Mr. Hogg had suggested that an intermediate coefficient be determined by locating the high-pressure tap at the point of restoration and the low-pressure tap at the vena contracta. This was a very good suggestion and to take care of it a modification of Fig. 6 had been prepared for inclusion in Transactions.

The suggestions made by A. F. Spitzglass were a slight addition to the work he had done in preparing the results of the paper.

In reply to Mr. Hendrickson's inquiry, he would state that the coefficient of venturi tube did vary with the velocity of the flow similar to the variation shown on the impact-tube curves. This variation was due to the effect of friction on the approach part of the venturi tube or nozzle. Since the coefficient of friction was generally increased at low velocity, there was a corresponding decrease in the coefficient of discharge, because the additional friction drop increased the relative differential pressure.

As to whether the roughness of the pipe affected the coefficient, he would say that from his experience the nature of the surface was not noticeable except in very high-ratio orifices. For that reason he preferred not to use orifices over the 70 per cent ratio of squares, in which the effect of the surface became noticeable.

If Mr. Dawley would examine Fig. 3 carefully he would see that the first two turns were really long-radius bends and of a size considerably larger than the approach of the flow nozzle. The air flow through any of the pipes lost practically all its velocity when entering the second manifold, which was 14 in. in diameter. The entrance to the third manifold was a long-radius bend of the same 14-in. size. On the top of this manifold each riser was over 6 ft. long and the diameter of the riser was about half the diameter of the manifold and double the diameter of the flow nozzle. With this construction of approach there should be no disturbance or eddies in the flow stream.

Mr. Dawley's suggestion to explore the whole area of the nozzle was carried out during the test. It was found that in case of the 4-in. nozzle the impact pressure did not vary at all until the impact tube was placed $^1/_4$ in. from the circumference of the nozzle. At that point it varied about 1 per cent of the total impact, and when the impact tube was placed so that its edge was in line with the edge of the nozzle, the reduction of the impact pressure was only 3 per cent of the total. This variation was the same in either direction of the nozzle, whether in line or across the turn of the flow at the bottom of the riser.

Mr. Bailey had objected to the method used in the paper to plot the results of the test on the basis of diameter square instead of diameter ratio; which he said was the basis used in Mr. Judd's paper and in others published on the subject. Referring to Figs. 18 and 20 of Mr. Judd's paper, it would be noted that the coefficient of discharge and the factor of correction for velocity of approach were plotted on the basis of the ratio of orifice area to pipe area, and not on the ratio of orifice diameter to pipe diameter. If Mr. Judd chose to call a $2^1/_2$-in. orifice in a 5-in. pipe a 50 per cent orifice, while the results obtained with this orifice were plotted on the 25 per cent line in his main curves, it did not entail any difficulty to compare the author's results with his when he chose to call it a 25 per cent orifice, inasmuch as it really amounted to that figure in the actual comparison of results.

With reference to higher-ratio orifices, the tests had not been limited to 70 per cent, but the results obtained for higher ratios had indicated that extreme accuracy was required in centering the orifice plate and in measuring the pipe diameter. Higher ratios were being investigated at present and the results would be reported later.

Mr. Hodgson's objection to the contour of the impact nozzle used did not apply to this case, because in the author's tests the nozzle was only a means of conveying a stream of fluid and measuring the velocity pressure with an impact tube faced against the stream. The preliminary tests referred to in the paper were made with a nozzle tube, similar to the one shown in Fig. 1 of the paper presented by Sanford A. Moss to the Society in December, 1916 In the final tests the design adopted by Mr. De Baufre was used to see whether the change in design made any difference. In both cases the same velocity pressure was obtained throughout the full area of the nozzle. There was only a change of 3 per cent in the velocity head, which would mean approximately 1.5 per cent velocity at the very circumference of the jet. This proved conclusively that the form of rounding the nozzle was immaterial when used in connection with an impact tube for obtaining the velocity pressure. The use of pressure taps at the point of restoration was recommended because the curve of the coefficient was much flatter at that point in the case of the high-ratio orifices.

Mr. Hodgson did not recommend the use of orifices of over 50 per cent ratio, for the reason that small errors in centering or in the diameter of the pipe would cause considerable error in the measurement. With the method of centering shown in the paper and the correct measurement of the diameter of the pipe, the results appeared to be equally reliable up to an orifice ratio of 70 per cent. As earlier stated, higher ratios were being investigated at present and the results would be reported later.

Mr. Hodgson regretted that readings were not taken of the pressures in the plane of the orifice. This was not necessary, as by extending the numerous points in the first diameter length toward

(Continued on page 399)

Steel-Car Construction at the Angus Shops of the Canadian Pacific Railway, Montreal

By H. R. Naylor,[1] Montreal, Canada

In 1909 the Canadian Pacific Railway, to meet the increasing severity of modern traffic requirements, originated a box car having its entire frame built of steel. The production of such equipment in quantity necessitated the erection of an additional shop for the fabrication of the steelwork, and the structure built embodied in its arrangement many novel features for the rapid handling of material to and from the machines and also during the various stages of assembly.

The present paper describes this shop very completely, giving particulars regarding its layout, crane facilities, machine equipment, etc. The various machining operations and the jig method of car assembly, first put into practice at the Angus shops, are presented in detail, and the methods used in the final erection and finishing of cars are dealt with at some length.

IN REVIEWING the improvements that have been effected in railway engineering in recent years, reference is usually made to the heavier and more powerful locomotives employed, grade elimination, heavier rails, improved train control, and terminal facilities; but while great advances have been made in all these directions, it is a question whether the relative advance in any one of them has equaled that in car construction.

The locomotive of higher capacity has been built without material change in the shops or their equipment, grades are removed today in practically the same manner as when the lines were originally built, and the same remarks hold good in regard to rails, train control, and terminal facilities, but in car construction the situation is substantially different. To particularize, a comparison of the modern 60-ton steel-frame box car with the 30-ton wood-frame box car commonly built fifteen years ago brings out two points: the complete change in design, and the effect this change in design must have had on the car shops. It is obvious that the facilities for building the wood-frame car would be quite inadequate for the steel car and must have created new problems with which the car builder had to contend; and it is the author's intention to deal with this phase of steel-car construction, especially as the Canadian Pacific Railway was responsible for many of the important developments.

Development of the Steel-Frame Box Car

The gradual increase in locomotive capacity, making possible the hauling of longer and heavier trains, subjected the wooden cars to severe service conditions, which were in turn met by steel underframes and other steel reinforcements; and at each stage of advancement wood framing was gradually replaced by steel, until in 1909 the Canadian Pacific Railway originated a box car having the entire frame built of steel.

Within a period of six years (1909–1914) this road added 30,811 steel-frame box cars to its equipment and others soon adopted the same design, in some cases with slight modifications. After ten years of extensive service these cars had evidently proved their utility, for the United States Railroad Administration in one order alone included no less than 50,000 of this type.

The Angus shops were already well equipped for building passenger and freight cars on an extensive scale, and the output of wood-frame box cars had reached as high as 40 cars per day. This remarkable organization, however, was rendered obsolete to a large extent when the Canadian Pacific Railway introduced the steel-frame box car to meet the increasing severity of modern traffic requirements, necessitating the erection of an additional shop. This shop was designed for building the steelwork of both passenger and freight equipment, and embodied in its arrangement many novel features for the rapid handling of material to and from the machines, and also during the various stages of assembly. At the time of its erection it probably represented the best practice on this continent, being a combination of the good features observed in other shops with the original ideas developed at the time the layout was being planned.

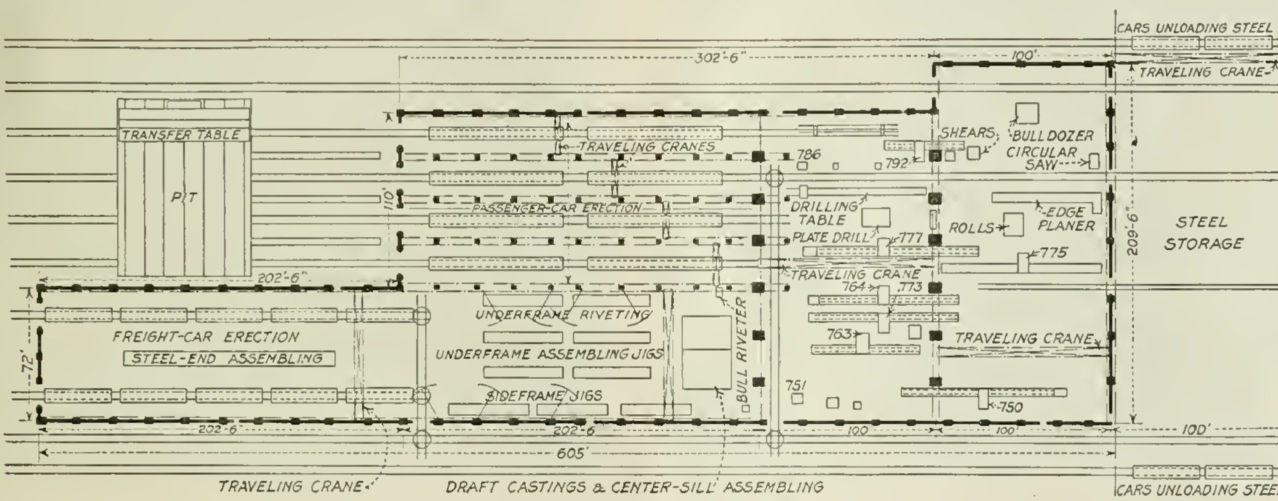

Fig. 1 Plan of Steel-Car Shop of the Canadian Pacific Railway Co. at Angus Shops, Montreal, Canada

The Steel-Car Shop and Its Equipment

The new shop, which is shown in plan in Fig. 1, was located adjoining the wood-freight-car shop, facing a midway upon either side of which were also located the supplementary shops, the midway being served with overhead traveling cranes. It is a steel-frame structure, with steel columns carried on concrete piers, the lower foundation walls being of concrete, 24 in. thick to the ground level and 20 in. thick to a height of $2^3/_4$ ft., above which the walls are of red brick and 16 in. thick. The sash frames are of steel, the total sash area being approximately 40 per cent of the total wall space. The roof is carried on steel trusses with ample skylight area. The floors are of 4-in. concrete with a top surface of $^5/_8$-in. mastic.

There are three main divisions to the shop. The front one facing the midway and occupying the entire front is the machine section consisting of two 100-ft. bays running parallel to the midway, the one adjoining the midway being $209^1/_2$ ft. long, while the inner bay is 182 ft. long. Each bay is served by a 10-ton elec-

Contributed by the Railroad Division, and presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Slightly abridged. All papers are subject to revision.

trically operated crane of the open-latticework type having a span of $96^1/_4$ ft., and a height to base of rail of $28^1/_2$ ft.

The freight-car erecting section is situated in the rear of the machine section, is 72 ft. wide and 405 ft. long, and was originally equipped with one 10-ton traveling crane having a span of $67^1/_2$ ft., and a height to base of rail of 27 ft. An additional crane of similar capacity has since been installed in this section.

Situated also to the rear of the machine shop is the passenger-car erecting section, consisting of four bays having a total width of 110 ft. These four bays with the 72-ft. freight-car bay complete the full width of the back of the machine shop. Each bay of the passenger-car section is provided with a separate 2-ton traveling crane having a span of 24 ft. 10 in. and a height to base of crane rail of 21 ft.

Along the entire front of the shop, between it and the midway, there is ample provision for storing material. This storage yard is 100 ft. wide and is served by a 10-ton crane whose span and height are identical with those in the machine section in anticipation of future shop extension.

Through the freight-car erecting shop, entering from the rear end, are two standard-gage tracks 18 ft. center to center which extend the full length but do not enter the machine shop. Outside the shop and parallel to the south wall a standard-gage track connects with a track on the midway through turntables. This track is used for delivering the car trucks from the truck shop to the final-assembly tracks.

Through each of the passenger-car erecting bays there is a standard gage track leading in from the rear of the shop, also a transfer table for moving the cars during the various stages of completion. Through the center of the material storage yard there is a standard-gage track connecting by turntables with three tracks running into the machine shop.

Crane Facilities. The crane facilities are unique in that the whole area of the shop is traversed by electrically operated traveling cranes so arranged that it is possible to install an unusual number and yet maintain for each crane complete freedom of operation at all times. In this instance the crane arrangement was the deciding factor in the shop layout. It was decided that the machine section of the shop should be independent of the erecting sections in so far as crane service was concerned, and for this reason the crane runways in this section were installed in a direction transverse to those in the erecting shop. This arrangement made it possible to equip the two machine bays with separate cranes, each having a wide range of action with no interference.

The machine layout is arranged with the view of relieving the overhead cranes to the greatest possible extent. This applies particularly to the handling of the larger members, such as center and side sills which are required to pass over two punching machines situated in the different bays. As the first operation is completed the sills are transferred to the second machine by special devices independently of the overhead cranes. On completion of the machining operations the sills are then skidded over to the assembling trestles in the erecting shop without assistance from the overhead cranes.

The two cranes in the freight-car erecting shop, operating on the same runway, are entirely free from machine-shop handling, and as the first one is assigned to the preliminary assembly positions and the second to the final assembly positions, there is no overlapping or interference. The crane facilities in the machine and freight-car erecting shops will be better appreciated if one will endeavor to imagine four cranes on a single runway attempting to handle an equivalent amount of work.

The Machine Equipment. The machine shop is equipped with the following machinery: Four automatic spacing punches, five coping punches, five high-speed punches, two horizontal punches, one 7-ft. 6-in. gate shear, one angle shear, one 36-ft. plate-edge planer, one 30-in. circular saw, one 30-in. metal band saw, one 7-ft. plate roll, one 10-ft. brake, one bulldozer, two special plate-drilling machines, and miscellaneous drill presses, all driven by independent motors.

The arrangement of the machines is such that the material after each operation moves forward in the direction of the erecting shops, backward movement being carefully avoided, thereby reducing material handling to a minimum.

The high-speed punches are belt-driven direct from motor to flywheel, gears being dispensed with. Clutches are of the 6-point type. The heads are equipped with two punches which are controlled by gag levers. These machines are well adapted for punching the smaller plates for which metal templets are made up and into which holes are drilled; by inserting a pin or gage in each successive hole and butting the plate against the pin, the desired spacing is obtained. In certain classes of work the operator can move the material fast enough to catch every hole with the punch running at the rate of 60 strokes per minute.

An unusual plan was followed as regards the installation of machines for heavy punching. The usual practice had been to install a small number of high-capacity machines for the punching and slotting of the sills, side plates and similar members, necessitating frequent changing of dies and templets, with further limitations in the event of breakdowns. It was therefore decided to overcome these handicaps by installing four automatic spacing punches of moderate capacity to obviate the expense and delay of die changing and double handling, and as the five additional coping punches are duplicates of those used in the automatic spacing tables, replacement can be made with but short delay should they become disabled.

Machining Operations on the Car Steelwork

The machines are served by narrow-gage service tracks running from the material storage yard, special care being taken to unload the material close to the track by which it will enter the shop. The progress of material through the machine shop is as follows: Center sills and side-sill channels are loaded by overhead crane and brought into the shop on service lorries and deposited on trestles opposite the traveler at rear of center- and side-sill web spacing punch No. 775. Two air-operated traversing jacks lift the sills in pairs and place them on the traveler rollers ready to pass through the machine. On the far side of this punch, as shown in Fig. 2, is an elevated runway carrying the traveler head which grips the sills with its projecting jaws and automatically spaces the punching. Along the traveler runway steel templets with projecting pins engage a trip lever suspended on the head of the traveler, close the electric circuit, arrest the travel of the head, and close the circuit of the punch control; the punch then completes the operation. After passing through this machine the sills are released from the jaws of the traveler, lifted by jib cranes as shown in Fig. 2, and deposited back to back on the rollers of sill-flange-spacing punch No. 777, which are placed directly opposite the delivery end of the web punch. On completion of the first operation the sills are disengaged from the head clamp and pushed back over the rollers to the starting point, where they are again turned over by a special device attached to the jib cranes and passed through the machine for the second operation on the opposite flanges. The sills are then lifted by the traveling crane of the inner section of the machine shop and placed on the rollers of coping punch No. 763 directly opposite, where draft-key and lever slots are punched, completing the operations on the sills.

The center-sill and body-bolster cover plates and similar plates are punched on spacing punch No. 750. The side plates are punched on automatic spacing punch No. 764 in a similar manner to the sills, passing through for the first and second operations in pairs.

In all of these operations the passage through the machines is rapid and the accuracy of the spacing mechanism is such that the punching error is slight and far less than it would be were each hole marked off and punched independently.

There are certain parts which cannot be handled satisfactorily on the spacing punches, yet the punching must be equally as accurate or otherwise much of the benefit obtained from the spacing punches is lost when the parts are assembled. The machining of the ends of the side posts and braces is an example of this kind. In this case special combination dies are used to shear the ends to shape and punch the group of holes in one operation.

The bolster cover plates and diaphragms are machined in a similar manner, the cover plates being passed over the spacing punch and the diaphragm flanges punched on one of the coping punches equipped with special dies for punching the flange holes in one operation. During these operations the machine is relieved

of excessive load by varying the length of the punches, resulting in the holes being punched consecutively.

The usual practice for freight-car work is to punch rivet holes to a diameter not exceeding that of the rivet, and, when the parts are bolted together, to ream the holes to a size not exceeding that of the rivet by more than $^1/_{16}$ in.

The Jig Method of Car-Frame Assembly

The erecting of steel-frame box cars by the jig method was originated at the Angus shops. By this method the underframe, side frames, and end frames are assembled on jigs as complete units ready for the final assembly of the car. The jigs consist of stands or cradles by means of which the various members are accurately placed and held in proper relation to each other until they are riveted together. The advantages of this method are manifold. As each member lies flat in the jig, the drawing together of the parts is reduced to a minimum, wedge bolts being used extensively for this purpose as they can be rapidly applied. A complete unit being assembled in one operation, the possibility of accumulative error is avoided. The jigs dispense entirely with checking for squareness, alignment, and location of connection holes, thereby simplifying the final assembly to a considerable extent. Before any of the parts are assembled, all concealed surfaces are painted to prevent corrosion.

The center-sill channels after passing through slot-punching machine No. 763 are skidded from the idler rollers to trestles just inside the erecting shop, where the draft castings are temporarily bolted on and the holes reamed ready for riveting. An electric hoist operating on a runway below and clear of the overhead cranes, swings the sills into position and the draft castings are riveted on by a compression riveter. The individual sills are then moved across to a position on the left where the two center sills are assembled and riveted with bolster center castings and separators in position. The sills are placed on stands on which are four fixed pins corresponding to four rivet holes in the sills at the center line of the bolsters. By placing the sills flange down on these pins perfect alignment of the two sills is assured, which simplifies the application of cover plates later on. The draft gear is also applied in this position.

The next step is the assembling of the underframes, and as this is a lengthy operation, four positions are assigned for the purpose as indicated in Fig. 1. These jigs, as shown in Fig. 3, consist of four steel cradles located at bolster and cross-bearer centers, and so arranged that each member of the underframe is held in proper alignment and at centers that will coincide exactly with connections on the side frames. The bottom cover plates of the bolster and cross-bearers are first placed on centering pins; the overhead crane then places the center sills in position, to which are attached the bolster and cross-bearer diaphragms with their cover plates and center-sill cover plate complete, after which the assembly is bolted together and the holes reamed ready for riveting.

The underframes are then swung over by the overhead crane to the riveting jigs on the right, which are constructed similar to those used for assembling, thereby maintaining the proper alignment. Each riveting position is equipped with two 50-ton compression riveters suspended from swinging jib cranes, the posts of which are in line with columns to the right. The crane jibs are 21 ft. in length with runways for air hoists, the suspension mechanism being so arranged that the riveters can be tilted to drive the rivets in the inclined bottom flanges of the bolster and cross-bearers, which otherwise would have to be driven by an air hammer. The compression riveters were specially designed on the scissors principle, with a thin nose to permit of the top and bottom rows of rivets being driven without turning the underframe over in order to complete the operation.

The side frames, consisting of the side sill, side-plate, posts, braces, door posts, and track, are assembled as a unit on a jig frame situated abreast of the underframe jigs. This jig, as shown in Fig. 4, consists of channel-iron stands, the four corner ones of which are capped with short sections of channel iron in which are holes for locating exactly the side sills and plates. The stands on either side are tied together with angle bars which carry additional cross-bars upon which the various members of the side frames are placed in proper relation to each other. In this position the side frame is temporarily bolted, reamed, and riveted ready for the final assembly position.

Originally the end frames were assembled on jigs similar to those used for the side frames, but in recent years the end-post construction has been replaced by corrugated-steel ends. These steel ends and the end sills are assembled on trestles located between the final assembling tracks, and when temporarily bolted together they are skidded to the second and third positions where they are then reamed and riveted. In the fourth position the end ladders, roof-frame brackets, and other parts are applied, the ends as completed being then placed opposite the final assembling position.

Erecting and Finishing the Cars

As the trucks are assembled and painted, they are delivered from the truck shop and enter the erecting shop by the side door immediately ahead of the underframe and side-frame jigs, where they are turned on a turntable and placed in position on the assembling track. The underframe completed in the riveting jig is then lifted by the overhead crane and placed on the trucks, the slings are released, and a steel end is next placed in position and bolted on the end farthest away from the side-frame jigs; the side frames are then placed in position as in Fig. 5, and finally the second end, along with the center and side-sill cross-ties. The brake-cylinder reservoir and piping are also applied at this time.

The car is then moved by car haul to the second position where the assembled members and the roof framing are riveted in place. In the third position the safety appliances, brake rigging, couplers, uncoupling rods, etc., are applied, the remainder of the riveting completed, and the entire frame as shown in Fig. 6 is then sprayed with the priming coat of paint, when the car is ready for finishing.

The steel frames are switched each day to the wood freight-car shop where the decking, sheathing, roofing, and doors are applied and the painting operations are completed. The decking is of $1^3/_4$-in. red pine and the sheathing of $1^1/_2$ in. Douglas fir, both having tongued-and-grooved joints. High-grade lumber free from knots, checks, or cracks is selected for this purpose and is then kiln dried, the moisture content being carefully limited in order to prevent the possibility of further shrinkage later on; the only objection of any importance raised against the steel-frame box car, as compared with other box cars, having been one arising from improper drying of the sheathing.

Before leaving the planing mill the sheathing, roofing, and running boards receive their priming coat of paint in a painting machine recently developed at the Angus shops and which differs from those in use elsewhere. The boards on leaving the matcher pass automatically through this machine where they are sprayed by a series of nozzles which can be set in any desired position according to the surfaces required to be painted. The paint is drawn up through suction pipes from the bottom of the box by means of air jets blowing across the nozzles, and as ejected it is atomized by the air and blown on to the boards in the form of a fine spray. The amount of paint to be applied is controlled by air valves or by regulating the speed at which the boards pass through the machine. No brushing or wiping is necessary. The boards on leaving the machine are piled on trailer trucks and distributed by tractors to the shops when dry. These machines will paint at the rate of 200 running feet per minute, which is about as fast as the boards can be conveniently piled for drying.

The first operation in the wood freight-car shop is to apply the decking, the joints of which are previously coated with a thick paint compound, as are also the ends of the boards making contact with the bottom boards of the side sheathing previously applied.

The side sheathing which has already received the priming coat of paint is next applied, and to insure that the sides of the car will be watertight, the joints are coated with paint compound, after which they are wedged down into position and bolted to the framing. The end lining is then applied in a similar manner but vertically. In the succeeding operation the roof is applied, the boards and metal sheets of which have previously been primed.

After the doors are hung in place and the remainder of the safety appliances have been installed, the car is given two additional coats of paint and stenciled, when it is complete and ready for service, as shown in Fig. 7.

Recent Developments in Balancing Machines

By CARL RICHARD SODERBERG,[1] EAST PITTSBURGH, PA.

The balancing of rotating machinery is still far from being an exact science, although it has received a great deal of attention during recent years. The balancing of small high-speed motors for domestic use has been neglected to a great extent because satisfactory balancing equipment has not been available. The necessity for balancing this type of rotating apparatus is continually growing with the increase in speed and capacity and the customers' demands for a lasting product. The present paper is a brief description of efforts made to solve this problem and of a balancing machine finally developed that eliminated the difficulties and made it possible to manufacture quietly running motors.

SEVERAL fundamental difficulties, in addition to those encountered in balancing rotors of ordinary size, are involved in the problem of balancing small rotors.

a The balancing operation must be performed in a few minutes because the total cost of each unit is so low

b The high speed necessitates a very accurate balance

c The actual values of the centrifugal forces that are produced by a considerable unbalance are so low that it has been found extremely difficult to obtain an indicating device for the vibrating motion.

Because of these difficulties several attempts to produce a balancing machine for small armatures, operating on the usual principles of separating the static and the dynamic unbalance, have failed. It was decided, therefore, at the beginning of the investigation, to follow a plan that would procure complete balancing in one operation, without previous static balance. Arrangements of this type have been used before, but in these the balance is obtained by three weights, two of which cause considerable inconvenience in computing.

It is shown in an appendix to the complete paper that the general state of unbalance can be corrected by two masses, one in each of two transverse planes of the body. This can easily be understood by recalling the fact that any system of forces emanating from a straight line may be counteracted by two forces.

The most common type of balancing machine now on the market consists of a vibrating table so supported on springs and a fulcrum that the table is capable of performing small vibrations around a fixed axis. On this vibrating member are mounted the rotor to be balanced, a "dynamical image" of this rotor, usually consisting of a variable couple, and a driving mechanism for rotating the body and its image. If the fulcrum axis is parallel with the axis of rotation, the unbalanced dynamic couple is eliminated and the static unbalance can be ascertained and corrected. By shifting the fulcrum axis to a position at right angles to the axis of rotation, the remaining couple will be effective and may be determined and corrected. In both instances the vibrating table performs a forced vibration under the influence of the unbalanced forces in the body, and the amplitude of this motion is increased by adjusting the speed of rotation so that resonance occurs. Thus the sensitiveness of the machine is magnified without undue increase of speed. The original dynamic balancing machine, the squirrel-cage machine, devised by Akimoff[2] several years ago, was the first arrangement of this kind. Quite frequently the static balance is performed on parallel ways.

The static-dynamic balancing machine has the following fundamental disadvantages:

a The static balancing generally increases the magnitude of the unbalanced couple because of incorrect longitudinal location of the correction weights. Thus, the amount of balancing weights is greater than necessary

b The number of places in which correction weights are applied is frequently four and cannot be reduced to less than three, while the theoretical minimum is two

c Any error in the static balancing will have a serious effect on the determination of the couple. The effect of residuary static unbalance is frequently magnified on account of the large moment arm. In order to obtain a balancing result with a certain tolerance it is therefore necessary to perform the static balancing with exaggerated accuracy.

With the disadvantages in the existing equipment and the special requirements for the balancing of small rotors, the following demands were made on the new type of machine:

a Balance should be obtained by adding the theoretical minimum of weights to the body; that is, the two theoretical masses necessary for counteracting the system of unbalanced centrifugal forces should be given in the result

b The balancing operation should be performed with uniform accuracy; that is, the effect of one mass should be eliminated while the other mass is determined

c The balancing operation should take short time and be inexpensive, so that it can be applied to quantity production.

Balancing Machine with Movable Fulcrum

Fig. 1 shows schematically an arrangement whereby the general

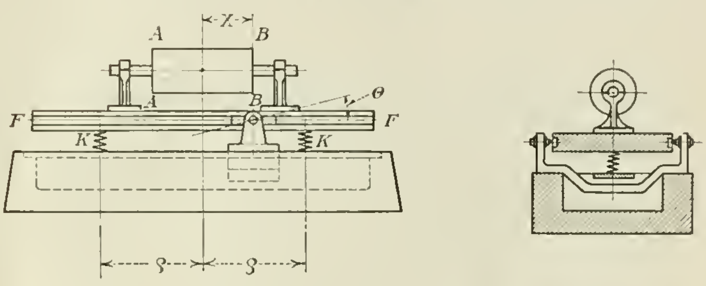

Fig. 1 Schematic Arrangement of Balancing Machine

state of unbalance may be obtained without segregation into static and dynamic unbalance. The body to be balanced is mounted in bearing blocks on a vibrating table supported by two spring members and a movable fulcrum member. This admits of motion around any axis in the plane *F-F* at right angles to the axis of rotation. Assuming that the transverse planes *A-A* and *B-B* have suitable arrangements for the application of correction weights, it is certain, from the above, that any unbalance in the body may be corrected by one weight in each of these planes. By placing the fulcrum axis in one of these planes, say, *B-B*, the theoretical weight in this plane is eliminated as far as its effect upon the motion of the vibrating table is concerned. This will now be produced by the unbalance in the other plane.

If a counterbalancing device for measuring the amount and the angular position of this weight is added to the arrangement, the unbalance may be determined in the same manner as static or dynamic unbalance is determined in the old type of balancing machine. By subsequently placing the fulcrum in the plane *A-A* the effect of the unbalance in this plane is eliminated, and the same procedure may be applied for determining the weight in the plane *B-B*. It is evidently of no importance whether the balancing weights are applied during the operation or not, since the effect upon the vibrating table is reduced in each case to that of one unknown weight. It is also evident that this arrangement meets the requirements.

This arrangement, which has been called a balancing machine with a movable fulcrum, was adopted as the most suitable one for balancing small armatures. There is, however, no indication that its application will be restricted to small rotors.

Features of the First Design

The subsequent design of an operative machine offered a number

[2] Dynamic Balance, by N. W. Akimoff, Trans. A.S.M.E., vol. 38 (1916), p. 367.

Presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y. Abridged. All papers are subject to revision.

of interesting problems. There are two possibilities with reference to the operation of the device:

a Determining the magnitude and the location of the unbalanced masses by means of a counteracting device

b Determining the magnitude of the unbalanced masses by the amplitude of the motion, and the location by "cut and trial" or by "marking" the rotor.

Although these two systems are different, they have no bearing upon the following theories. The first model was built and operated in accordance with the second alternative mainly because unbalance on the type of motors for which the model was built could easily be corrected by inserting wedges into the slots. It seems probable that, in this particular case, no gain could be obtained in speed of operation by applying a counterbalancing device. The following principles relate to either one of these alternatives and will be discussed separately for the sake of clearness.

Speed Variation for Different Locations of the Fulcrum Axis. Since the moment on inertia of the vibrating system varies with the location of the fulcrum axis, it is to be expected that the natural period, and hence the resonance speed, should vary. It has been found, however, that an arrangement can be made in which the restoring element receives a corresponding variation, so that the quotient remains constant. The theoretical explanation is given in a second appendix to the complete paper. Result of this investigation shows that if the two spring members are identical and located symmetrically with reference to the center of gravity of the vibrating bed and at a given distance, the natural period of the system is independent of the fulcrum location. Fig. 2 gives an illustration of the principle for the specific case where the center of gravity of the vibrating system is located in the fulcrum plane.

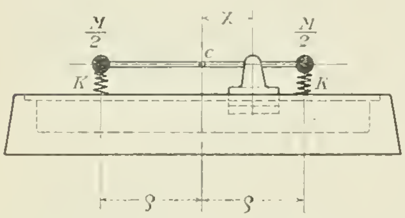

Fig. 2 Special Case with Center of Gravity of Vibrating System in Fulcrum Plane

A constant balancing speed is very essential for efficiency and accuracy. The latter is largely dependent on the degree of resonance, and a slight error in the speed may distort the result altogether. The type of indicating device that was adopted served to increase the importance of constant speed.

Naturally the principle does not admit a variety of armatures to be balanced on the same set-up. As far as small rotors are concerned, they are manufactured in large lots, thus making it necessary to have a balancing machine for each type. When frequent changes have to be made, a vibrating table may easily be supplied for each type of armature.

Indicating Device. The indicating device proved to be a stumbling block. Attempts to use the ordinary type of dial gage indicators failed altogether. There was always the possibility of using the conventional mirror and light beam, but it was not considered practical in production routine. A vibrating reed was finally applied with success. Spring steel 0.125 in. by 0.006 in. is used on the present model and the amplitude of the reed is a tolerably good measure of the angular deflection of the vibrating bed. The resonance of a reed of this type is considerably sharper than the resonance of the vibrating table itself. This is a decided advantage, because erroneous readings are eliminated. It necessitates, however, a constant speed of the driving arrangement.

Driving Mechanism. The requirements for constant speed magnified the importance of the driving motor. Several attempts were made with a small motor mounted on the vibrating table, but without success. The kinetic energy of the rotating masses must be sufficient to resist variation in the friction load. As long as the driving motor is mounted on the vibrating table, its weight must be restricted in order that the vibrating mass may not be too great. In the arrangement used at present the rotor is being driven by a fairly large a.c. motor mounted on the solid foundations. The driving belt consists of a silk ribbon. This arrangement has proved to be satisfactory. The disturbance of the belt is not sufficient to influence the motion of the vibrating bed.

Predetermination of Sensitiveness. The problem of predetermining the amplitude for a given unbalance necessitates a closer study of the factors that limit the motion at resonance, and a better knowledge of the internal friction of springs is therefore of extreme importance. Little work has been done along this line, however, and there are no reliable methods available for the predetermination of the internal friction in springs. It is generally assumed that the damping of a spring is a linear function of the speed, and this appears to be fairly true for small motions. A variation of the spring characteristic for different degrees of compression will also limit the amplitude at resonance, although in a manner different from that of internal friction. If this variation is large it may seriously impair the resonance. The requirements of springs for balancing machines are therefore:

a Straight-line characteristics

b Low internal friction.

The relation of the amplitude, that is, the angular deflection of the vibrating bed, to the unbalanced moment is explained in a third appendix to the complete paper. It is shown that the angular deflection is directly proportional to the unbalanced moment with regard to the fulcrum axis and inversely proportional to the damping factor. This is true for perfect resonance and for the assumption that the damping is proportional to the first power of the speed. It has also been found in this investigation that the major part of the damping effects occurs in the springs themselves. The total damping is therefore a function of the location of the fulcrum axis. The minimum of damping occurs at the central location of the fulcrum. Therefore the amplitude is not a direct measure of the unbalanced moment; it is always possible, however, to place the rotor in such a manner that the readings have the same value for the two planes in which the unbalance is corrected, because the variation of the damping factor is symmetrical with reference to the central location of the fulcrum.

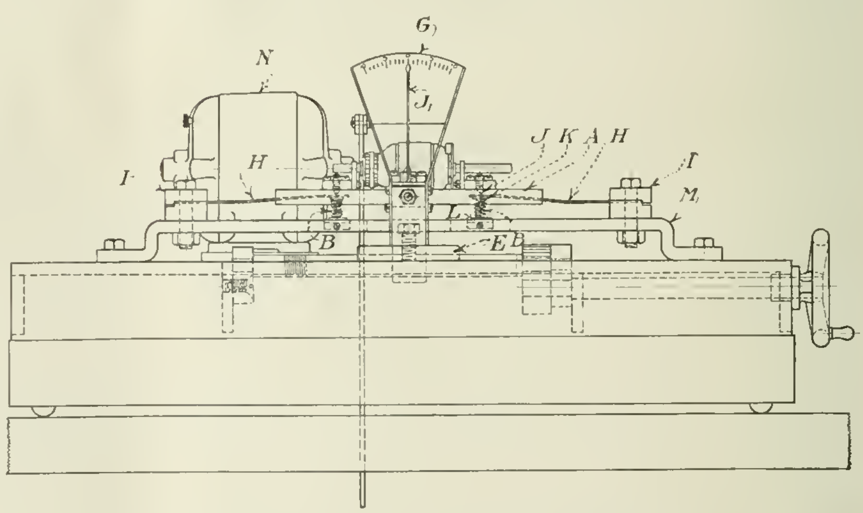

Fig. 3 Side View of Balancing Machine with Movable Fulcrum

There is, however, another factor of importance in this connection. It is theoretically true that if the springs have straight-line characteristics and a sufficiently low internal friction, a small disturbance (unbalance) will produce a considerable amplitude. If the disturbance is small, however, the time required by the vibrating system to absorb sufficient kinetic energy to attain its maximum amplitude will increase. This introduces another element into the problem, namely, the proportion between the moment of inertia of the vibrating system and the magnitude of the disturbance. Common sense tells us that there is a certain limit to the moment of inertia of the vibrating system for each amount of unbalance to be measured, but no attempt has previously been made to establish actual values. In the author's

opinion, the time required for the balancing machine to "pick up" and the amount of internal friction are the two elements that enter into the question of sensitiveness. It is shown in a fourth appendix to the complete paper that this time element is largely dependent on the quantity P/I; that is, the proportion between the unbalanced moment and the moment of inertia of the vibrating system. The minimum value of P/I will thus be a logical measure of the sensitiveness of the balancing machine. Below are given minimum values of P/I that were obtained in the model with a movable fulcrum and three other balancing machines of the usual type.

	Value of $(P/I)_{min}$
1 Model with movable fulcrum	15×10^{-6}
2 125–500-lb. balancing machine	0.6×10^{-6}
3 500–3000-lb. balancing machine	0.45×10^{-6}
4 3000–10,000-lb. balancing machine	0.4×10^{-6}

These values were obtained by experiments on the balancing machines. They are influenced, therefore, by the following factors:

a The nature of the indicating device
b The damping factor
c The actual value of the moment of inertia of the vibrating system with regard to the axis of oscillation.

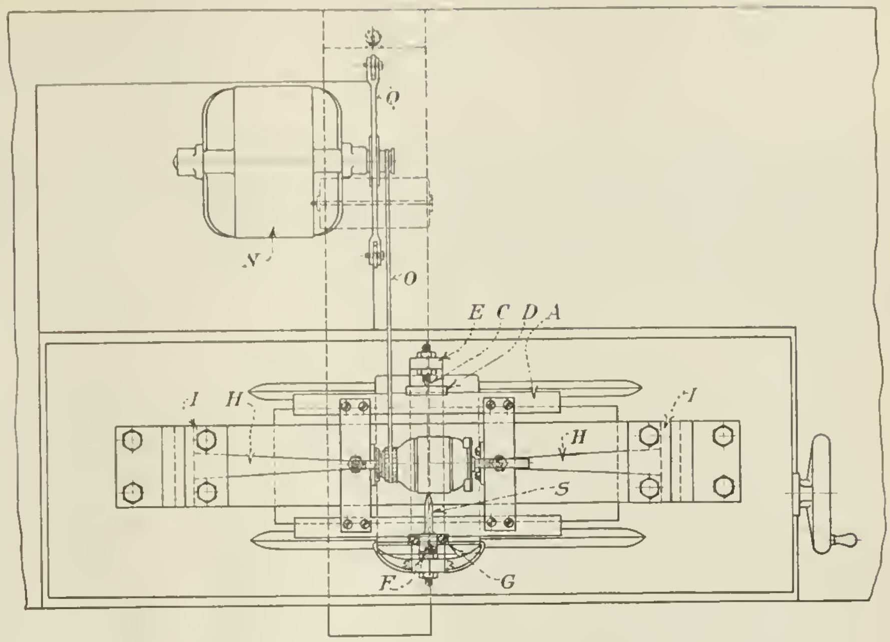

Fig. 5 Plan View of Balancing Machine with Movable Fulcrum

The model with a movable fulcrum has an indicating device which records the angular deflection of the vibrating bed so that only the sensitiveness of this device (amplitude per radian) enters into the expression P/I. The other machines, however, are equipped with dial gage indicators so that in the sensitiveness of the indicator is also included its distance from the axis of oscillation. This distance is usually made as large as possible. The larger machines therefore have the advantage of a more sensitive indicator. The dial gage indicators on these machines are all of the same type. A total amplitude of 2 deg. (0.002 in. linear motion) is considered the minimum detectable motion.

The damping factor and the moment of inertia are variable in the model with a movable fulcrum. Therefore, the value of P/I refers to the central location of the fulcrum.

The balancing machines in cases 2, 3, and 4 are of the same type. They show a tolerable consistency in the minimum value of P/I with a slight increase for the lower capacities. The model with a movable fulcrum has a capacity of an entirely different order and the value of P/I is increased correspondingly. This illustrates the difficulty in obtaining an accurate balance of small rotors. In order to keep the minimum unbalance sufficiently low it is necessary to have the moment of inertia of the vibrating system exceedingly small.

It would be highly desirable if the limiting values of P/I could be learned when a balancing machine is purchased. The buyer would then be able to tell if the lower limit is consistent with the accuracy of balancing that he wishes to obtain on the smallest rotor to be balanced. At the present time balancing machines are rated with reference to the maximum and minimum weights of rotors to be balanced. The upper limit may be necessary from the point of view of stresses in the mechanical structure. The lower limit does not, however, give reliable information with regard to the accuracy of balancing.

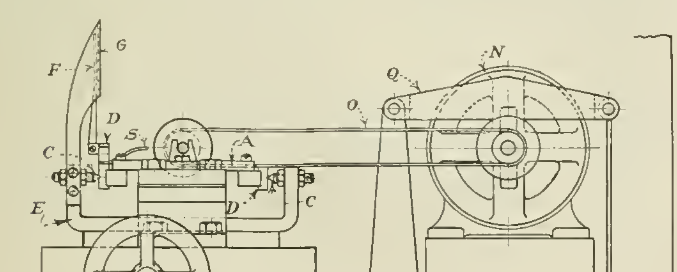

Fig. 4 End View of Balancing Machine with Movable Fulcrum

Description of First Model

Figs. 3, 4, and 5 show a balancing machine with movable fulcrum adapted to balance an electric armature weighing about 9½ oz. Fig. 3 is a side view, Fig. 4 an end view, and Fig. 5 a plan view. The machine is shown mounted on a working bench with a foot-operated starting and braking arrangement of the driving motor.

The vibrating bed *A* is supported by the coil springs *B* and the pivots *C*. These pivots engage in centers on the sliding blocks *D* so that by moving the carriage *E* the axis of oscillation is moved relatively to the armature. The location of the pivots with reference to the armature is indicated by the pointer *S*. One of the sliding blocks carries the vibrating reed *F*, which vibrates across the graduation on the scale *G* attached to the carriage *E*. The indications of the reed are therefore proportional to the angular deflection of the vibrating bed.

The bed is prevented from moving in the horizontal plane by the flat springs *H*, clamped in the blocks *I*. These flat springs press against the knife edges *J* which have center pins engaging in centers on the caps *K* of the coil springs. The flat springs have slots to fit these pins. The slots are machined so that there is practically no clearance in the lateral direction but a considerable clearance in the longitudinal.

The coil springs are supported on the longitudinal member *M* by the adjustable seats *L*. Thus the length of the springs may be adjusted so that the entire weight of the vibrating system is carried by the springs. In this case the pivots carry no other load than that of the inertia forces. The carriage *E* moves underneath the spring-supporting member *M*. This admits of moving the fulcrum member past the springs if desired.

The driving motor *N* is a single-phase induction motor starting as a repulsion motor. The load is very small so that it runs at

The Development of Industrial Safety Codes

By M. G. Lloyd,[1] Washington, D. C.

After giving statistics showing the need for accident-prevention work from both the humanitarian and the economic viewpoint, this paper shows the value of state inspections and national codes. It then presents a brief history of the American Engineering Standards Committee's activity in this field and of the Safety Code Correlating Committee. The paper closes with an outline of the manner in which safety codes are now formulated.

The past dozen years have shown a growing interest in accident prevention and a rapid development of activities for the elimination of casualties. The extension of compulsory compensation laws, which now cover all but the District of Columbia and five states of the Union, has given accident prevention in industry an economic status which it did not previously possess. Prior to this era claims for damages by employees could be resisted in the courts by employers and the defense of contributory negligence acted to eliminate many such claims. Under the present compensation laws, however, the payment of such claims has become more certain and definite in amount. Compensation insurance is very general and its cost is in most cases dependent upon the accident experience of the policy holder. There is consequently a very definite economic incentive for the reduction of industrial accidents.

In the fiscal year ended June 30, 1920, the Federal Government spent about $1,350,000 for accident prevention and sanitation work in industry, representing an expenditure of about 1.3 cents per capita. The part of this amount used for accident-prevention work in the manufacturing industries represents an expenditure of about 8 mills per thousand dollars of value of manufactured products. In the case of mineral products the disbursement is about 9.5 cents per thousand dollars of value of products.

Most of the states have a department of labor or industrial commission administering compensation, and many of them have authorized such commissions o undertake work for the prevention of accidents or else provide an independent state factory inspector. In 1919 the various states spent for accident-prevention work $2,723,000, or about twice as much as the Federal Government spent for safety and related purposes.

No reliable estimate can be made of the amount of money expended each year by the industries themselves in improving the physical conditions of their plants and in other activities related to accident prevention. In addition to such expense they must also meet compensation costs, attorneys' fees, and other expenses occasioned by accidents. The expenses of many individual corporations annually in connection with accidents and safety work mount into six figures, and the total for all industries must run into many millions. The railroads of the country alone paid out in 1917 over $33,000,000 chargeable to accidental injuries. There were in that year 10,087 fatalities and 210,729 cases of injuries. The average cost was thus over $150 per accident.

This immense waste of human resources has both a humanitarian and an economic aspect. The economic waste involved is of great importance to industry. So far as it depends upon physical conditions of plant equipment and operation it can be largely eliminated by compliance with the principles of accident prevention which it is the function of safety codes to apply in detail to specific industries or operations.

State Inspection

The principal activity by which the state officials can reduce accidents is the inspection of factories and other work places and insistence that they shall be so constructed and operated as to provide for the safety and health of employees. In making such inspections it is necessary that the inspector should have some standard of comparison by which to judge of the conditions which he encounters. Only by having such a standard of reference is it possible for different inspectors to treat different cases upon a uniform basis or even for a single inspector to be consistent in his decisions with reference to different industrial plants. Such a standard may exist only in the mind of the inspector and be subject to development and change from day to day. Much more satisfactory results, however, can be obtained by having written standards subject to change only by definite action of the administrative authority and capable of being known to factory managers, manufacturers of machinery, and others concerned with them before installations are made. It is then possible for such persons to plan their installations so as to meet the requirements of the state officials. In that way more complete compliance on a more satisfactory basis is obtained.

It will be apparent that the greatest satisfaction to both inspector and factory manager will result from inspections and the enforcement of regulations when the latter consist of a definite set of written rules which have been given full consideration before adoption and which are applied uniformly by all inspectors within a given jurisdiction and are modified only by definite administrative action after due notice and full consideration. Consequently most of the states which are active in factory-inspection work have definite regulations, and it is the duty of their inspectors to see that such regulations are complied with.

These regulations may take the form of statute laws or of rules promulgated by some administrative authority. Where the regulations are established by statute it is impossible to alter or amend them except by the same legislative process. Where the regulations are promulgated by administrative authority, changes and amendments can be made from time to time as experience or progress in the art makes it advisable to do so, and a system which is more flexible and in general more satisfactory to all parties concerned is obtained.

Whatever legal form the regulations may take, it is desirable that they be as definite as possible, be so drawn up as to be easily understood, be available in printed form for the guidance of all interests concerned, and be given very thorough consideration by all parties and interests before their mandatory adoption.

Such a code of safety rules is valuable not only for mandatory enforcement by administrative authorities and for authorized inspectors, but as a guide to the industry concerned in improving its methods and modifying its previous practices. Many manufacturers are only too glad to make improvements in the physical condition of their plants when the possibility of such improvements is pointed out to them, and many of them are eager to apply any information which will improve the welfare of their employees. The greatest value of the safety code is probably in providing such information as a standard for the guidance of the factory manager, and the author considers its usefulness as a regulation for legal enforcement to be secondary to this.

Advantages of National Codes

Most of the safety codes heretofore adopted and enforced by state boards and commissions have been developed locally and usually with the coöperation of a committee representing local interests. In the preparation of such codes, use is frequently made of standards already adopted by other states or by industrial and engineering associations. In some cases such standards already available are adopted without change, but more often changes of greater or less extent are made for the purpose of improvement or of meeting some real or fancied need caused by local conditions. This is well illustrated by the Boiler Code prepared by The American Society of Mechanical Engineers and the Electrical Safety Code prepared by the Bureau of Standards. If the national codes were generally prepared by processes which would take into consideration local variations and conditions, and which guaranteed the full consideration of the viewpoint of every interest involved and freedom from domination by any one interest, particularly such as might

[1] Chief of Safety Section, U. S. Bureau of Standards; vice-president. American Society of Safety Engineers.

Presented at a joint session of the American Society of Safety Engineers and the A.S.M.E. Safety Codes Committee at the Annual Meeting, New York, December 4 to 7, 1922, of The American Society of Mechanical Engineers. Slightly abridged. All papers are subject to revision.

be of a commercial character, it would seem advantageous to adopt such national codes without the introduction of local variations. This would give the advantage of uniformity in requirements in different jurisdictions. The manufacturers of equipment could then supply a single line for use in all states, thus reducing production costs, and the work of the contractor and inspector would be simplified. It would also be easier for the insurance companies to harmonize their own requirements with those legally enforced by the state authorities. As it has been in the past, and is now, the requirements of state inspectors and insurance inspectors are frequently different, resulting in confusion and friction, and a disinclination upon the part of the factory manager to comply with either. If these standards were made uniform, and all concerned with safety agreed upon the physical conditions for attaining it, there would be greater readiness to follow such standards in practical shopwork.

To obtain national codes of this character it is necessary that their preparation be accomplished by the widest and most thorough consideration of those familiar with the particular problems of the industry concerned and that full weight be given to the viewpoints of all interests involved.

Realizing the importance of safety codes prepared upon a national basis, and as the result of the contacts made by its previous work in this field and the demands for more extensive work of the same character, the Bureau of Standards called a preliminary conference on this subject in Washington in January, 1919, and a second conference in December of the same year. At these conferences the subject was fully discussed, the need for national codes generally recognized, and the best method for preparing them given full consideration. It was finally agreed that the scheme of procedure in establishing national standards which had been inaugurated by the American Engineering Standards Committee would be the most satisfactory to utilize in the preparation of safety codes, and it was finally voted by a large majority that they should be prepared under the auspices of this committee. It was realized, however, that in order for this plan to be widely acceptable it would be necessary to enlarge the scope and membership of the American Engineering Standards Committee, and this was done as a direct result of these conferences.

Safety Code Correlating Committee

As a result of the 1919 conferences a National Safety Code Committee was formed which is now known as the Safety Code Correlating Committee. It acts as an advisory body to the American Engineering Standards Committee in all matters relating to safety codes, its membership being such as to give it more direct contact with the desires and needs of those most intimately concerned with safety matters. Its present membership includes representatives of the following:

- American Gas Association
- The American Society of Mechanical Engineers
- American Society of Safety Engineers
- Association of Governmental Labor Officials
- International Association of Industrial Accident Boards and Commissions
- National Association of Mutual Casualty Companies
- National Bureau of Casualty and Surety Underwriters
- National Electric Light Association
- National Fire Protection Association
- National Industrial Conference Board
- National Safety Council
- U. S. Bureau of Labor Statistics
- U. S. Bureau of Mines
- U. S. Bureau of Standards

The first report of this Committee in 1920 included a list of thirty-seven codes which were considered of the most immediate importance and for which sponsor bodies were recommended. Since that time it has made additional recommendations from time to time and the Engineering Standards Committee has referred to it questions concerning safety codes which required investigation before decision.

The members of the Safety Code Correlating Committee are frequently designated by the chairman of the Engineering Standards Committee to serve upon special committees which investigate the make-up of Sectional Committees for safety codes or advise the Engineering Standards Committee as to the suitability of approval of standards in this field which have been submitted to it. The Committee thus functions in general to advise the Engineering Standards Committee and keep it informed when necessary on matters relating to the field of safety codes.

The Preparation of Safety Codes

When, after recommendation from the Safety Code Correlating Committee, the American Engineering Standards Committee recognizes the need for the development of a particular safety code, it designates one or more sponsors to manage the formulation of such a standard and the sponsor body organizes a Sectional Committee containing representatives of all organizations which are considered to have an interest in the development of this particular code. Such Sectional Committees usually contain representatives of the following groups of interests:

- Manufacturers of the equipment
- Employers
- Employees
- Regulatory government representatives
- Technical experts
- Casualty-insurance companies

The Sectional Committee must have its make-up approved by the American Engineering Standards Committee as being properly representative and well balanced as to interests which may have different viewpoints. This Sectional Committee may itself carry out the work of formulating a standard or it may merely pass upon such work when it has already been done, and is free to modify any standard before its adoption. When the Sectional Committee agrees that a standard or code is in acceptable form for final adoption it reports to the sponsor, and if the sponsor body is satisfied with its work and approves it, it so reports to the American Engineering Standards Committee. That Committee then approves the standard as an American Standard, as a Tentative Standard or as Recommended Practice.

The American Engineering Standards Committee has already approved eight standards which may be classed as safety codes, as follows:

- Industrial Lighting Code
- Safety Code for the Use, Care, and Protection of Abrasive Wheels
- National Safety Code for the Protection of the Heads and Eyes of Industrial Workers
- National Electrical (Fire) Code
- National Electrical Safety Code
- Foundry Safety Code
- Power Press Code
- Permissible Explosives

More than twenty other safety codes are now being actively worked upon and some of them are about completed. Almost an equal number in addition have been given preliminary consideration.

It will be apparent from the foregoing that the American Engineering Standards Committee, with the coöperation of the Safety Code Correlating Committee, furnishes the machinery for the formulation of safety codes in a manner which will insure thorough consideration of the merits of proposed rules and thorough consideration of the viewpoint of the various interests which are concerned with safety codes. The actual formulation of such codes may be by a Sectional Committee, by a working sub-committee of such Sectional Committee, or by the technical staff of a sponsor body, but in every case the entire Sectional Committee must pass upon the work and approve the tentative draft of a code before it is submitted to the American Engineering Standards Committee. The Sectional Committees are made up of representatives from the six groups previously mentioned and in the case of safety codes always include some representatives from state departments of labor or industrial commissions. When such codes have been approved by the American Engineering Standards Committee the assurance is given that they have had just as thorough consideration as is ever given locally to the formulation of a state code, and in most cases they will have had wider consideration and criticism; and in adopting such a code any state authority may feel sure that he is putting into effect as reasonable and as complete a set of rules as it is feasible to formulate at the time. Such codes may consequently be taken as models for local adoption and application and there will usually be no good reason for modifying the form in which they have been nationally approved.

SURVEY OF ENGINEERING PROGRESS

A Review of Attainment in Mechanical Engineering and Related Fields

AERONAUTICS

The Reed Solid-Metal Semi-Flexible Propeller, S. Albert Reed. Description of a new propeller which is said to be marketed by the Curtiss Company. It is a semi-flexible, solid, thin one-piece metal propeller of about the same weight as a wooden propeller. It is claimed that it can be twisted to varying pitches and twisted back again, permitting combinations of two-bladed propellers to make four at will and turning at the velocity of sound.

The original article describes in some detail the principles underlying the design and tests made with the propeller, particularly those at McCook Field. (*Aerial Age*, vol. 16, no. 4, Apr., 1923, pp. 182–185, 6 figs., *d*)

Light Plane and Glider Notes. A competition probably to be held some time in September has been arranged for in England for light planes fitted with engines not exceeding 750 cu. cm. capacity.

In this connection it is stated that Barbot has been recently flying at Toulouse, France, with a machine fitted with a 7–10-hp. motorcycle engine. He took it up to a height of about 1500 ft. and made a cross-country flight. It is further stated that the machine requires only 4 hp. to keep it in the air and that the maximum speed is about 60 miles per hour. The machine is called the "Dewoitine."

In England a light plane has been designed by W. O. Manning for the English Electric Company and fitted with a two-cylinder A.B.C. motorcycle engine nominally of 4 hp. but developing about 7 or 8 hp. This machine was tested by Squadron Leader Morris Wright, first in straight flight and then in a flight of seven minutes' duration with satisfactory results.

The "Wren," as this design is called, is an ordinary glider in appearance with enclosed fuselage and a cantilever wing with a pronounced dihedral, and the under carriage nearly hidden in the fuselage. The engine drives directly a tiny tractor screw.

In this glider both the pilot and the engine are in front of the wing and yet the machine is not nose heavy, which may be due to the fact that the tail is set at a large negative angle. (*Flight*, vol. 15, no. 15, 746, Apr. 12, 1923, pp. 199–200, 2 figs., *d*)

Lacierva Autogiro Aeroplane

New Type of Flying Machine—The Lacierva Autogiro. Description of a machine designed by the Spanish inventor Juan Lacierva and tested near Madrid by an officer of the Spanish army.

The "Autogiro," as the machine is known, is not a helicopter. In it the large four-bladed screw which is mounted on the vertical shaft fixed on the fuselage is not actuated by any power plant. Instead it is made to turn freely on its bearings. It is therefore really a wind vane which operates like the small propellers which are used to actuate the fuel pumps of aircraft engines or wireless generators.

This big vane is mounted in ball bearings and is not controlled by the pilot. The blades of the vane are set at a fixed angle of incidence relative to the axis of rotation, but they are hinged to the bearing shaft in such a way that in flight they place themselves in the resultant of their lift and the centrifugal force.

Outside of these vanes the machine is an ordinary tractor aeroplane. The following is given to explain the principles involved in its operation.

It is known from experiments that when a stationary airscrew is exposed to an air current, the blades, being in position *A* (Fig. 1), have a resultant *R* which makes an angle with the airscrew shaft. The resultant *P* of the opposite blade (position *B*) has always a smaller angle than *A* or is negative. Therefore a rotation is established by the airscrew in the sense of the arrow. The speed of rotation will increase until the resultant of *R* and *P* is parallel to the axis of rotation of the airscrew. The whole lifting body does not transmit to its shaft any torque except the one produced by the friction of the bearings, which can be neglected, therefore eliminating the necessity of using two propellers.

However, the resultant velocity of the blades relative to the air in position *A* is greater than in *B* and its lift will be greater also. Therefore the total resultant of this airscrew will not pass through its center and the whole system will tend to bank. This banking effect has been overcome in the Autogiro by fixing the

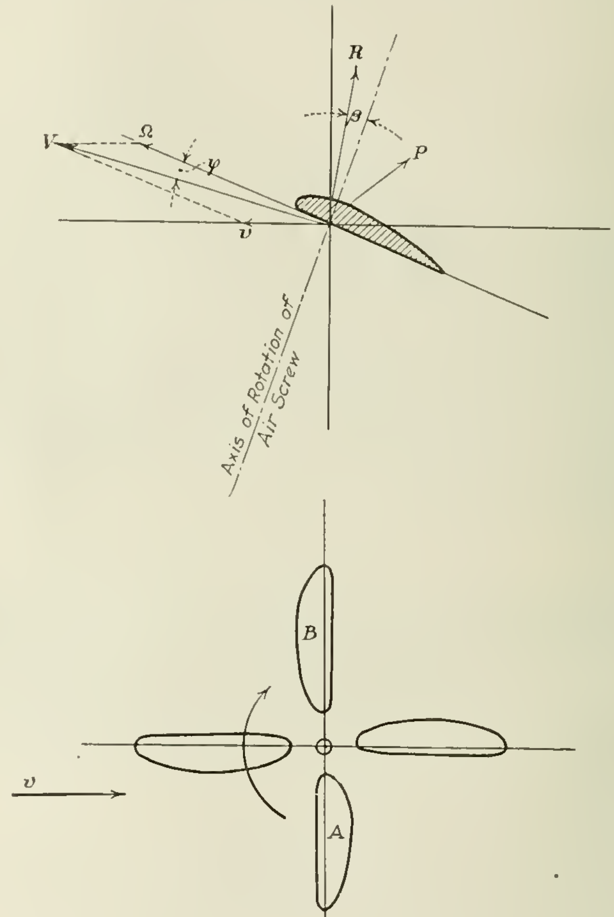

Fig. 1 Wind Vane of the Lacierva Autogiro

blades to the shaft by means of a hinge, which permits them to set themselves automatically in the resultant position of the centrifugal force and lift. In such a way blades *A* will bank slightly, while blades *B* will remain horizontal and the total resultant of the lifting airscrew will always pass through its center.

If we analyze the effect of the hinged blades of the vane, we see that the shaft can freely change its angle with the plane of rotation of the blades, but that the blades have a strong tendency to return to their original position relative to the shaft. This gives an automatically perfect banking in the turns and stability in flying.

The velocity of the blades relative to the air is much greater than the translational speed of the whole machine. The angle of attack is a function of the translational speed of the machine and the angle between its direction of motion and the plane of rotation of the blades. This allows a much greater range of speeds and angles of flying to the whole machine, and will permit landings in very small spaces without horizontal motion.

It is stated that in tests it did land with the engine shut off with practically no forward speed and that it has remarkable stability for it can be flown without assistance of any lateral control while the elevator controls could be locked for any length of time without influencing the behavior of the machine. (*Aviation*, vol. 14, no. 15, Apr. 9, 1923, pp. 397–398, 2 figs., *d*A)

BUREAU OF STANDARDS (See Engineering Materials; Refrigeration)

ENGINEERING MATERIALS (See also Refrigeration)

West African Palm Oil Manufacture and Uses

West African Palm Oil, "Agricola." Down to quite recent years virtually the whole of the palm oil produced in West Africa has been laboriously and crudely prepared by hand labor, chiefly that of women and girls, while the quality of the product has been admittedly below attainable standards; moreover, it has long been known that enormous quantites of oil are lost annually in consequence of the wasteful methods adopted.

The situation would seem to present a splendid opportunity for the introduction of machinery, and it is remarkable that only within the last decade or so have serious attempts been made to tackle the question.

At the present time, however, serviceable machinery is being employed which removes the pericarp from the fruits, the oily pulp being then transfer ed to presses where the expression of the oil is effected under controlled conditions of temperature.

The employment of such machines effects great economies in production, and also results in the production of a clean oil of good, dependable quality. So far, plant of this kind is almost entirely in the hands of European companies.

The palm "nuts" which were separated from the oily pericarp, and set aside for subsequent treatment, have now to be dealt with in order to obtain the kernels.

As the first step, the nuts are spread out in the sun for a week or more in order to cause the kernels to shrink from the shells and so render their removal easy.

The subsequent procedure, however, is almost incredible. Millions upon millions of palm kernels are exported from West Africa every year, yet, until comparatively recently, every single kernel has been obtained by the deliberate cracking by hand, between two pieces of stone, of the separated individual nuts, one by one, followed by the picking out, separately, of the individual kernels.

Effective machines for this purpose are now available, but in spite of their increasing use (chiefly by European undertakings), the great bulk of the palm nuts are still cracked by hand.

The kernels are collected and shipped to Europe where the oil is obtained either by pressure in machine presses, or extracted by solvents from which the oil is obtained subsequently by evaporation.

The nut shells form a good fuel, but at present have no regular industrial use. During the war, however, palm-nut shells (as in the case of cocoanut shells) were largely used for the manufacture of a charcoal which was found to be admirably suited for use in gas masks as an absorbent of noxious fumes.

The primary value of palm oil to the West African native is as a foodstuff which is chiefly used as an oily basis for the preparation of soups, stews, and dishes of all kinds; and "palm-oil chop" is familiar enough to Europeans on the Coast.

The oil used for this purpose is usually carefully prepared from fresh fruit, and has considerable dietetic value. When fresh it has an odor of violets, and is much appreciated by the natives.

In certain districts the natives are also acquainted with the use of the oil for making soap, which they prepare by mixing the oil with ashes obtained by burning banana leaves. This fact is interesting, since the manufacture of soap and candles is one of the chief uses to which palm oil is put in industrial Europe, especially in this country, where enormous quantities are employed for soap making.

Another important use is in the Welsh tin-plate trade, where palm oil (commonly mixed with cottonseed oil and certain mineral oils) is extensively used for coating the heated iron plates previous to the "tinning" process, in order to prevent oxidation. It will also be remembered that, as mentioned in a recent issue of *Imperial Commerce*, oil engines have now been designed which successfully use palm oil as a fuel.

The oil from the kernels (palm-kernel oil) finds somewhat different uses. Like palm oil it is solid fat (white) at temperatures obtaining in this country. Relatively small quantities of the kernels are used locally, the bulk being exported.

Before the war this trade was very largely in the hands of Germany, as is shown by the fact that in 1913 of a total export of 174,720 tons of palm kernels from Nigeria, valued at £3,109,820, no less than 131,886 tons, valued at £2,405,624, were sent to Germany, the British import being only 30,345 tons valued at £511,541. Further, Germany in the same year obtained an additional 100,000 tons of kernels, worth over £1,000,000 from other West African countries, British and foreign. During the war, however, the kernels were sent to this country and an important trade in them has been built up which it is hoped will be retained.

Two products are obtained from the kernels, viz., white palm-kernel oil, and oil cake.

The oil has a pleasant nutty taste and is used not only for making soap and candles but also to an increasing extent for the manufacture of margarine, vegetable butters, cooking fats, and fats used in making chocolates and confectionary. The oil is well suited for margarine, and it is estimated that probably 40,000 tons are now used annually in Europe for this purpose.

The oil cake is a most valuable feeding stuff for live stock and is especially useful as a food for dairy cattle, for which purpose it was highly prized in Germany and other European countries. In this country, however, it is by no means widely known. (*Imperial Commerce and Affairs*, Aug., 1922, abstracted from a publication of the Bureau of Foreign and Domestic Commerce, Department of Commerce, 9 pp., *gd*)

Chromizing

Chromizing, F. C. Kelley. Paper giving a brief summary of the work which has been done to date on the diffusion of metals in the solid state and describing in detail the process of chromizing and its effects on the physical and chemical properties of iron.

The method of chromizing described by the author is somewhat similar to the well-known process of calorizing and depends upon the property possessed by many metals of diffusing at temperatures below their melting points.

The process consists of packing the material to be treated into a powdered mixture of alumina and chromium. The amount of the material used in the mixture is 45 per cent of alumina and 55 per cent of chromium by weight. The material is usually packed into a tube of iron, and then heated at 1300 to 1400 deg. cent. in hydrogen, in vacuum, or in some neutral atmosphere for a length of time depending upon the penetration and concentration of chromium desired. Certain precautions as to the presence of oxygen and water vapor have to be observed.

The furnaces used for this work consist of alundum tubes wound with molybdenum wire as a heating wire. These tubes are placed in a suitable furnace casing and surrounded with alumina powder, which acts as a heat-insulating material. The chief use for these furnaces thus far has been in the chromizing of turbine buckets, which latter have been installed in various turbines throughout the country in order to test them for corrosion under actual operating conditions.

The structure of the metal is next discussed and illustrated by photomicrographs. In order to get the best results it is necessary to use an iron or steel of low carbon content, as iron of high carbon content does not chromize well. The difficulties of the process are discussed and data given as to the penetration of the chromium into the material.

As regards resistance to corrosion, chromized-iron samples were tested alongside with sherardized samples and gave equally good results.

The samples under test showed up so well that additional tests upon turbine buckets were made. These chromized nickel-steel buckets proved so satisfactory that it was decided to put them into various turbines throughout the country, and into some of the turbines of ocean-going vessels. The best comparison of

resistance to corrosion of chromized and unchromized turbine buckets under service conditions is illustrated in a figure in the original paper. These buckets were run side by side in the same wheel of a turbine for one year. The unchromized nickel-steel bucket had its edge entirely corroded and eroded away, and in addition the face of the bucket was badly corroded. The chromized bucket was in perfect condition, showing no signs of corrosion.

In cases where the chromized material must stand high tension and fatigue stresses, the high temperature of chromizing lowers the resistance of the material to these stresses, but by proper heat treatment the original properties may be almost entirely restored.

Carbonizing of chromized iron lowers its resistance to corrosion, and polished samples of chromized iron which have been case-hardened will show numerous globules of water if allowed to stand in the open air for only a short time.

Chromized iron itself is quite soft and ductile, but by case-hardening and heat treatment it may be made very hard.

Chromized-iron samples were tested in 10 per cent HCl, HNO_3, and H_2SO_4. They stood up for five months in the 10 per cent HNO_3 without discoloring the solution or showing any signs of attack, but they broke down almost immediately in the other two acids.

In addition to these characteristics, chromized iron has a silver color, it takes a high polish, and the most remarkable thing about it is its softness, even where large percentages of chromium are present.

Chromium may be applied to other metals besides iron and may be used for purposes other than preventing corrosion. (Paper presented before Forty-third General Meeting of the American Electrochemical Society, May, 1923. Abstracted from advance copy, pp. 233–250, 8 fig., *eA*)

Lathe Breakdown Tests of Some Modern High-Speed Tool Steels, H. J. French and Jerome Strauss. This report is concerned with comparisons of performance of modern high-speed tool steels in so-called "lathe breakdown tests," in which endurance of tools is measured under definite working conditions, and likewise with the limitations of this method when applied to the purchase of steel. The modern steels are first classified according to chemical composition, and this division is made use of in discussion of results obtained.

Important features developed or conclusions drawn may be summarized as follows:

1 Breakdown tests are not satisfactory as the basis of purchase for high-speed tool steels.

2 While competitive comparison of brands of nearly similar performance are not justified, owing to the qualitative nature of this type of test, relatively large differences may be ascertained with certainty, provided sufficient tools are tested and averages of at least two grinds are used in the interpretation of results.

3 In certain severe breakdown tests with roughing tools on 3 per cent nickel-steel forgings, in which high frictional temperatures were produced, it was found that the performance of commercial low tungsten-high vanadium and cobalt steels was superior to that of the high tungsten-low vanadium type, and special steels containing about $^1/_4$ per cent uranium or $^3/_4$ per cent molybdenum. The average power consumption in all cases was practically the same, so that this factor need not be introduced in comparisons which may be made on the basis of endurance of the tools.

4 Modification in test conditions, including small changes in tool angles but principally changes in cutting speed, more markedly affected the performance of steels containing cobalt or special elements such as uranium or molybdenum than that of the basic types (plain chromium-tungsten-vanadium steels).

5 The relatively poor endurance of the high-tungsten steels under severe working conditions was not observed in more moderate tests which were made on the same test log with equal cutting speed and depth of cut but with reduced feed, and in which the frictional temperatures produced were not so high. Also in these latter tests the performance of the cobalt steels was better than that of either the low- or high-tungsten steels.

6 Hardness determinations and examination of fractures indicate that the various types of commercial high-speed steel show differences in behavior under heat treatment and in physical properties which probably are of importance under moderate working conditions, and might counterbalance slight advantages in performance. (Abstract of *Technologic Paper of the Bureau of Standards*, No. 228, *e*)

Solders for Aluminum. All metals or combinations of metals used for aluminum soldering are electrolytically electropositive to aluminum. A soldered joint is therefore rapidly attacked when exposed to moisture and disintegrated. There is no solder for aluminum of which this is not true.

Joints should therefore never be made by soldering unless they are to be protected against corrosion by a paint or varnish, or unless they are quite heavy, such as repairs in castings, where corrosion and disintegration of the joint near the exposed surface would be of little consequence.

Solders are best applied without a flux or by using paraffin as a flux, after preliminary cleaning and tinning of the surfaces to be soldered. The composition of the solder may be varied within wide limits. It should consist of a tin base with addition of zinc or of both zinc and aluminum, the chief function of which is to produce a semi-fluid mixture within the range of soldering temperatures.

Suggested Ranges of Composition

Tin-Zinc Solders:	
Tin	remainder
Zinc, per cent	15-50
Tin-Zinc-Aluminum Solders:	
Tin	remainder
Zinc, per cent	8–15
Aluminum, per cent	5–12

The higher the temperature at which the "tinning" is done, the better the adhesion of the tinned layer. By using the higher values of the recommended zinc and aluminum percentages given above, the solder will be too stiff at lower temperature to solder readily and the workman will be obliged to use a higher temperature, thus securing a better joint. A perfect union between solder and aluminum is very difficult to obtain.

The joint between previously tinned surfaces may be made by ordinary methods and with ordinary soft solder. Only the "tinning" mixture need be special for aluminum.

There is no reason why a good solder for aluminum need be brittle as several commercial varieties are, and it is very undesirable that it should be.

The tensile strength of a good aluminum solder is about 7000 lb. per sq. in.; those with higher tensile strength have, in general, their temperature of complete liquidation too high for soldering purposes. The strength of a joint depends upon the type and upon the workmanship. Much dependence should not be placed on the strength of a joint. (*Circular of the Bureau of Standards*, no. 78, Mar. 20, 1923, 14 pp., 7 figs., *dp*)

Some Tests of Steel Wire Rope on Sheaves, Edward Skillman. Tests on wire ropes on sheaves, to determine their strength under static load, were made on sizes $^5/_8$, $^3/_4$, $^7/_8$, 1 and $1^1/_4$ in. in diameter. They were all of 6-strand, 19-wire construction, made from "plow" steel.

It was found that the strength was less than that of the straight rope having socketed ends. Considering the strength of the straight rope as unity, the strength of $^5/_8$-in. rope on 10-in. sheaves was 87.4 per cent and on 18-in. sheaves 95.3 per cent, while $1^1/_4$-in. rope had a strength of 75.8 per cent on 10-in. sheaves and 84.7 per cent on 18-in. sheaves. The other sizes had corresponding values.

Tensile tests of wires from the ropes showed that the wires had the high strength of 230,000 lb. per sq. in., an elongation of 2 per cent, and a reduction of area of about 46 per cent. The strength was practically the same for all series of the wires.

The strength of the straight ropes followed closely the equation $S = 83{,}000\ d^2$, in which S is the strength in pounds and d the diameter of the rope in inches.

One worn rope which was tested showed a surprisingly high strength when its condition is considered.

A point of inflection in the load diagrams was found at from 56 to 65 per cent of the ultimate load, above which the elongations increased rapidly.

A wire rope under tensile load undergoes considerable elongation and reduction of diameter. The total elongation near the ultimate was about 2.5 per cent after repeated loads.

The modulus of elasticity of steel wire rope may be assumed to be about 8,500,000 lb. per sq. in. for new rope loaded a number of times to one-fifth its ultimate strength.

Some conclusions are drawn upon the effect of heavy loads in squeezing lubricant out of the core of the rope and the wear which follows. (Abstract of *Technologic Paper of the Bureau of Standards*, No. 229, *c*)

FUELS AND FIRING

The Utilization of Lignite, Prof. Bancroft Gore. A review of the fuel situation in South Dakota, showing the necessity of substituting lignite to replace costly eastern coals. An account is given of experiments made at the Mining Experiment Station in burning lignite in dust form, both dried and undried, to determine the best combustion conditions. The use of unit pulverizers for central heating stations, small power plants, laundries, etc., is advocated and illustrations of several types adapted for this work are presented. The expediency of upgrading lignite at the mine by crushing, followed by drying and removal of dust on impact screens, is emphasized and shown to be an important factor in adapting this fuel for both domestic and industrial purposes.

The lignite received at the Mining Experiment Station of the State School of Mines at Rapid City, South Dakota, from the State Mine, showed a B.t.u. content varying from 7312 as received to 10,744 on a dry basis. It has a high water content and a tendency to break down into fine particles and even powder on air drying. It is softer than any other type of coal. Its main impurity is water.

As regards burning lignite as dust, it is claimed that it is an almost ideal substance to start with as it pulverizes easily and is high in volatile matter. It is interesting to note that as found accidentally by one investigator, lignite coal with as high as 17 per cent moisture was readily pulverized and burned in dust form.

As regards the cost of drying lignite at the mine, data are presented from an estimate prepared by the Ruggles-Coles Engineering Co., who claim that the total cost per short ton of dry coal at the mine is 25.5 cents.

One of the features of the experiments made at the Mining Experiment Station was that after the furnace had been brought to a high heat it was fed with undried lignite having a moisture content of 31.93 per cent. The feed was increased to provide the same quantity of actual combustible matter. The results were so satisfactory that subsequent tests were made on the undried crushed coal, with the exception of special tests or intervals of tests where the highest possible temperature was sought. So far as the author is aware, this is the first record of burning in dust form crude lignite slack containing the original moisture content as received.

The article contains interesting data on the velocity of dust jet carburetion and, in particular, on the dust firing of wet lignite. (*The Black Hills Engineer*, vol. 11, no. 2, pp. 85–126, 24 figs., *epA*)

Stoking Anthracite Culm and Gashouse Tar, Joseph Harrington, Mem. A.S.M.E. Description of the installation at the plant of the Consolidated Gas and Electric Co., Long Branch, N. J., for burning a mixture of anthracite culm and liquid tar from gas producers on forced-draft chain-grate stokers without any modification of the furnaces.

The furnace had a total furnace volume of 7.7 cu. ft. per sq. ft. of grate area, and 0.25 cu. ft. per sq. ft. of heating surface. It was of conventional design, and with bituminous coal was smokeless and admitted of ratings up to 250 per cent without destructive temeratures.

The material used accumulated as waste in such quantities as to become a nuisance. With the installation described here it proved to be feasible to use it as a fuel with loads up to 225 per cent of rating, it being possible even with this fuel to carry the loads well over the peak and still have a fair margin to spare.

The material initially had the appearance of a load of asphalt and sand such as is used for the surfacing of macadam roadways. Stepping on this material would pack it into a soggy mass, and precautions had to be taken to prevent such consolidation.

Ready surface ignition was anticipated, but what would happen thereafter could not be predicted. It was feared that the tar would be driven down by the heat of the fire into a more liquid state and render the lower layers of the fuel bed so dense that no air could pass up through. This proved, however, to be wrong. A strong pressure was maintained in the front compartment for the purpose of overcoming any such tendency, and with apparent success, since the mixture ignited with readiness right up to the gate and combustion proceeded with great density until the fuel had progressed approximately one-half the length of the grate. At this point apparently all the tar was burned out, leaving a porous bed of fine anthracite of uniform texture which burned much as any anthracite fire burns. In other words, there were short tongues of flame shooting up through the fuel, a volume of transparent monoxide gas at the surface burning to a complete CO_2 product in the upper part of the furnace. Smokeless combustion resulted, and in due course the anthracite culm had all burned down to a perfect ash.

Draft in the furnace was maintained as usual at a point near neutrality. The pressures in the stoker compartments, of which, in this instance there are four, were maintained much as usual with anthracite fuel, except that care was taken to keep the front compartment under full pressure, which, in this instance, averaged about two inches. The second compartment, where the most active combustion took place, was maintained under high pressure, although of slightly less degree, and the third compartment stepped down to perhaps half an inch. The fourth compartment was cut down sometimes to zero, and sometimes to a quarter of an inch according to the appearance or disappearance of fuel over the compartment. (*Power*, vol. 57, no. 14, Apr. 3, 1923, pp. 523–524, 3 figs., *d*)

HANDLING OF MATERIALS

Coal Handling by Suction at the Brimsdown Power Station of the North Metropolitan Electric Power Supply Company. The pneumatic system described is designed to perform three distinct handling operations by means of the one receiver and vacuum pump.

Coal can be discharged from barges lying in an arm of the canal alongside the station at the rate of 50 tons per hour, or, by means of a simple linking up of piping, can be taken from the dumps and conveyed to the bunkers. Further, provision has been made for withdrawing coal from a hopper below a railway track, and this will be put into operation as soon as the siding is completed.

The greatest distance which the coal is taken by the pneumatic plant from the dumps to the coal bunkers is approximately 350 ft., and from the canal arm to the nearest point of the bunkers is 115 ft. The fuel dealt with is usually washed small coal up to $1^1/_2$ in., but at times rough slack is also handled.

The coal lifted by the intake pipes is delivered into a receiver which discharges through an oscillating tippler to an automatic weigher, whence the coal is delivered to the belt conveyor arranged with a traveling throw-off carriage for feeding the overhead bunkers. The air from the receiver passes through a high-vacuum-type textile-sleeve suction filter which collects the dust, after which the air is run direct into the pump.

The article describes the installation in considerable detail. The pump is of a design (Simon) in which the valves are situated around the outside of the cylinder head, the cylinder being divided into two parts, the inner liner and the outer casing, one side of which is used for exhaust and the other for suction. The piston is fitted with rings having a special system of dry lubrication which has been found most suitable for this class of work; all of the moving parts of the pump are fitted with sight-feed lubricators.

In a recent test of the plant the average capacity during barge discharging, including all trimmings, was over 50 tons per hour, with a maximum rate of 56 tons per hour. (*Iron and Coal Trades Review* vol. 106, no. 2873, Mar. 23, 1923, pp. 426–427, 5 figs. *d*)

INTERNAL-COMBUSTION ENGINEERING

Internal-Combustion Engineering Characteristics of the Vertical Eight, P. M. Heldt. New developments in eight-in-line engines probably will take place in the United States within a few months. The author discusses this type with particular reference to questions of torque, balance, and crankshaft design.

As regard the latter, the author indicates two basic rules for the design of crankshafts for eight-cylinder vertical engines and works out a number of designs that will give equally spaced explosions and no rocking couple, and then proceeds to the discussion of the various designs from the point of view of ease of manufacture. He shows mathematically that in a straight-line eight-cylinder engine the inertia forces are balanced out. Therefore, as far as balance of the reciprocating parts is concerned the eight-cylinder vertical engine is equal to the six-cylinder vertical and twelve-cylinder V-type, and superior to the eight-cylinder V-engine. (*Automotive Industries*, vol. 48, no. 15, Apr. 12, 1923, pp. 817–820, 10 figs., *eg*)

MACHINE PARTS

Roller Bearings on Railroad Cars

The Stafford Roller Bearing for Railway Cars. Description of a bearing which has been in successful operation for a number of months on several cars of the Michigan Central Railroad. It has been applied in a six-wheeled truck running under an American Railway Express car and also to an 80,000-lb.-capacity box car and a flat and gondola car of the same capacity. It is

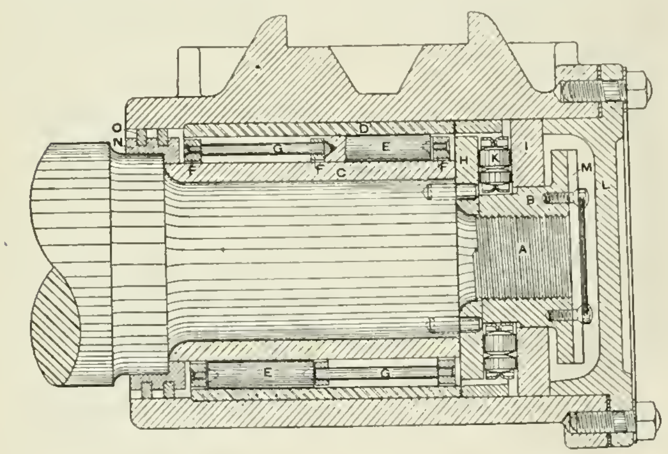

Fig. 2 Vertical Section of Stafford Roller Bearing

stated that these cars traveled a total of 8375 miles after the bearings had been applied. Practically no repairs had to be made to any of these bearings.

The principal claim made for the bearing is the great reduction in resistance effected by its use. While no dynamometer tests have yet been made with cars equipped with this bearing, there is one rough test that may be used to obtain an approximate idea of its possibilities. The flat car already alluded to was loaded with axles until the gross weight amounted to 122,600 lb. and one man was able to push this car on a level track.

The construction of the bearing in its essential parts is shown in Fig. 2. Essentially it consists of a set of horizontal rollers held in a cage to take the vertical load and another set held in another cage to take the end thrust of the axle.

The axle is turned with the ordinary dust-guard seat and journal bearing, the latter having a very generous fillet at the inner end. At the outer end, however, instead of the usual collar there is a projection *A*, which is threaded to take the adjusting nut *B*. In distinction from other roller bearings that have been tried, the turned surface of the axle journal is not used as a raceway for the rollers, but is protected by an inner bushing *C* which is made of high-carbon, high-chrome special roller-bearing steel which is ground and polished on both sides and then pressed on to the journal with a pressure of 4 tons.

The journal box is made to fit the ordinary truck pedestals, whether for trucks having those of the regulation pattern for passenger cars or merely bolts as in the diamond type of freight truck. Its interior, however, is bored to a circular form to meet the requirements of the roller bearing. Like the axle it is provided with a raceway in the form of an outer bushing *D*, which is of the same material as that used on the axle; and is ground and polished on both surfaces and pressed into place with a pressure of 12 tons.

It is between these two bushings that the rollers *E* work. These rollers are held in the cage *F* which is formed of three rings held together by the spacing rivets *G*. These rivets, like the rollers, are staggered in the two sections of the cage, as will be clearly seen in the reproduction of the photograph of this part assembled. The rollers themselves are held in place on 60-deg. centers or trunnions which set into corresponding 70-deg. centers cut in the ends of the rollers. This allows a clearance of 10 deg. for lubrication and also prevents any friction between the trunnions and the counterbore in the ends of the rollers, which latter is 1/4 in. deep. The remaining part of the rollers is solid.

The end thrust is taken by two plates *H* and *I* with the rollers *K* between them. The plate *H* is provided with dowel pins that fit into the axle by which the two are made to turn together. The inner thrust bearing plate *H* is held in place by the adjusting nut *B* which is screwed tightly against it. The outer thrust bearing plate *I* is held in place by the inside diameter of the journal box, into which it is fitted, there being a clearance between it and the adjusting screw on the inside. It (*I*) is held up against the rollers *K* by an inwardly projecting ring cast solid with the box cover *L*. This journal-box cover is so adjusted that the pressure which it exerts through the outer thrust bearing plate against the end-thrust bearing rollers is neither too heavy nor too light. In short, these parts are so manufactured that the pressure against the thrust-bearing assembly or parts is neither too light nor too heavy.

The adjusting nut *B* is locked by the locking bar *M* which fits in the slot in the nut that can be seen in the reproduction of the photograph, and in a corresponding slot in the end of the axle. The locking bar is itself held in place by two tap bolts that are screwed in to the adjusting nut and are prevented from turning by running a wire through small holes in their heads and tying them together. (*Railway and Locomotive Engineering*, vol. 36, no. 4, Apr., 1923, pp. 102–104, 4 figs., *d*)

The Process of Gear Grinding and a Discussion of Tooth Form. Glenn Muffly. The author claims that ground gears are more durable, probably because they cause less vibration. He also contends that grinding is justified on the cost basis because fewer tear-downs are required and no finishing cut need to be taken iu machining.

According to the author, it is now possible to make gear teeth so accurate that it is necessary to consider the deflections under load and so form the tooth as to compensate for even this minute deflection if the maximum silence is to be desired. He also calls attention to the need for accuracy from tooth to tooth, that is, of having each tooth identical in size and contour. There is a possibility of gears being accurate when measured for perhaps one-half the circumference of the gear, but when the measurements from tooth to tooth are considered, the gear is sometimes very inaccurate. This would result in a noisy installation, although by some methods of checking the gears would appear to be exceptionally good.

Looking ahead at the possibilities which may be realized through gear grinding, the author points out that if real quietness can be secured, in the transmission gears, for instance, there might well be a tendency toward overgeared four-speed gear sets. With traffic conditions as they now exist in large cities there is more gear changing, and if quiet gears can be secured it will be possible to narrow the engine speed range and consequently increase the economy of the vehicle. He cites the Citroën car which with a four-speed gear box is reported to have obtained mileages as high as 40 per gal.

Another possible effect of accurately ground gears is the return from helical to straight-tooth spur gears for timing purposes.

The grinding time per tooth can be very quickly calculated. As an example, on a 15-tooth gear taking one cut per tooth the

time averages 14.4 sec. per tooth; on a 21-tooth gear, 9.6 sec., and on a 29-tooth gear, 8.4 sec. These figures refer to 6–8 pitch gears.

The grinding process employed is a wet grinding, hence the heat generated does not draw the gear material.

In the case of one type of gear set it has been found that after 38,850 teeth had been ground on both sides, with two cuts to each side, the cost was $1.75 per gear set.

It makes little difference how close the center distances are held, but the shafts must be parallel. It must be remembered that shafts are not necessarily parallel even when the distance between them at each end is exactly the same.

The stock left for grinding after the rough cut on the gear averages from 0.002 to 0.003 in. on 8–10 pitch gears.

It is not advisable to grind both sides of the gear at once as it brings in too many factors which must be kept synchronized. The maximum variation for backlash in these ground gears is 0.00025 in. (Paper read before the Detroit Section of the Society of Automotive Engineers in April, 1923. Abstracted through *Automotive Industries*, vol. 48, no. 15, Apr. 12, 1923, p. 809, *pg*)

Six Kinds of Riveted Joints. According to E. E. Rohrer, of the Coatesville Boiler Works, there are in general six types of riveted joints. First, the lapped and single-riveted seam is almost entirely used for storage-tank work. The efficiency of this type of seam is approximately 50 per cent. Second, the lapped and staggered double-riveted seam, used where medium pressure may be required. The rivets in this type of seam usually have about 1 in. greater pitch than those in the single-riveted seam. This type of joint has an efficiency of about 70 per cent. Third, the lapped and triple-riveted seam, which is comparatively seldom used. Fourth, the butt-strapped double-riveted seam (the butt-strap seams here mentioned have inside and outside butt straps) has an efficiency of about 82 per cent. Fifth, the butt-strapped triple-riveted seam, having an efficiency of about 87 per cent. Sixth, the butt-strapped quadruple-riveted, having an efficiency of about 93 per cent. These latter two are used on larger diameters and for higher pressures. (*Chemical and Metallurgical Engineering*, vol. 28, no. 15, Apr. 16, 1923, p. 679, *g*)

Power of Worm Gearing, Arnold A. Arnold. The author discusses the various formulas for the power which worm and worm-wheel gearing will transmit, and in this connection the formulas derived from Bach and Roser's experiments published in the *Zeitschrift des Vereines deutscher Ingenieure*, Feb. 14, 1903; Unwin's formula (Machine Design, vol. 1); and those in Oberg's Spiral and Worm Gearing.

These formulas, the author claims, are not quite suitable for ready calculations as they involve the use of logarithms. He therefore gives four diagrams showing the relation between the horsepower transmitted, the pitch of the worm threads or worm-wheel teeth, the maximum permissible pitch-circle diameter of the worm, and the revolutions per minute of the worm, all these diagrams being based on the formulas referred to above. These diagrams apply only to single, double, treble and quadruple worm threads within certain limits of revolutions. (*Mechanical World*, vol. 73, no. 1890, Mar. 23, 1923, pp. 184–186, 4 figs., *g*)

MACHINE SHOP (See also Engineering Materials)

Experimental Machine Building—Pictorial Assemblies

Controlling Costs in Building Experimental Machines, Fred H. Colvin. The second article of a series, showing how tools are to be decided upon and the operation times set. Among other things, the article describes so-called pictorial assemblies, the pictures being sketches in perspective which show the design of the piece, so that there can be no mistake as to what it looks like. This is particularly useful when it comes to assembly work. An example is given in Fig. 3 which shows a unit assembly of a controller. This consists of seven sub-assemblies, one of each being required for the complete unit. Each sub-assembly is numbered and full details of it can be found under that number. Each of the sub-assemblies may be represented by a special pictorial assembly, which, in its turn may include minor sub-assemblies, as is, for example, the case with the sub-assembly No. 3192

The assembly sheets may be, however, a good deal more complicated than that shown in Fig. 3. For example, one of the illustrations in the original article shows a complete assembly of a separator involving a number of sub-assemblies, and finally one

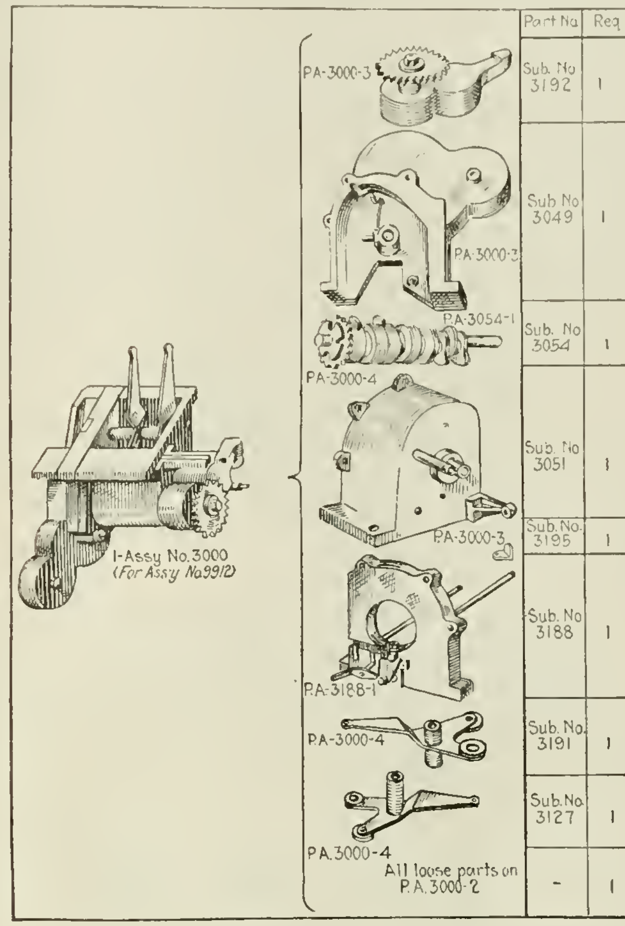

Fig. 3 Pictorial Assembly of Controller Unit

assembly which shows a complete machine comprising five separators, a carrying unit, loader connections, etc.

Such assembly drawings are valuable in that they leave little room for error and make it possible for mechanics to assemble a machine without difficulty, even if they are not especially familiar with the machine. (*American Machinist*, vol. 58, no. 14, Apr. 5, 1923, pp. 503–507, figs. 3–14, *dp*)

MANAGEMENT ENGINEERING (See Machine Shop)

METALLURGY (See Engineering Materials)

MOTOR-CAR ENGINEERING (See also Internal-Combustion Engineering)

Large-Section Tires on Passenger Motor Cars, Herbert Chase. Important results are expected from the development of a so-called "balloon" tire, which is essentially a tire of the same outside diameter as those in use at present but of much larger section and fewer plies. This is accomplished by using a smaller rim diameter. For example, in place of a 33 by 5-in. 8-ply cord tire on a 32 by $4\frac{1}{2}$-in. rim 23 in. in diameter, is used a 34 by 7-in. 4-ply tire on a 29 by $4\frac{1}{2}$-in. rim 20 in. in diameter. Instead of a pressure of 65 lb. the new tire operates at 25 lb. inflation pressure.

The results are said to be very remarkable. In the first place, road inequalities are transmitted to a far lesser extent than with ordinary tires. The brakes become more effective, and slipping and skidding on wet pavements are largely eliminated. There are not enough data available to show the comparative wearing qualities of the conventional type of cord tire and the newer type

which is also of cord construction. The use of the new-type tire is claimed to result in saving in unsprung weight and, consequently, in a secondary saving by way of lesser impact on the road surface.

The new large-section tires with their lower inflation pressure absorb a much larger proportion of the shock due to the road inequalities. There is less fatigue to the operator and also less vibration transmitted to the chassis, which makes the cars quieter in operation. It is claimed that the use of new tires increases the maximum speed of the car and lowers its fuel consumption. On the other hand, however, it is pointed out that when the car is traveling at high speed there is an increased danger of accident due to blowout because of the thinner wall of the tire.

Among the disadvantages may be mentioned the necessity of changing the design of the chassis, for approximately the same diameter of large-section tire will have less side clearance in relation to body and chassis parts. In some cases this might require a decrease in the width of the rear seat and a decrease in the width of the chassis at the front in order to enable the use of the same steering lock and to maintain the same turning radius.

It is said that a number of prominent car manufacturers are said to be seriously considering the adoption of 34 by 7-in. or 32 by 6-in. tires as standard equipment in the near future.

The article is accompanied by expressions of opinion from several car and parts manufacturers, as well as from various tire companies who have been doing work along this line. (*Automotive Industries*, vol. 48, no. 15, Apr. 12, 1923, pp. 812–816, *dg*)

POWER-PLANT ENGINEERING

Solar Power Plant—Design and Costs

The Berland-Caufourier Solar Power Plant, P. Caufourier. There have been many attempts to utilize solar heat for power generation, of which the author mentions and briefly describes the Mouchot, Tellier, and Shuman projects, the last being the only one to be applied for actual work. (See Journal A.S.M.E., vol. 37, 1915, p. 661.)

The present installation is a combination of the Caufourier self-vaporizer for generation of steam from water at temperatures of 50 to 75 deg. cent. and the Berland system of mirrors. The Caufourier self-vaporizer was initially designed for purposes of power generation from natural hot waters and was described in Mechanical Engineering, vol. 43, no. 3, March, 1921, pp. 200–201.

The Berland solar receiver, as the apparatus is called, is shown in Fig. 4. It is a mirror shaped as a parabolic cylinder—similar to the mirrors in the Shuman Egyptian installation, yet differing therefrom in certain essential points. The axis instead of being horizontal is parallel to the axis of the earth and hence in the Sahara has an inclination of 25 to 30 deg. to the horizontal. Under these conditions the solar rays are normal to this axis at the equinoctials and even at solstices their inclination does not exceed 23 deg. The apparatus is therefore better capable of receiving the insolation (solar radiation) than if it had a horizontal axis, and furthermore the inclination to the horizontal favors a natural circulation of the water. The angle of inclination of the solar rays remains constant throughout the day period, provided the mirror has a movement of uniform rotation, which may be automatic. To effect this the mirror is mounted in a series of large circular tracks traveling on rollers, as shown in Fig. 4, where E is the driving gear, G the rollers, C the rolling track, M the parabolic metal mirror, T the boiler tube—which may be of copper or aluminum with a black exterior face, and V a glass sleeve. The frame supporting the mirror is not shown. The boiler tube T is enclosed in one or two glass cylinders, the purpose of which is to prevent dark heat radiating from the tube and thus to reduce the heat losses therefrom. This particular feature was first proposed by Mouchot. The air between these glass cylinders and the boiler tube is partly exhausted in order to reduce convection losses.

According to calculations made by the Swedish scientist Svante Arrhenius, 1 sq. m. (10.764 sq. ft.) of the great circle of the terrestrial sphere receives 25 calories of solar heat per minute. Taking into account the inclination of the solar rays and atmospheric absorption, 1 sq. m. of the mirror will receive from 8 to 9 cal. per min., and as the efficiency of the mirror is of the order of 60 per cent as shown by tests made on the Cairo installation, the water in the boiler tube is capable of absorbing, roughly, 300 cal. per hr. per sq. m. of mirror surface.

On the other hand, if we assume that the water is heated to 90 deg. cent. in the solar receivers and reduced to 80 deg. in the self-vaporizers, the production of steam will equal 18 kg. per cu. m., equivalent to 3.18 i.hp., or 2.5 hp. on the turbine shaft, figuring the condenser at 25 deg. cent. The author further shows that the mirror surface would have to be 18 sq. m. per hp.

The solar power plant illustrated in Fig. 5, will therefore comprise—

1 A sufficient number of Berland solar receivers

2 One or more intermediary reservoirs

3 A sufficient number of self-vaporizer steam generators

4 A water circulation pump and a vacuum pump

5 A superheater, which is essential for drying the steam and at the same time increasing its temperature and hence the Carnot efficiency. A superheat of 35 to 40 deg. cent. would appear to be sufficient. This is the only part of the apparatus that will consume fuel

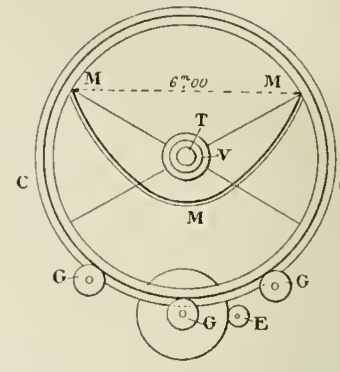

Fig. 4 Berland Solar Receiver

(*Sud* = south; *Solstice d'hiver* = winter solstice; *Equinoxes* = equinoctials; *Solstice d'ete* = summer solstice; *Nord* = north; *Recepteurs Berland* = Berland solar receivers; *Reservoir tampon* = intermediary reservoir; *Generateur auto-evaporateur Caufourier* = Caufourier self-vaporizer steam generator; *Surchauffeur* = superheater; *Pompe de circulation* = circulating pump; *Condenseur* = condenser.)

6 A reciprocating steam engine, or still better, a steam turbine

7 A condenser with its auxiliary equipment.

In the climate of southern Algeria the average time the installation is capable of operating is 10 hr. per day, 330 to 340 days per year, and it is proposed to use the power generated primarily for pumping water for irrigation purposes and also for generating comparatively small amounts of power for lighting and industrial power.

In order to deliver power continuously it will be necessary to have a number of solar receivers approximately double the power of the evaporators, and an intermediary reservoir of sufficient dimensions and properly protected against heat losses.

The condensers will use the irrigation water, and where this is not available shallow pools may be used. A fairly complete project of the application of this type of power plant has been worked out for the Touggourt oasis, which is of interest in that it demonstrates the conditions under which a power plant of this character may pay. The Touggourt oasis has a population of 12,000, and a flora comprising 350,000 palm trees. It was initially irrigated by 200 artesian wells, which in 1861 had an output of 1000 liters (265 gal.) per sec. The boring of new wells, however, has depressed the subsoil water level and made it necessary to go to much lower levels in order to obtain new sources of water, and even these have been gradually failing.

The project calls for a solar power plant with a mirror area of 2400 sq. m. (25,833 sq. ft.) giving an output of 100 kw. with an insolation of 7 cal. per sq. m. (10.764 sq. ft.). The power output per year will be 300,000 kw-hr., consumed as follows:

In the power plant itself	30,000
Lighting of villages	30,000
Small industries	20,000
Ice manufacture	10,000
Irrigation pumping	210,000
Total kilowatt-hours	300,000

It is estimated that the cost of construction will be 600,000 fr. ($42,000) of which 150,000 fr. ($10,500) will be for the mirror plant. The income and expenditures are estimated as follows:

Expenditures (in francs = 7 cents)		
General expenses		3,000
Personnel	Manager	15,000
	Electrician	9,000
	Four native workmen	7,000
Lubrication, waste, etc., 0.01 fr. per kw-hr.		3,000
Superheater service, 0.200 kg. (0.44 lb.) of coal per kw-hr.		20,000
Maintenance and repairs		20,000
Amortization at the rate of 6 per cent in 15 yr.		60,000
Interest, etc.		115,000
Total		252,000
Receipts		
Lighting, 30,000 kw-hr. at 1.50 fr.		45,000
Petty industries, 20,000 kw-hr. at 1.00 fr.		20,000
Ice, 100 tons at 200 fr.		20,000
Distilled water, 360 tons at 75 fr.		27,000
Irrigation pumping,[1] 200,000 kw-hr. at 0.70 fr.		140,000
Total		252,000

In the above plans no mention is made of the depreciation of the distribution system, the item "Interest" being sufficient to take care of this.

The item "Distilled water" corresponds to a daily consumption of 1000 liters (265 gal.) which is double the present consumption, but it is to be sold at a price of 0.075 fr. per liter as compared with the present price of 0.20 fr. Water from the wells contains too much magnesia salts to be fit for drinking. (*Génie Civil*, vol. 82, no. 14, Apr. 7, 1923, pp. 327–329, *d*)

Water-Tube Boiler Troubles

Constructional Defects in Water-Tube Boilers, R. Schirmer. This paper calls attention to the fact that of later there have been increasingly frequent reports of trouble with water-tube boilers, in particular ruptures of the boiler walls, and that the causes of these troubles are not yet as clear as they should be.

The author believes that many of these accidents have been due to the constantly increasing specific loads imposed on the boilers, as a result of which the boiler parts do not take up the heat supplied to them fast enough and distribute it uniformly enough, which brings about stresses in the material. To this kind of damage are particularly exposed boilers which have been at first operated at comparatively light loads and from which a much higher output had been demanded later. In some cases, in order to obtain this higher output larger grates have been installed in the expectation that the boiler would deliver the greater output as it had worked satisfactorily in the past. Of course this does not always happen.

H. Schonger, in a recent German publication, has called attention to the fact that cracks in boilers operating in central stations are particularly frequent in the header flanges and end plates of water-tube boilers. All conditions, however, go to show that it is not the defective manufacture of the parts but the circumstances of their operation that are the cause of trouble. It is pointed out particularly in this connection that such flange ruptures do not occur in other boiler systems or in old water-tube boilers, possibly because these latter have operated at only a fraction of their present specific loads. It would therefore appear that the accidents in boiler operation are due at least in part to the increasing loads which have been demanded from boilers since the introduction of the Stirling type of generator. There has been of late a sort of competition between the Stirling and the straight-tube types of boiler, each attempting to surpass the other either in specific output or in the reduction of space for a given output. The Stirling type is well adapted for this kind of competition, whereas the straight-tube boiler has been made to perform at the enhanced rate without a thorough alteration of its design, which is unfortunate, because a straight-tube boiler appears to be unsuited by its construction for the rapid equalization of thermal expansion of the parts. As a result there have been numerous breakages of parts which can be directly ascribed to stresses of thermal origin.

It is stated in the report of H. Schonger, referred to above, that the flange cracks reach their greatest depth at the lowest part of the end plate, and in extending toward the water line on both sides gradually lose in depth. The same thing has been observed on the lower drums of a large Stirling-type boiler. These drums, it may be stated, were in this instance made not of a single shell plate but of three rings.

Figs. 6 and 7 show these lower drums. All such boilers have two boiler drums connected by short curved tubes, the water circulating in the direction indicated by the arrows. It is usually

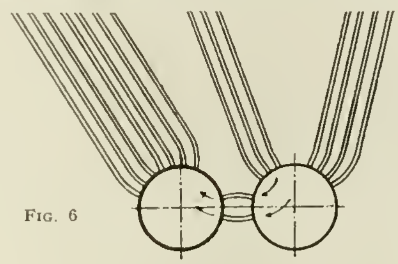

Fig. 6

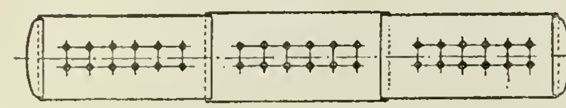

Fig. 7

Figs. 6 and 7 Construction of Lower Drums of a Boiler Where Leaks Due to Unequal Heating Appear

Fig. 8

Fig. 9

Fig. 8 Diagrammatic Representation of Distribution of Leaks in the Drums of Boiler Shown in Figs. 6 and 7.

Fig. 9 Diagrammatic Representation of Water Circulation in the Drums of Boiler shown in Figs. 6 and 7.

assumed that the total drum water content is free to circulate at a uniform rate and therefore that there are no dead spaces in the lower drum. While firing up this boiler, however, leaks appeared at the circular seams as soon as the temperature of the water in the upper drum approached the boiling point. When the steam pressure increased the water spurted through the seams in jets, the interesting part about it being that this occurred only on the lower part of the two lower drums, while the upper parts of the same drums have never shown any lack of watertightness. Moreover the leaks increased with the approach to the middle plane of the drums as shown diagrammatically in Fig. 9, but ceased entirely at the level of the lower connecting tube. No matter how slowly and carefully the boiler was heated up, it proved to be impossible to prevent these leaks, and even after the upper drum began to deliver steam, cold water could be obtained from the lower drum by opening the bottom cock. It was, however, possible to combat this source of trouble by letting off from time to time the water from the lower drums during the heating up of the boiler, this operation being repeated until the water in the lower drum attained a temperature corresponding to the steam pressure, whereupon the danger of leaks disappeared.

There is no doubt that these leaks are caused purely through thermal stresses, which in their turn are due to the imperfect water circulation in the lower drums.

As shown in Fig. 8, there forms in the lower drum a dead layer of cold water at the level below the interconnecting tubes, while the water above this dead layer circulates with the rest of the boiler water. This results in the fact that the upper part of the shell of the lower boiler is heated up faster than the lower part,

[1] Attention is called to the fact that in a previous paragraph the power consumption for irrigation pumping is estimated at 210,000 kw-hr. and no mention made of distilled-water production, possibly because the latter is merely a by-product.

and as the circular rivet seams are not strong enough to withstand the stresses created by this unequal expansion, leaks appear in the drum. It is only after all the cold water from the bottom of the lower drums has been drawn off through the cocks that the two parts of the shell become heated up uniformly and the irregular thermal expansions and consequent leaks disappear.

It is permissible to assume that the rupture of a welded seam in the lower drum in another large Stirling-type boiler may have been due to the same cause. In this case it is well to avoid the use of welded circular seams, or at least when using them to employ reinforcing straps.

From this the author proceeds to a discussion of straight-tube boiler troubles, which he believes may be likewise due to thermal stresses produced by unequal heating. In fact, he believes that the straight-tube boiler is exposed to this kind of trouble in an even greater degree than the Stirling type. Furthermore the lower half of the shell of the upper drum in the straight-tube boiler is exposed to additional stress due to the fact that the tube system expands to a greater degree than the boiler drum located above it. If, therefore, the circular seams of the upper drum lying between the collars of the headers are strong enough to take up these additional stresses, the flanges of the header covers or connecting expanders will be frequently overstressed to such an extent as to produce ruptures. These stresses applied initially to flanges are transmitted to the end plates with all the greater ease the nearer the latter are forced to the connector expanders. Furthermore, since the rear end plates are located closer to this critical connecting place the front end plates are more exposed to the successive stresses, which would explain the greater frequency of cracks and ruptures in these rear end plates.

It would be natural to expect that damage of this kind would occur with particular frequency in boilers which are fired up often rather than in boilers operating continuously. After a boiler has been operated for any length of time the heat throughout becomes equalized to such an extent that the stresses in the material disappear. In central-station practice the boilers have to be cut in and out with comparative frequency. Furthermore, when high peak loads have to be taken care of, extra boilers must be heated up quite frequently and rapidly. Conditions of boiler operation in central stations are therefore such as to be particularly favorable to the formation of cracks and ruptures. On the other hand, of course, boilers should be adapted to take care of conditions in central-station operation rather than that these latter should suffer in their adaptation to boiler limitations. Boilers should be so built that even when fired up in a hurry the heat will distribute itself throughout the boiler in as short a time as possible, not only uniformly but without the production of local stresses even when the load is varied with great rapidity. This requirement can be satisfied only by the establishment of a perfect water circulation of the entire water content, which is far from being the case with the present conventional construction of straight-tube boilers.

From this point of view greater advance has been made in Stirling-type boilers and of late there has been an increasing tendency to provide large connections to the upper drums, the only limit to this tendency lying in the strength of the boiler shell. Larger passages are also provided for the flow of steam between the upper drums.

At the same time it should not be forgotten that all connections between the upper drums may result in hindering the water circulation, as improper dimensioning of such connecting elements may lead to violent variations of the water level, priming, etc. It is because of these difficulties that there is still considerable distrust in many circles with respect to the Stirling-type boiler. (*Die Wärme*, vol. 46, no. 2, Jan. 12, 1923, pp. 15–18, 4 fig. *p*)

RAILROAD ENGINEERING (See also Machine Parts)

New 4000-Hp. Electric Locomotives for the N. & W. Railway, T. C. Wurtz. Description of the design of four locomotives recently ordered by the Norfolk & Western Railway, the particular points of interest being the design of the cab and drivers, and some of the electrical features.

The new unit will consist of two cabs permanently connected to form a locomotive. The equipment in each cab will be identical so that any two cabs can be coupled together back to back to form a locomotive unit.

The cab structure is not supported by springs and sliding bearings as formerly but is fastened rigidly to and is carried by side frames. These latter are massive vanadium-steel castings connected by cross-ties which are also used to support the heavier pieces of electrical apparatus mounted in the cab.

The four pairs of drivers on each cab are single-truck, the former practice having been to have two trucks on two pairs of drivers each connected by a Mallet hinge.

As regards the electrical features, the most interesting is the use of an oil-insulated force-cooled transformer. The oil-insulated type of transformer has been almost universally used in single-phase European electrifications, but up to this time the air-blast transformer was the standard in this country in all trunk-line installations. Cooling of the oil-insulated transformer is accomplished by means of pumping the oil through a force-ventilated radiator.

The service to be performed by these locomotives is unquestionably the most severe to which any electric locomotive has ever been subjected. The traffic consists of heavy-tonnage coal trains of 4200 tons hauled up six miles of 2 per cent grade on a road noted for its curves. The speed of the train up this heavy grade with two locomotives is 14 m.p.h. Acceleration of these heavy trains on a 2 per cent grade with reverse curves is part of the normal operation, and is accomplished with ease. The performance of this type of locomotive has been so remarkable that the operating officials of the railway are enthusiastic in their praise and more than satisfied with their operation, as shown by the recent order for four additional locomotives having 30 per cent greater capacity than those now in operation. (*Railway Review*, vol. 72, no. 15, Apr. 14, 1923, pp. 647–650, 4 figs., *d*)

REFRIGERATION

The Compression Refrigeration Cycle

The Compression Refrigerating Cycle, W. H. Motz. Paper based upon the results of the recent Bureau of Standards experiments on ammonia and what may be termed good operating practice. The author gives numerous interesting charts plotted for the first time from the Bureau of Standards tables and also from actual tests on a refrigerating machine. The paper is not generally suitable for abstracting, but attention may be called to the following.

In the original article a chart is given showing the values of the theoretical volumes of compressor piston displacements for the assumed conditions in the evaporator and condenser. (The amount of ammonia evaporated per minute per ton of refrigeration has been taken for standard conditions as 0.442 lb.)

As regards volumetric efficiencies of a compressor cylinder, they appear to depend generally on a large number of factors. However, in vertical single-acting compressors in which the clearance has been reduced to the minimum and in which valves of large area are used, the principal factor affecting the efficiency of the cylinder is that of the superheating of the vapor during the suction stroke. With respect to the volumetric efficiency due to the superheat of the vapor during the suction stroke, it is said that there are a number of factors which affect the relative magnitude of this efficiency. In consideration of this fact it is practically impossible to determine these efficiencies by mathematical analysis, and they can be determined only by actual tests on actual ammonia-compressor cylinders and should therefore be termed an operating characteristic of the compressor cylinder.

For the purpose of comparison and calculation in this paper the author has used tests made on actual ammonia-compressor cylinders for the purpose of determining the relative magnitude of the efficiency due to superheating. Data taken from the most authoritative tests were plotted on curves, from which, by means of extension and extrapolation, the values of the volumetric efficiencies for the assumed conditions were obtained. The values of the volumetric efficiencies due to superheating, as determined by this means for vertical single acting ammonia compressors, are shown in Fig. 10. These values are the volumetric efficiencies with a factor of safety of approximately 10 per cent. As previously

indicated, these may be termed volumetric efficiencies due to superheating, due to the fact that a very large proportion of the loss of efficiency is due to the superheating effect. The tests on the actual refrigerating machines were conducted by experts after all parts of the system had been put into as nearly perfect mechanical condition as possible, clearance reduced to the minimum, etc. Therefore the values of the volumetric efficiencies may be taken to present primarily the effect of superheating. It is well to

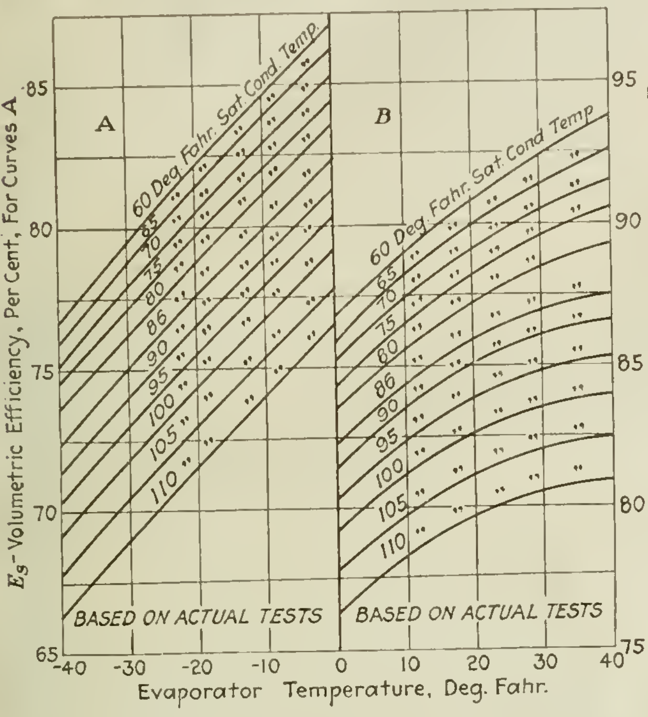

Fig. 10 Volumetric Efficiencies for Vertical Single-Acting Compressors

point out that it is possible to obtain volumetric efficiencies which are better than those shown by Fig. 10, but that these values may be assumed to represent good practice.

The author next discusses the effect of clearance upon the volumetric efficiency of a compressor cylinder, which may be determined mathematically if the amount of clearance is known, and gives a

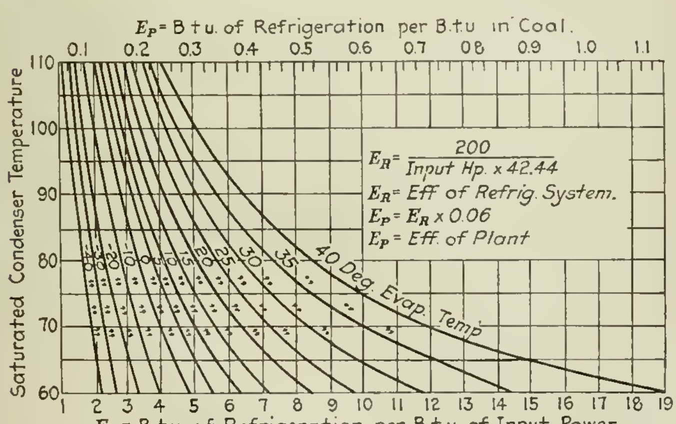

Fig. 11 Overall Efficiencies of Refrigerating Plants

chart showing the value of factors determining this clearance.

The thermodynamical expression for the volumetric efficiency due to clearance [the formula is given in the original article] involves the exponent n of the characteristic law of compression PV^n = constant. This exponent varies within certain limits as ammonia vapor is not a perfect gas, but the latest data from the Bureau of Standards on the properties of ammonia vapor seem to indicate that the average value of n may be taken to be 1.28, and the author uses this value both to express the volumetric efficiency due to clearance and to determine the total efficiency due to clearance. This latter, on the assumption that the clearance is 3 per cent of the cylinder volume, is found to be 92.56 per cent for a given case.

The true volumetric efficiency of the compressor cylinder is a function of the product of the volumetric efficiency due to superheating and that due to clearance. The mean effective pressure of ammonia in a compressor cylinder is also affected by the amount of clearance.

The second part of the article is devoted to the subject of power and water requirements, and is accompanied by interesting charts. Among other things, the author establishes in the form of an equation the relationship between the gallons of water required per minute, the heat removed in the condenser, and the temperature range of water, and gives a chart showing the relative amount of water required in gallons per minute per ton of refrigeration for rises of temperature of the water from 4 deg. to 20 deg. for certain assumed operating conditions.

The efficiency or coefficient of performance of refrigerating systems is next discussed and expressed in several ways. The general conclusion at which the author arrives is that the smaller the temperature range the better the performance. In other words, a smaller amount of energy is required to cool a substance a few degrees than is required to cool a part of it through several degrees, such as one-tenth of the substance through ten times as many degrees. For standard conditions the overall efficiency on performance is expressed as a formula. The ratio given may be termed B.t.u. of refrigeration per B.t.u. in the coal. In the original article such ratios of B.t.u. of refrigeration to B.t.u. in coal have been calculated for the assumed operating conditions and are shown in Fig. 11. (Paper presented at the Annual Meeting of The American Society of Refrigerating Engineers, December, 1922, abstracted through *Refrigerating Engineering*, vol. 9, no. 9, March, 1923, pp. 267–274 and 279–280, 12 figs., *pt*)

Composition, Purification, and Certain Constants of Ammonia, E. C. McKelvy and C. S. Taylor. In this paper methods for the testing of commercial ammonia are described and applied to eight standard American brands and three brands of German origin. The results of these analyses indicate that most commercial ammonias contain less than 0.1 per cent of impurities. Previous methods used for the preparation of pure samples are reviewed briefly. Apparatus used for fractional distillations at pressures greater and also less than atmospheric pressure are described.

Emphasis is placed upon the removal of non-condensing gases, and methods of removal and testing are described in detail, together with a method for opening sealed glass containers and testing the contents for non-condensing gases.

Five methods for the preparation of samples are described in detail and the physical measurements made upon each sample indicated. The different preparations are tabulated, together with the analyses and uses.

Ammonia has been prepared which contained, as far as any known test indicated, no organic impurities, less than 1 part in 1,000,000, by volume, of non-condensing gases, and less than 0.003 per cent, by weight, of water.

The following physical properties of pure ammonia were determined: The density of the solid, 0.817 gram per cu. cm. at —79 deg. cent. and 0.836 gram per cu. cm. at —185 deg. cent.; the freezing point, —77.70 deg. cent., and the vapor pressure at that temperature, 45.2 mm. of mercury. (*Scientific Paper of the Bureau of Standards*, no. 465, Mar. 9, 1923, pp. 655–693, 6 figs., *e*)

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general, *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

Proposed Code for Care of Power Boilers

Preliminary Report of Sub-Committee of A.S.M.E. Boiler Code Committee on Rules for Care of Steam Boilers and Other Pressure Vessels in Service

THIS Report of the Sub-Committee of the Boiler Code Committee on Code for the Care of Power Boilers is suggestive only and will be proposed for discussion at the Spring Meeting of the Society at Montreal, Que.

The work of this Sub-Committee of the A.S.M.E. Boiler Code Committee has been actively pushed forward during the past year and its report is here presented for public discussion. This report is intended to form a section of the A.S.M.E. Boiler Code, the Sub-Committee which was appointed in 1922 to consummate this work being as follows:

F. M. Gibson, *Chairman*	W. H. Larkin, Jr.
E. G. Bailey	J. S. Schumaker
W. G. Diman	H. F. Scott
J. R. Gill	N. Stahl
J. W. Hays	J. Wolff
S. F. Jeter	

It is the request of the Committee that these proposed rules be fully and freely discussed so that it may be possible for any one to suggest changes before the rules are brought to final form and presented to the Council for approval. Discussions should be mailed to C. W. Obert, Secretary of the Boiler Code Committee, 29 West 39th St., New York, N. Y., in order that they may be considered by the Boiler Code Committee.

A.S.M.E. BOILER CODE

Report on Rules for Care of Steam Boilers in Service

POWER BOILERS

These Rules apply only to steam boilers constructed in compliance with Part I, Section 1, of the A.S.M.E. Boiler Code and for operation at a steam pressure exceeding 15 lb. per sq. in. above atmospheric pressure. These rules do not apply to boilers which are subject to federal inspection and control, including marine boilers, boilers of steam locomotives and other self-propelled railroad apparatus.

INDEX

RULES FOR THE PREVENTION OF DIRECT CAUSES OF BOILER FAILURES

OVERPRESSURE

Indicators

C-1. Steam Gages. Steam gages shall be placed where they will be free from vibration and where they can be conveniently adjusted. They shall be so placed that they will not be subjected to a temperature of less than 40 deg. fahr. or more than 150 deg. fahr. They shall be of such size and so proportioned and marked that the position of the pointer and the graduations can be clearly determined by a person with normal vision standing on the operating floor at any point within a radius of one and one-half times the width of the boiler setting measured from the center of the boiler front. Steam gages on all boilers, where set in battery, shall be practically the same in size and graduation of face.

C-2. Steam gages shall be well lighted at all times. When natural light is used the gage shall be so placed that the rays of light will not cause a reflection upon the glass cover thus obscuring the dial when viewed from the most desirable points of observation. When artificial light is used the light shall fall directly upon the face of the gage. Whatever form of light is used, no light shall fall directly into the eyes of the operators when looking at the gage from the most desirable points of observation.

C-3. Where steam gages are installed with waterleg, compensation shall be made in the gage to neutralize the effect of the water in the gage connections. Where steam gages are placed high above the operating floor, they shall be tilted forward at a sufficient angle (not to exceed 30 deg. with the vertical) to permit a proper view of the dial graduations.

C-4. Piping for steam gages shall be as short as practicable and shall be free from pockets and air traps. When the pipe line is longer than 10 ft., the pipe size shall not be less than $^3/_8$ in. standard pipe size.

C-5. A steam gage shall be considered tested when it has been compared and made to agree with a test gage or dead-weight testing device, unless compensation for waterleg has been made, in which case an equivalent allowance shall be made in the reading of the test gage or dead-weight testing device. The test gage shall be a reliable gage that is used exclusively for testing gages in service and one that is tested and maintained in agreement with a dead weight testing device.

C-6. Boiler gages shall be tested frequently, at times of external inspection, when boiler is placed in service, and when safety valve is operating and the pressure indicated by the steam gage is not in agreement with the pressure at which the safety valve is set to open.

C-7. A master gage is an auxiliary gage attached to the main header indicating the composite boiler pressure of the whole battery; it is used in the general operation of the plant mainly as a matter of convenience. Master gages shall be tested at least every three months and more frequently when trouble is experienced with boiler compounds, foaming, priming and other feedwater troubles that are apt to cause choking of the gage piping.

C-8. All steam gages shall be within two per cent of error in the range between the working pressure and the pressure of the opening of the safety valve.

C-9. Before a steam gage is tested, it shall be disconnected at the gage union while the piping, cock and siphon are being cleared

by blowing through. A tee with a plug shall be placed between the siphon and the gage for the purpose of connecting the test gage. Care shall be taken not to admit steam directly into the gage, making sure at all times that the siphon is filled with water. In opening the connection to the gage, the operator shall open the cock slowly while holding one hand on the siphon until the gage indicates full boiler pressure; if the temperature of the siphon indicates that steam instead of water is entering the gage, the cock shall be closed until a sufficient amount of water has accumulated in the piping.

C-10. When laying up a boiler, particularly in freezing temperatures, the gage connection shall be drained and the gage shall be disconnected and stored away in a non-freezing room.

C-11. The dial and glass cover of steam gages shall be kept clean at all times. The glass cover joint shall be tight and, whenever the glass is broken, it shall be replaced as soon as possible.

C-12. Water Glasses and Gage Cocks. The valves and connections between the boiler and water column shall be kept free and clear and shall be tested by blowing down the water column, noting the return of water in the glass, and trying the gage cocks until sure of the water. They shall be tested by the responsible operator on the relieving shift before the relieved shift has gone off duty, also after replacing or cleaning the water glass and when a boiler is put in service.

By *shift* is meant a person or group of persons who relieve a person or group of persons in rotation in standing watch or operating a steam generating plant for an allotted time. It is synonymous with watch, vigil, or tour of duty.

C-13. The water glasses and their connections shall be kept free from leaks and no alterations, allowing a flow of water from the piping between the water glass and the boiler, shall be made.

C-14. The outlet end of the discharge pipes from the water columns, water glasses and gage cocks shall be kept open and either in sight or in hearing of the operator while blowing down.

C-15. The water glasses shall be so lighted that the level of the water in the glass can be readily seen from the most desirable points of observation and the light shall be so shaded that it will not shine directly into the eyes of the operator when looking at the glass. The inner and outer surfaces of the water glass shall be kept free from deposits of dirt and the connections of the water glass shall be so arranged that the inner surface of the glass can be cleaned by forcing through the glass a piece of cloth, free from lint and dirt, wound about a smooth piece of wood. Types of gage glasses and guards which prevent the free observation of the glass shall not be used.

C-16. Where automatic alarms for indicating extreme low water level or extreme high water level are used, they shall at all times be kept in good working order but shall not be depended upon in maintaining a proper level of water in the glass. When an automatic alarm sounds and the level of the water is not visible in the glass, the operator shall test the try cocks to determine the water level before manipulating the feed water valves.

C-17. Fusible Plugs. Flusible plugs, if used, shall be kept in good condition and shall not be used for more than one year as provided for in Par. 428 of the Rules for the Construction of Power Boilers. When the boiler is open, the exposed surfaces of the fusible metal shall be scraped clean and bright and the surface of the boiler near the plugs shall be scraped clean. If the fusible metal does not appear sound, the plug shall be renewed. If used plugs are refilled, all of the old filling shall be removed, the surfaces of the shell scraped bright and properly tinned and the plug filled with pure tin as specified in Par. 428 of the Rules for the Construction of Power Boilers. Fusible plugs shall not be refilled with used metal.

Relief Equipment

C-18. Safety Valves. All safety valves shall be kept clean and in working order.

C-19. The capacity of safety valves shall be calculated, as provided for in Pars. 269–290 (inclusive) of the Rules for the Construction of Power Boilers, under the following conditions and if necessary a larger safety valve installed; when the allowable working pressure of a boiler has been reduced, when a boiler is equipped with increased stoker capacity or when a change in fuel permits increased combustion.

C-20. Whenever the stipulated blowing pressure of a safety valve is 10 per cent higher or lower than the pressure for which the spring of the valve is designed, the safety valve shall be equipped with a new spring complying with the requirements given in Pars. 269–290 (inclusive) of the Rules for the Construction of Power Boilers.

C-21. When a safety valve spring has weakened and has been further compressed to secure the stipulated blowing pressure, an examination of the spring shall be made in order to insure its compliance with the rules given in Pars. 281, 282 and 284 of the Rules for the Construction of Power Boilers.

C-22. Where boilers are set in battery and operating under the same working pressure and some of the boilers have allowable working pressures greater than others, all safety valves shall be set to blow off at a pressure not in excess of that allowed on the weakest boiler.

C-23. Safety valves shall be tested at least once a day by gently raising the valve off the seat by hand and, when practicable, shall be tested daily by raising the steam pressure to the blowing pressure of the safety valve. Small chains or wires attached to the levers of pop safety valves and extended over pulleys to other parts of the boiler room may be used.

C-24. When a safety valve sticks or fails to operate at the stipulated blowing pressure, no attempt shall be made to free it by striking the body or other parts of the valve but the boiler shall be taken out of service and the safety valve examined.

C-25. The safety valve, when blowing, shall be checked against the boiler gage and when the pressure noted on the boiler gage varies more than 5 lb. from the stipulated blowing pressure, the boiler gage shall be tested and if found correct, the safety valve shall be corrected.

C-26. The setting and adjusting of safety valves shall be done by a competent person. When safety valves are set or adjusted, the level of the water in the boiler shall not be above the highest gage cock.

C-27. In order to insure that the freedom of the spring is in compliance with the Rules given in Pars. 282 and 284 of the Rules for the Construction of Power Boilers, it shall be tested whenever the valve spring is adjusted.

C-28. After a hydrostatic test has been made, special care shall be taken to see that the safety valve is immediately restored to its proper operating condition.

C-29. Leaking safety valves shall be repaired or replaced as soon as discovered.

C-30. Care shall be exercised to prevent the accumulation of dirt, scale or other foreign matter between the coils of the spring.

C-31. The discharge from the open end of escape pipes shall be unobstructed and, if practicable, inside of the boiler house within hearing of the operator.

C-32. All supports and anchors that are attached to the escape pipe, shall be tested every six months and the proper tension maintained.

C-33. Escape pipe drains shall be examined monthly and the escape pipes shall be disconnected once a year in order that the drain may be kept free and clear at all times.

C-34. Intercommunicating Valves Between Systems of Different Pressure. Where intercommunicating systems of different steam pressures are installed with boilers on each system, the boilers on the low-pressure systems shall be equipped with non-return check valves. All low-pressure headers and their outlets shall be protected by a relief valve or valves whose combined capacity shall be equivalent to the total amount of steam that can pass from the higher-pressure system into the lower pressure system. Where a reducing valve is used, a hand valve shall be installed. Also a steam gage shall be installed at a convenient point for the guidance of a person when operating the hand valve in lieu of the reducing valve.

C-35. Whenever the total amount of steam that can pass from a higher-pressure system into a lower-pressure system has been increased, the relief-valve capacity shall be increased an equivalent amount in accordance with Par. C-34.

Feedwater Control

C-36. Pump Regulators. Feed-pump pressure regulators shall

be maintained in good condition and shall be frequently tested under closed discharge. When duplicate pump is not installed the pressure regulator shall be by-passed.

C-37. When feedwater pressure increases above normal, the feed lines shall be examined for possible choking due to scale or other causes.

C-38. Feedwater Regulators. Where feedwater regulators are used they shall be by-passed and shall be kept in good working condition, but shall not be depended upon to maintain a proper level of water in the boiler.

Excessive Combustion

C-39. Damper. Damper regulators and draft-control devices shall be kept in good working condition and shall be so installed that any failure of or accident to the mechanism of the damper will cause the damper to open and not to close.

C-40. Fuel Supply. Fuel-supply regulators shall be kept in good working condition and shall be so installed that any failure of or accident to the mechanism of the regulator will shut off the supply of fuel to the boiler and, once having shut off the supply of fuel, will not automatically resume the supply of fuel.

Operation

C-41. Manipulation of Valves. When cutting in a boiler, the stop valve shall be opened slowly to avoid water hammer and, where non-return check valve or stop and check valve is not installed, it shall be opened only when the pressure in the boiler is exactly the same as the pressure in the main boiler header. Where a non-return check valve or stop and check valve, as the case may be, is installed, it shall always be used automatically for cutting in and cutting out of the boilers; the main stop valve, in cutting in a boiler, shall be opened when the pressure on the boiler is still 10 or 15 lb. less than that on the main and, in cutting out the boiler, the main stop valve shall not be closed until after the non-return check valve has closed. Care shall be taken to drain the piping between the main stop and non-return check valves before cutting in the boiler.

WEAKENING OF STRUCTURE

Overheating

C-42. Lack of Water Supply. Special and constant care shall be exercised to maintain a proper and uniform water level in the water gage glass and to provide a continuous rather than intermittent supply of water to the boiler.

C-43. The water tender or any operator responsible for maintaining water in the boiler shall not permit any inattention, other duties or reliance upon automatic devices to interfere with the performance of his duty in preventing low water level in the boiler.

C-44. Where practicable, a duplicate source of supply of feedwater, pump or injector and piping systems to the boilers shall be installed. Where two systems of piping to the boilers are used, it is recommended that the two systems enter the boiler at different points. Feed pumps and injectors shall be maintained in good condition.

C-45. Leaks in the feed discharge line or elsewhere shall be stopped as soon as possible.

C-46. Sufficient water shall be maintained in feedwater tanks to prevent loss of suction in the feed pumps and, where hot water is fed to or allowed to splash in feedwater tanks, sufficient water shall be maintained in the tank to prevent entrainment of vapors.

C-47. Feed lines shall be free from objectionable vibration due to feed pump.

C-48. Where electrically driven feed pumps are used, there shall be maintained, ready for service, steam-driven feed pumps of sufficient capacity to safeguard the boilers in case of failure of electric power.

C-49. Restricted areas in feed lines, such as meter tubes, orifice plates, etc., shall have a by-pass equivalent in size to the pipe line.

C-50. Where economizers are installed in the feed line, they shall have a by-pass equivalent in size to pipe lines.

C-51. All feedwater tanks shall be cleaned out frequently to prevent the accumulation of objectionable sediment.

C-52. When feedwater tanks are installed, and the water level cannot be observed easily by the water tender, suitable water-glass or water-level indicators shall be installed.

C-53. Frequent inspections shall be made to detect scale and defective check valves in the feed line.

C-54. Feedwater regulators or other automatic devices shall be maintained in good working order.

C-55. If difficulty is experienced in maintaining the proper water level, the combustion shall be checked and the draft dampers and ashpit doors closed until the cause is discovered and corrected.

C-56. If the level of the water is not visible in the water glass, the gage cocks shall be tested to ascertain whether the level of the water is above or below the water glass. If the level is below the water glass, the supply of fuel and air shall be stopped and the dampers and ashpit doors closed. The feedwater valve shall be closed and under no circumstances shall any attempt be made to admit water to the boiler. The fire shall be hauled or in case of stokers or chain grates, the grates shall be kept in motion and the fire doors shall be left open. Water from fire or other hose shall not be thrown upon the fire. The safety valve shall not be opened, steam outlet valves shall not be changed nor shall any change be made that will cause a sudden change in the stresses acting upon the boiler. The blow-off valves shall be examined and, if found defective, repaired. The cause of the failure of water supply shall be determined and remedied.

C-57. Where both cock and valve are used in the blow-off line, the cock shall be placed between the valve and the boiler. All blow-off cocks and valves shall be kept free from leaks and in good working order.

C-58. Blow-off piping shall be extra heavy from boiler to valve or valves, and all fittings between the boiler and valves shall be of steel. Blow-off pipes shall be so located that all exposed portions within the building, and within any pipe tunnel, opening directly into the boiler room, can be inspected and such portions of the blow-off piping which occur within the boiler room, or within any pipe tunnel opening directly into the boiler room, shall be installed to withstand full working pressure of the boiler.

C-59. Blow-off valves shall be in such location that they are accessible, and if located in a trench or tunnel, an extension shall be applied to the valve stems so that they may be operated from the floor, or some convenient location.

C-60. In operating blow-off cocks and valves, they shall be opened and closed carefully and slowly; care shall be exercised to make sure that when the valves or cocks are closed, they are closed tight. Where both valve and cock are used in the same blow-off connection, the cock shall be opened before the valve and closed after the valve. In blowing off a boiler, the valve or cock shall be opened half way and remain so until one inch of water has been blown down and then the valve shall be fully opened and remain so until the blowing off is completed.

C-61. The amount of blowing off shall depend upon the amount of suspended matter in the feedwater, the number of hours per day that the boiler is in service and the rating at which the boiler is in operation; the minimum amount shall be one gage every twenty-four hours, except where the amount and frequency of blowing down is determined by chemical analysis. The blowing off shall be done when the boiler is operating at its lowest rating; a boiler shall be blown off as soon as it has been cut off the line and just before it is cut in.

C-62. When the operator is blowing down a boiler and cannot see the water glass, another operator shall be placed to watch the water glass and signal the operator blowing down the boiler.

C-63. The pipe and fittings between the blow-off valve and the boiler and their insulation shall be occasionally inspected in order to maintain them in good condition.

C-64. When practicable, the end of the blow-off line shall be visible in order to detect leakage.

C-65. Fouled Heating Surface. Boilers shall be kept free from scale, mud and sediment as far as possible at all times, particular care and attention being given to the heating surfaces, tubes and fire sheets.

C-66. Waters containing salt, magnesium chloride or nitrates should not be used in the boiler without outside treatment as they will cause pitting and foaming in the boiler.

C-67. Feedwaters should be made slightly alkaline with com-

mercial sodas or lime where free organic or mineral acids are present.

C-68. Feedwaters should be treated with commercial sodas where the impurities in 10,000 gallons of water are precipitated by one pound or more of carbonate of soda.

C-69. Where feedwaters contain 3 grains per gallon or more of carbonate of soda, or its equivalents in other sodas, the soda concentration within a boiler should not exceed 100 grains per gallon.

C-70. All feedwater should be passed through a heater before it is introduced into the boiler in order that any temporary hardness will be eliminated as far as possible and precipitated in the heater from which it can be removed easily.

C-71. Feedwater which is treated should be raised in temperature to a minimum of 180 deg. fahr., and the treatment should take place in an external vessel or heater separate from the boiler, which is suitable for receiving the precipitate formed by the elimination of the temporary hardness and the reaction of the chemicals thus obviating use of the boiler as a sludge tank as far as possible.

C-72. Commercial boiler compounds should not be used without intelligent supervision or without an exact understanding of their chemical composition, the exact nature of the scale-forming material in the water and the reaction which will be brought about by their combination.

C-73. Where water-softening apparatus is found necessary, operator should check by analysis, with frequency, the quantity of chemicals or other substances used in the softener against the scale-forming matter in the water.

C-74. Proper technical supervision should control the operation of any water softener.

C-75. Recommended procedure for treatment of boiler feedwater to obtain the best results and greatest assurance of safe operation is the daily sampling and analysis of feed and blow-down water, regulation of the blow down and prescription of feedwater treatment by some qualified chemical engineer at frequent intervals.

C-76. Where carbonate of soda or soda ash is used in the treatment of feedwater, it must be kept at a point below $^1/_2$ of 1 per cent normal alkaline strength or concentration to avoid pitting; that is about 15 grains per gallon, normal solution of sodium carbonate being 5.3 grams to 100 cc.

C-77. Graphite should be used with caution as a boiler-water treatment. It tends to choke up connections to draft regulators, steam gages, etc.

C-78. Kerosene should be used with caution in boiler as a scale remover. It is liable to leave behind inflammable gases, which have caused dangerous explosions in the past on the introduction of lights into the boilers, and it may distil into elements which will attack gaskets and joints of piping and fittings.

C-79. When soda ash is used to remove scale from boilers, it must be done under proper supervision, and when conditions are bad it is recommended that daily record be made of alkalinity and chloride content of the water in each boiler.

C-80. Where priming is experienced, a sample of trap discharge from steam main near boilers shall be tested for chloride and alkalinity frequently and the result recorded.

C-81. When scale is being removed from boilers by the treatment of feedwater, care must be used not to bring it down too fast as it may accumulate in piles and patches on the sheets over the fire causing bagging or blistering of the plates.

C-82. A piece of zinc should be hung in the interior of boilers which are subject to electrolytic action and a tendency to pitting. There should be a good electrical contact of low resistance between the boiler structure and the zinc, which must be fitted in a basket designed to prevent the danger of the disintegrated zinc from fall in a pile on the shell of the boiler or plugging tubes in the vicinity. Zinc should not be used where boiler compounds are being employed for treating feedwater.

C-83. Care shall be used to prevent the entrance of oil into a boiler, as it will collect in clots on the heating surfaces, causing bagging or rupture.

C-84. Where there is a possibility of oil in returns, feedwater heaters should be provided with oil filters. Entrainment return lines should be passed through some suitable filter bed such as excelsior, exhaust mains should be dripped and the oil separated out.

C-85. Discharge from heaters or heater coils for fuel-oil installations shall be wasted or diverted to other uses to prevent any oil reaching the boilers.

C-86. When boilers are taken off the line for cleaning and washing, they should not be blown down and opened before the brickwork of the setting has cooled, otherwise the scale will be baked hard on the metal surfaces making its removal difficult.

C-87. Boilers should be blown down at regular intervals under the supervision of some competent person for the removal of mud which has precipitated because of the elimination of temporary hardness in the water by heat, removal of scale-forming elements by treatment, and the ordinary settling down of impurities in general.

C-88. It is recommended that a feed trough be used with water-tube boilers which have longitudinal upper drums into which the feed line is connected, for the purpose of catching and facilitating removal of mud deposited from the temporary hardness in the water.

C-89. Boilers should be taken off the line at such regular intervals, especially where the water is being treated, blown down, opened and given a thorough washing, as to clear all tubes and heating surfaces of mud, slime and loose deposits.

C-90. Boiler tubes should be turbined as required, to free tubes from scale but with proper feed treatment and control very little turbining should be necessary. Removal of scale from the exterior of fire tubes by vibrating them with internal cleaner or hammer must be practiced with caution as it is a serious strain on thin tubes.

C-91. Boilers shall be provided with the necessary manholes and handholes so that all areas can be reached, lighted, inspected and washed with facility.

C-92. Soot should be removed from heating surfaces frequently. In addition to the use of mechanical soot blowers, the front tubes of many water-tube boilers should be blown and cleaned over the fire with a hand-operated steam or air lance.

C-93. The engineer in charge should make inspections of the internal and external surfaces of the boiler at frequent intervals, logging the result of such inspections in detail to form a basis of comparison from time to time.

C-94. Excessive Combustion. Care shall be used that there is no weakening of the boiler structure due to fire cracks, crystallization of parts, etc., because of an increase in the rate of operation, where stokers are substituted for hand firing, or there has been a change from low- to high-grade fuel, etc.

C-95. Furnaces shall be guarded against leakage of cold air which striking against hot surfaces of the boiler cause dangerous stresses.

C-96. In case of stokers and oil fires care shall be used to keep furnace temperatures down to safe limits and to see that only the best available refractories are used.

C-97. Oil flames shall not be allowed to impinge on side walls or arches as they will cause excessive spalling and endanger safety of the structure. Air pressure in the furnace shall not be allowed as it will force hot gases out through any crevices in the setting and tend to destroy it.

C-98. Secondary Combustion and Flaming Through. Where possible, the combustion chamber and the gas passages with their connections shall be constructed without blind pockets or spaces where unburned gas can accumulate; where such pockets or spaces are unavoidable, they shall be properly ventilated.

C-99. Where waste gases are used as fuel, they shall be by-passed to the chimney.

C-100. Before lighting a fire, the combustion chamber and gas passages shall be thoroughly ventilated. After the ventilation (in a gas-, oil- or pulverized-fuel-fired boiler) a torch or other flame shall be placed in the combustion chamber before the supply of fuel is admitted. If a torch is used the operator shall stand clear of the opening. In oil-, gas- or pulverized-fuel-fired boilers, a torch shall be used to light all burners until the brickwork becomes intensely hot and even then when all burners are out.

C-101. In the event of flare back or the snapping out of burners, the fuel supply shall be shut off and the boiler thoroughly ventilated before the fire is again lighted.

C-102. Secondary combustion shall be prevented by admitting sufficient air at all times to guarantee the complete combustion of the fuel before the gas has traveled one-half of the distance from

the fire bed or burners to the exit of the setting. Care shall be exercised to prevent the leakage of air into the latter passes and thus burning the gases in the latter passes.

C-103. When a fire is banked, the admission of air below the fire shall be checked and only sufficient air admitted to the combustion chamber above the level of the fire bed to prevent the accumulation of gases of imperfect combustion. The damper in the uptake shall be left slightly open or perforated to insure a slight draft.

C-104. In shutting down a boiler, the air supply shall be maintained until after the fuel supply is discontinued and in the case of oil-fired boilers until any oil on the floor of the combustion chamber is consumed. After all combustion has ceased, the air supply shall be continued only until the combustion chamber and gas passes are thoroughly ventilated.

C-105. Localized and Uneven Heating. Ample time shall be allowed for raising steam pressure to prevent uneven heating of the boiler and setting, especially where circulation of water may be sluggish, as in internally fired types; also on new installations where uneven expansion might effect the brickwork.

C-106. The surfaces in the steam space of drums shall not be exposed to the direct heat of the combustion chamber, or to the direct products of combustion. Baffles and brickwork shall be kept in repair at all times to prevent surfaces in the steam space of drums from becoming exposed to the direct heat of the combustion chamber.

C-107. When superheaters are a part of the boiler, some means shall be taken, when firing up, to blank off the direct affect of the hot gases by a damper, unless superheater is flooded or unless they are of a type protected to withstand the heat.

C-108. Cast-iron or wrought-iron sleeves of ample size shall be provided wherever pipes pass through the brickwork, to provide for expansion and contraction.

C-109. Rivet heads shall not be exposed directly to the heat of the combustion chamber, except where they are within the water space.

C-110. Boilers shall not be emptied until brickwork cools, as uneven expansion may take place.

C-111. Damper Regulation. Each boiler shall be provided with a draft gage and a recording temperature device in the stack used in connection with each battery. Every boiler shall be provided with a back damper which can be operated and adjusted conveniently from the firing floor by the fireman on watch.

C-112. Smoke flues from batteries of boilers shall be baffled in such a way as to equalize the draft between the boilers.

C-113. Where draft-control systems are used they shall not be considered as relieving the fireman of responsibility. He shall be alert at all times to detect unusual conditions which may cause excessive combustion and affect the safety of the structure.

C-114. Where electric devices are used to actuate draft-control apparatus, the operator shall use care to see that the current does not fail and to handle the situation promptly in case of failure of the electrical supply.

C-115. Should the damper connection break, the mechanism shall be arranged so that the damper will open automatically and the fuel supply shut off automatically.

C-116. Damper regulators, where used, shall be preferably of the so-called "dead beat" type with valve lever so arranged that after pilot valve has been opened by a slight shifting of the pressure-actuated lever, it will be returned to closed position by the movement of the piston rod which handles the damper, thus causing gradual changes in the draft condition.

C-117. Damper regulators and draft-control apparatus shall maintain the steam pressure within a total range of not more than 5 lb. for boilers carrying under 150 lb. gage pressure, and within 10 lb. for boilers carrying higher pressure.

C-118. In the case of oil-burning or powdered-coal furnaces, the back damper shall be opened wide when the fire is to be lighted.

C-119. Insulation. Blow-off pipes shall be protected from the products of combustion by firebrick or other heat-resisting material so arranged that the pipe may be inspected.

C-120. Structures supporting the boiler, or structures which are a part of the building, shall be protected from the heat of the combustion space by insulating material, or air space, and shall not be subjected to temperatures above 600 deg. fahr., which might affect the strength of the material, and cause strains to occur due to expansion. This applies particularly to structures located between the settings of boilers in a battery.

C-121. With the suspended settings the steel work shall be so designed and be of sufficient strength and rigidity to eliminate any strain on the brickwork, under conditions of temperature which might cause the steel to expand or contract.

C-122. Firebrick linings shall be set in such a manner that when heated the expansion will not affect the outside walls.

Internal Corrosion

C-123. General. The interior of all parts of boilers shall be examined frequently and watched continually for evidences of corrosion in the shape of grooving, pitting, wasting away or thinning of metal.

C-124. Upon the observation of any indications of corrosion, steps shall be taken promptly to counteract the condition. In case of steaming boilers, clear water or grayish color in the gage glass may be an indicator of safe water, while reddish or blackish colored water may be an indicator of corrosion in the boiler or its connections.

C-125. Boiler operators shall watch their raw-feed supply to guard against the possibility of corrosive elements becoming mixed with the water.

C-126. The presence of air and oxygen may be detected by warming a sample of boiler feedwater in a glass flask and noting the bubbles which collect.

C-127. Feedwater shall be examined from time to time for organic matter both by filtering and by testing with pure sulphuric acid which, when added to a sample of the water in test tube, will turn it brown should organic material be present.

C-128. Chlorides which are particularly active agents of corrosion shall be tested for by the addition of silver nitrate to a sample of water which contains a little potassium chromate indicator which gives a brownish red color in presence of chlorides.

C-129. A test for acidity shall be made often, particularly if the source of supply of feedwater is a river or pond in a manufacturing district. This test can be made by taking a sample of raw water, adding a drop of methyl orange which will turn the sample yellow if it is alkaline and pink if acid and corrosive.

C-130. Where complete water analyses are available, it is recommended that they be checked by Stabler's corrosion formula which classifies them in accordance with their acid-forming tendencies. Stabler's coefficient of corrosion is

$$C = H + 0.116\ Al + 0.0361\ Fe + 0.0828\ Mg + 0.0336\ CO_3 + 0.0165\ HCO_3$$

where the CO_3 term represents the carbonates, the HCO_3 the bicarbonates, and all the terms are expressed in parts per million. Where $C + 0.0503$ (calcium ion) = negative quantity, there will be no corrosion due to acidity. Where C is negative but $C + 0.0503\ Ca$ is positive, corrosion may or may not occur, the probability varying directly with the value of expression $C + 0.0503\ Ca$.

C-131. Water shall be kept slightly alkaline when there is reason to expect acidity, and possible corrosion. This maximum alkaline strength should not exceed one-half of one per cent normal (about 15 grains per U.S. gallon) unless under the direction of an expert feedwater chemist or engineer. Normal alkaline strength is 5.3 grams of soda ash or sodium carbonate to 100 cc. of distilled water.

C-132. The percentage of normal-strength alkalinity shall be ascertained with frequency and checked by the formula:

$$P = \frac{Qn}{S}$$

where

P = per cent normal strength
Q = number cc. from testing burette
n = percentage of normal strength of acid used in testing burette
S = number cc. in sample of water being tested.

C-133. This test for alkalinity shall be made by titration using

$\frac{N}{5}H_2SO_4$ (i.e., one-fifth normal sulphuric acid) in burette and phenol-pthalein indicator which changes from pink to clear water at the end point. Tests made for the detection of possible tendencies to corrosion must be made not only on the raw water but especially on the blow down water of the boiler.

C-134. Feedwater. Air and gases like oxygen, carbon dioxide and sulphur dioxide either in solution or mechanically mixed with feedwater are corrosive agents. Such feedwater should be passed through an open heater which has a top breather pipe to the air through which the gas may escape.

C-135. Where considerable trouble is experienced from air, oxygen and carbon dioxide in feedwater, some form of deactivator should be used. Closed heaters should not be used where air and gas is encountered in feedwaters as they tend to collect the gas, are corroded rapidly, and are dangerous for that reason.

C-136. Where air and gas are carried into the boiler they tend to lodge below the water line in the form of bubbles which make pits in the metal. In such cases the feed shall be treated with lime or caustic soda to make the water slightly alkaline (see preceding paragraph on safe limit), the water should be fed above the water line in the form of a spray and in extreme cases a vacuum pump attached to the open heater to clear it of air and gas.

C-137. All feedwaters which have magnesium compounds in them must be regarded with suspicion. Magnesium chloride under the action of heat decomposes and gives off hydrochloric acid. Magnesium sulphate, if salt is present, will produce hydrochloric acid under the action of heat. Such waters should be treated with carbonate of soda.

C-138. Feedwaters which contain sea water will cause corrosion and should be treated with sodium carbonate.

C-139. Boiler waters which contain calcium sulphate and organic matter shall be taken care of as they will produce sulphuric acid, a dangerous corrosive agent.

C-140. Calcium sulphate scale shall be removed from boilers promptly as it will decompose into sulphur dioxide and oxygen under the action of heat. This free oxygen attacks the metal of the boiler corroding it rapidly.

C-141. All nitrates are corrosive agents, and where they occur shall be neutralized by treating the feedwater.

C-142. Ammonium carbonates which come from barn and outhouse drainage are a source of danger which must be guarded against as they are very corrosive.

C-143. Acids in general must not be allowed to get into feedwater supply. Rivers which flow past manufacturing towns frequently pick them up; they may come from the decomposition of fats, vegetable oils and greases which were compounded into lubricating oils used in the plant; water from swamps and bogs may contain humic acid, tannic acid and carbonic acid; some patented boiler compounds contain free acids like tannic acid; coal-region water contains sulphurous acid, etc.—all are corrosive and their possible presence should be checked regularly by means of the acid test described in the preceding paragraph.

C-144. Pure water and distilled water shall be used with caution as boiler feed. The pure water has a marked capacity for dissolving iron. Distilled water always has an equal volume of CO_2 in it. Both are corrosive and should be made alkaline with lime or soda.

C-145. Rain water, especially where it comes from roofs of buildings near manufacturing centers, will contain more or less soot, salt and sulphur dioxide, all of which are corrosive agents which shall be guarded against.

C-146. Where coagulants are used, especially alum (sulphate of aluminum) decomposition may take place from the heat of the boiler, which sets free sulphuric acid, a dangerous corrosive agent.

C-147. Stray electric currents are possible in power houses, giving rise to obscure electrolytic reactions in the boilers which will cause pitting of boiler metal. For this reason boilers shall be grounded thoroughly.

C-148. Electrolytic action should be avoided as far as possible by the insulation of copper and brass pipes from the boiler structure, by the use of iron rather than brass or copper ferrules at tube ends when needed, by avoiding contact of dissimilar metals in the boiler structure, and by using care in keeping coal, cinder, scale, chips of copper, brass and lead out of the boiler.

C-149. Mill scale from tubes and shell plates shall be removed from boilers as it tends to promote electrolytic action and corrosion, especially where salt is present.

C-150. Defective circulation and unequal strains on members of the boiler structure tend to promote corrosion and must be checked where trouble is experienced.

C-151. Where pitting is experienced, the surface of the metal shall be cleaned carefully, the pits filled with zinc oxide paste to decrease the possibility of gas lodging in their cavities and to check the corrosive action. Where slight grooving and thinning have occurred the boiler drum shall be given an inside coat of portland cement or zinc paint.

C-152. Boiler Out of Service. When boilers are taken out of service for any length of time care shall be used to prevent corrosion. If they are to be left empty, they shall be oiled down as they are emptied, dried out with the help of a hot-air stove, have suitable amount of quicklime placed on boards in the interior and finally be closed tightly.

C-153. Boilers shall, if idle for considerable periods, be opened up each three months for examination and the renewal of the quicklime.

C-154. If idle boilers are to be left with water in them, this water shall be made slightly alkaline and the boiler pumped full of water. This water shall be heated to a moderate temperature for a short time to eliminate all the air possible. The boiler shall then be closed tightly, allowed to cool and shall be kept cold. In such cases a piece of bright, clean iron shall be hung in the closed boiler in such a way that it can be removed and inspected for rust and corrosion at regular intervals.

C-155. Where boilers are idle long periods filled with water, great care shall be used to keep this water cold as the maximum amount of corrosion is promoted by lukewarm water. For this reason feed valves and all steam connections shall be tight at all times.

External Corrosion

C-156. Leaks, etc. Boilers in service are always exposed to external leaks of different kinds which tend to corrode the shell. The operator shall guard against leaky safety valves and steam mains which drip on the boiler and cause external corrosion, especially where the water runs under protective coverings.

C-157. Leaky manholes and handholes particularly where ash and soot can collect are especially dangerous as they corrode the shell rapidly. Such places shall be kept clean and tight.

C-158. Boiler operators shall keep under observation at all times the blow-off pipe nipple that screws into the mud drum. Corrosion is especially liable to weaken the pipe at this point causing possibility of serious accident.

C-159. The roof over boilers shall be maintained in good condition as roof water leaking down on settings tends to destroy them as well as to corrode the boiler itself.

C-160. Quenching water shall not be played on hot ash and cinder in boiler pits as there is danger of wet ash being carried up on to the shell and tubes of the boiler causing corrosion.

C-161. Care shall be taken to see that ashes do not come in contact with the boiler at any point.

C-162. Leaky tubes shall be rolled or replaced promptly to avoid possible corrosion of the tube sheet.

C-163. Boiler out of Service. When the boiler is taken out of service it shall be cleaned externally and inspected for wet ash and soot.

C-164. When boiler is to be out of service for a long period it shall be given a coat of red lead, black japan, or tar paint to prevent external corrosion. The damper shall be closed and lime placed on several points in the setting to dry the air as much as possible. All openings into the setting shall be closed.

C-165. Where boiler has been taken off the line for an idle period, it shall be made certain that all feed and steam valves are shut and do not leak.

Erosion

C-166. Soot blowers shall be supplied with practically dry

steam: they shall be well drained before using. Care shall be taken to prevent too direct an impingement with a steam jet upon the tubes and tube sheets.

C-167. In using a steam lance, care shall be taken not to blow with too much force or for too long a period upon any one point, particularly about the lower end of vertical water tubes.

Stresses Other Than Internal Pressure

C-168. Boiler Supports. Foundations for steam boilers must be of ample size to carry the load, and where large concentrated loads fall within a small area of the foundation, as in the vertical types of boilers, the foundations should be reinforced and spread to prevent any settling which might throw the boiler out of line. When the boilers are set in a battery, and when the foundations are not tied together by reinforcement, the joints in connecting pipes shall be broken open occasionally to see that no strains have been placed upon the piping on account of settling of any of the boiler foundations.

C-169. Foundations and structures supporting a steam boiler shall be built to withstand any strain which may be transmitted to them by expansion or contraction of boiler or supports, and shall be tied together in such a manner as to maintain their proper relation.

C-170. Vertical fire-tube or water-tube boilers whose bases cover a small area shall be carefully shimmed to distribute the load equally at all points. All shims shall be of steel or iron and properly secured or grouted.

C-171. Steel structures supporting boilers shall be carefully protected from water from roofs or steam leaks, and wood or inflammable material shall never be stored close to supporting structures.

C-172. Supports for water-tube boilers shall be so designed that unequal strain shall not be brought upon the tubes by expansion or contraction. Structures surrounding the boiler shall provide for any expansion which may take place and eliminate any possibility of straining the tubes or injuring the boiler setting.

C-173. On suspended type of settings care shall be taken at all times to see that the load is properly distributed over all points of suspension.

C-174. Pipe-Line Supports. Pipe lines connected to boiler shall be installed with provision for expansion and contraction, and expansion bends shall be used where possible. Pipe lines shall be braced to prevent strains on boiler or connecting pipe lines, and supports shall be of sufficient strength and designed to withstand strains set up by possible water hammer or vibration.

C-175. Pipe-line supports shall not be attached to temporary structures which might be removed, or to wooden structures which might be injured by fire. Supports for piping shall not be attached to wooden or steel structures such as floor or roof beams, which might be deflected by changes in load.

C-176. Supports of Equipment or Other Structures. When stacks are supported from structures directly above the boilers, or from the boilers themselves, care shall be taken to protect all steel work from corrosion caused by water at this location running down on the stack, or from the roof.

C-177. Shafting and belting shall not be located over the boiler in such a position as to cause injury to the pipe lines, or cause strains on the boiler if an accident should occur to the belt, or the line of shafting. Supports for shafting shall be of sufficient rigidity, or, if necessary, separate structures should be provided the shafting to prevent vibration being carried to pipe lines, or to the boiler.

C-178. Safety-Valve Escape-Pipe Supports. To prevent injury to the boiler and setting, if necessary a safety-valve escape pipe shall be installed to carry the discharge or any condensation away. Escape pipes should be supported to prevent any strain upon the safety valve.

C-179. Supporting Columns Between Settings. Where supporting columns between settings, or near boilers, are exposed to corrosion, they shall be set on concrete piers at least one foot above the floor level, or shall be encased in concrete at least 2 in. thick, to a point above which corrosion will not occur. Supporting columns not protected by concrete against corrosion shall be exposed so that they can be thoroughly inspected, and shall be kept well painted.

C-180. All structures over boilers, whether they are part of the boiler installation or building structures, shall be inspected regularly to see that corrosion does not occur, and shall be kept well painted at all times.

C-181. Supports of Blow-off Lines. Blow-off pipes shall be supported and anchored to prevent strain being put on the boiler structure on account of expansion or contraction.

Molecular Changes

C-182. Crystallization is caused by alternate heating and cooling of the boiler metal and can be minimized by avoiding frequent and sudden changes of temperature.

C-183. Embrittlement may be caused by too high concentration of soda in the boiler water and can be avoided by maintaining a concentration of less than one-half of one per cent normal alkalinity.

Mechanical Injuries

C-184. All boilers, with their auxiliaries and appurtenances shall be located, as far as practical, where they will be least liable to damage from external forces such as building failures, flywheel explosions, flood, fire or explosions from the storage of inflammable material, belt transmission failures, etc.

C-185. Tube Cleaning or Scaling. Power, for operating mechanical hammers and cleaners used in removing scale or slag, shall be generated outside of the boilers being cleaned. When such tools are actuated by air, steam or water, they shall be operated at the lowest pressure sufficient to accomplish the work when the motion of these tools, actuated by hot water or steam, is generated within the tube, care shall be taken not to heat the tube to the extent of causing undue strains by expansion. Mechanical hammers and cleaners shall not be operated for more than a few seconds at a time at any one spot.

C-186. Loose Connections. The fastenings of all interior fittings such as braces, baffles, feed troughs, gratings, zinc baskets, dry pipes, etc., shall be maintained secure and free from lost motion.

C-187. Repairs. All repairs and replacements shall be subject to the rules for similar material and workmanship as given in the Rules for the Construction of Power Boilers.

C-188. No repairs, other than those of a routine character, shall be made upon a boiler except upon and in accordance with the advice of authorized boiler inspectors as required in Par. 409 of the Rules for the Construction of Power Boilers.

C-189. All repairs shall be made as soon as possible and a record of all repairs upon boilers and upon any equipment or auxiliaries affecting the safety of the boiler shall be kept. A record of all repairs deferred shall be kept with the reasons for their delay.

C-190. All leaks, however small, shall be traced to their source and the proper remedy, not only to stop the leak but to prevent its recurrence, shall be applied at once.

C-191. No repairs shall be made upon a boiler or upon any of its equipment while it is under pressure.

C-192. The shell or drum of a boiler in which a typical "lap-seam crack" is discovered along a longitudinal riveted joint for either butt-seam or lap joints shall be permanently discontinued for use under steam pressure. By "lap-seam crack" is meant the typical crack frequently found in lap seams extending parallel to the longitudinal joint and located either between or adjacent to rivet holes.

C-193. Cracks caused by flexure of the metal shall be repaired by removing the part affected and replacing it with a new part. The new part shall be of greater strength than the defective part or other means shall be employed to prevent a recurrence of the trouble.

C-194. Where corrosion becomes dangerous or when cracks appear, the boiler shall be kept out of service until the affected parts have been repaired or replaced. No welding or patching shall be done except upon and in accordance with the advice of authorized boiler inspectors.

C-195. Where pits occur closely grouped or aligned and are deep enough to affect the strength of the material, the affected area shall be removed and replaced by a hard patch. Isolated pits, not affecting the strength of material, shall be prevented from becoming serious by cleaning the pit to bare metal, washing with strong alkaline solution and filling with zinc oxide.

C-196. Leaking rivets shall be calked about the edge of the head and, if the leak continues, the rivet shall be removed and a new rivet put in. In removing the rivet, the center of the head shall be removed with a cape chisel, the remaining portions of the head driven inward and the rivet driven out by punch and hammer. If the rivet cannot be removed except by heavy hammering, the rivet shall be drilled two-thirds of the way through its body with a drill $^1/_8$ in. smaller in diameter than the rivet and the remainder of the rivet backed out. Before driving a new rivet, the rivet hole shall be made clean and free from burrs and sharp edges.

C-197. No attempts shall be made to make a joint tight by putting undue stress on the bolts. If a joint cannot be made tight without stretching the bolts, the joint shall be opened and the cause of the poor joint determined and removed.

C-198. Increasing the leverage of a wrench by a piece of pipe or other means shall not be permitted as an average man with a

12 in. wrench will stretch a $^5/_8$-in. bolt
18 in. wrench will stretch a $^3/_4$-in. bolt
24 in. wrench will stretch a $^7/_8$-in. bolt
30 in. wrench will stretch a 1 -in. bolt

This represents the limit which bolts should be expected to stand.

C-199. In cleaning gaskets from finished surfaces care shall be taken not to score or cut the surface.

C-200. When water tubes are sufficiently warped to prevent proper inspection for soundness and cleanliness, no attempt shall be made to straighten them in place; such tubes shall be renewed.

C-201. A water tube with a series of bags closely connected shall be replaced. Bags on water tubes shall not be set back. When the bag leaks or is abrupt with a tendency to pod or point to such an extent that there is an appreciable stretching of the metal or that there is a possibility of scale or deposit collecting in the bag, the tube shall be removed.

C-202. Tubes, which have been rolled until the thickness of the metal has been considerably reduced or until the life of the metal is probably destroyed, shall be renewed.

C-203. Tubes in fire-tube boilers, which have been rolled several times and still leak, may be improved temporarily by rolling and beading the tube and then inserting a tight-fitting ferrule of tube stock of a gage equivalent to that of the tube and of a length equal to three times the thickness of the tube sheet. The inner end of the ferrule shall be chamfered on the inner edge and the outer end shall be rolled and beaded after the ferrule is in place. When a ferrule is installed immediate steps shall be taken to replace the tube. There shall not be more than 10 per cent of the number of tubes in the boiler so equipped and not more than two adjacent tubes at any one time.

C-204. Tubes shall not be reënded or pieced by autogenous welding.

C-205. In removing tubes exceptional care shall be taken not to injure the metal around the tube hole. A tube in being removed shall be cut with a flat chisel from the end to the header or drum at two places about $^3/_4$ in. apart and the strip, between the cuts, raised from its seat and bent inward with a bar. The tube shall then be split through and beyond its seat with a tool as wide as the strip and ground to the curvature of the tube hole. A crumpling tool shall then be used to break in the end of the tube.

C-206. When a new tube is to be installed, the surfaces of the metal about the tube hole shall be made free from any projections due to mutilation and shall be thoroughly cleaned of scale or foreign matter. Any grooves, scorings or holes in these surfaces shall, if slight, be filled with iron cement or zinc oxide paste or, if of any magnitude, be built up by welding. The ends of the new tube, where they come in contact with the tube sheet or header, shall be made clean and smooth before the tube is put in place.

C-207. The expanding of the tubes shall be done by a competent person. Before expanding a tube, the expander shall be examined to see that it is equipped with the proper rollers, straight or tapered in the proper direction. Rolling shall be stopped when the rollers operate evenly all around the tube with sufficient pressure on the mandrel. The beading of a tube shall be done by rollers especially designed for the purpose or by a tapered mandrel driven into the end of the tube. The flaring, beading and welding of tubes and nipples and the amount of projection of the end of the tube beyond the tube sheet or header shall be in accordance with the rules given in Pars. 250, 251 and 252 of the Rules for the Construction of Power Boilers. The tube ends should be lightly rolled after beading.

C-208. The rules applying to the care of tubes and the surfaces about the tube holes are equally applicable to the care of the nipples and the surfaces about the nipple holes.

C-209. In removing slag from the exterior surfaces of a boiler or its tubes, care shall be exercised not to injure the metal.

RULES FOR INSPECTIONS

C-210. All power boilers shall be given one internal and two external inspections per year by the state or municipal inspectors having jurisdiction or by the inspectors of the insurance company carrying the risk. These inspectors are hereinafter termed authorized inspectors.

C-211. Similar inspections shall be made by the person responsible for the boiler plant as a whole who is hereinafter termed the plant inspector. Such inspections shall be supplementary to and in no wise considered as supplanting or superseding the inspections made by authorized inspectors. Such inspections shall be made in accordance with the following rules.

C-212. Between periodical inspections by authorized inspectors, the plant inspector shall closely observe the operation and condition of the boilers and shall report immediately to the proper authorities any serious defects, doubtful conditions or unusual occurrences.

C-213. An external inspection shall comprehend the superficial examination of the boiler, its appurtenances and connections and does not necessarily require that the boiler be off the line. It is a form of examination to check up care and management mainly.

C-214. The internal inspection of the boiler shall be a comprehensive and thorough examination in every detail, embracing particularly the determination of the suitability of the boiler for load and pressure carried, strength of its parts, possible deterioration in service, and advisability of its continuance under the pressure carried previously to inspection.

C-215. No particular preparations shall be necessary for an external inspection other than giving the plant inspector convenient access to the boiler and its connections.

C-216. The internal inspection shall call for somewhat extensive preparation, mainly the proper cooling and opening up the boiler together with a thorough cleaning of the boiler, including setting.

C-217. The cooling of boiler shall be done cautiously so as not to put undue stress on the heated surfaces and setting. The damper shall be opened wide and the ashpit doors opened allowing circulation of air in the usual way. The fire doors shall remain closed until boiler is cooled.

C-218. During the cooling process the large doors in the boiler front shall be kept closed in order to prevent rapid cooling of tube ends.

C-219. After the furnace and lining have become well cooled the fire doors may be opened as well as the clean-out door at the rear preparatory to sweeping out the accumulated ash and soot.

C-220. The walls, baffles, tubes and shell shall be thoroughly swept down and the ash and soot removed to give the plant inspector opportunity to examine the parts closely and to eliminate danger from hot contact.

C-221. The tubes shall be well dusted and cleaned with steam soot blowers before the cooling operation has commenced. Steam shall not be used to clean tubes of a cold boiler as the moisture cements the soot and ash into a hard mass difficult to remove.

C-222. When boiler and setting are thoroughly cooled the blow-off valve shall be opened and the water removed. Then the manhole and handhole covers shall be removed to allow circulation of air.

C-223. The inside of shell, drums and tubes shall then be washed down thoroughly to remove mud, loose scale, etc. The washing operation shall be conducted from above as far as possible to carry the material downward to blow-off or lower handholes.

C-224. Before the washing operation is commenced a wire-gauze screen of cylindrical form shall be inserted in each blow-off opening, projecting up into the boiler several inches, whose function

is to prevent loose pieces of scale from entering and clogging the blow-off pipe.

C-225. The plant inspector shall have available the data on the boiler, dimensions, age, particulars as to previous defects noted, if any, and shall proceed to check up the pressure carrying capacity of boiler subject to conditions found during complete inspection.

External Inspection

C-226. The plant inspector shall examine the boiler for level, noting whether or not there has been any tendency to settlement, especially the level of the top tubes in horizontal-return-tubular boilers. He shall see that proper provision is made for expansion toward the back of boiler.

C-227. Examination shall then be made of the feed connection to see that it is clear and in good working condition.

C-228. Examination shall be made for evidences of corrosion on exterior of shell from rain coming down stack and leaking roofs, valves and pipes.

C-229. Inspection shall be made to see if there is any leakage of flame on dry sheets, particularly at the back arch of return-tubular boilers, which should be entirely clear of rear tube sheet with sheet metal or asbestos rope covering gap. Tie rods and buck stays shall be examined for condition and possible shifting from place.

C-230. Where the boiler top is covered with brick or other material, it should be removed sufficiently to allow proper inspection of riveted joints.

C-231. The plant inspector should note proximity of overhead shafts or any machinery which might drop down on or strike boiler in case of accident.

C-232. The plant inspector should note the presence of lumber, or other material piled on boiler or setting for purposes of drying or storage and which may endanger the setting or the safety and accessibility of the apparatus.

C-233. A careful examination shall be made of the safety valve, its connection to the boiler, escape pipe, its drip, supports, etc. He shall also test the safety valve by hand.

C-234. The water glass, gage cocks, water column connections and blow-offs shall be tested to see if the connections are free. Boiler pressure gages and master gages shall be tested.

Furnace and Parts Exposed to Fire

C-235. The plant inspector shall go into the furnace for the examination of the exterior of the tubes, shell, brickwork, etc.

C-236. He shall examine carefully for bulges over the fire, leaky rivets, loose rivets, rivets out of alignment, corrosion, wasting away of plates, cracks, etc.

C-237. The plant inspector shall scrape the shell and tap it thoroughly with hammer to detect thin places. He shall check thickness of plates with steel-scale measurement. He shall examine joints and sheets over the fire particularly for possible fire cracks.

C-238. The plant inspector shall examine the setting for cracks, settlement and loose brick which may lean against the boiler. Where brickwork is used as insulation of steel supporting numbers it shall be examined to see that it is in good condition and that the air space, if any, is maintained. The furnace lining shall be examined for spalling, cracking and settlement. In vertical boilers, bridge walls shall be inspected to see that the mud drum is properly protected. The plant inspector shall examine baffle and check walls particularly for holes which may permit flaming through.

C-239. The blow-off connection should be examined carefully for corrosion and weakness where it screws into the boiler. The protecting cover of brick or tile should be intact and not interfere in any way with the expansion of the boiler or pipe.

C-240. Particular attention shall be given the tube ends and tube sheets in the case of horizontal-return-tubular boilers, the plant inspector noting any corrosion of the sheets, signs of leaking tubes, excessive thinning of the tubes from repeated rollings, and any cracks in the tube ends.

C-241. The plant inspector shall note any tendency to corrosion from leakage of manhole and handholes under tubes in tube sheets of return-tubular boilers.

Internal Inspection

C-242. The plant inspector shall enter the drums of the boiler to make personal examination of conditions, first making sure that they have been properly ventilated and that there is no inflammable gas present from oil used to coat the boiler as the water level is lowered.

C-243. Before entering the shell or drum the plant inspector shall see that the blow-off valve, the main steam valve and other valves are locked and the keys in his possession.

C-244. Careful examination of the interior of the boiler shall be made for pitting, corrosion, scale and thin places in shell. The upper half of drums in the steam space shall be examined particularly for signs of grease and oil.

C-245. The interior of the tubes should be examined for scale and deposits and the space between the tubes in case of return-tubular boiler made visible by lowering candle or small light between them for the purpose of making sure that there is no restriction of the circulation.

C-246. The location of the feed discharge and condition of the trough under it shall be noted. Dry pipes shall be examined to see that their openings and perforations are free from deposits. All interior fittings shall be examined for loose connections.

C-247. The interior face of the riveted joints shall be examined for condition of riveting, thinness of metal, corrosion, cracks, etc. The plant inspector shall note any wasting away and cracking of stays and braces. Particular note shall be made of any welded stays or braces.

C-248. The fusible plug, if used, shall be examined, the top scraped to expose the condition of the metal and the plug renewed in case it has seen a year of service. The surface of the boiler about the plug shall also be scraped.

Inspection of Appurtenances and Supports

C-249. An examination of the condition of the main header and its connections to boiler shall be made to ascertain that it is properly supported, that due allowance is made for expansion without throwing strains on the boiler, that the non-return stop-valves are in good working condition and so placed that there is no pocket in the connection to hold water.

C-250. The plant inspector shall note the position of the steam gage, gage cocks, ascertain that the pipes leading to the water column and water glass are level, and by leveling across the top row of tubes or from the position of the fusible plug check the position of the water glass.

C-251. Check pipe line and all exterior supports to see that the proper tension and alignment is maintained. Where boiler foundations are independent of building foundations, joints on the steam and feed connections shall be disconnected once a year to check possible settlements.

C-252. In addition to the above inspections, the plant inspector shall observe the condition of the interior of boiler at least once in every three months or at more frequent intervals if the boiler is opened for cleaning or repairs. Each time the boiler is removed from service, the plant inspector shall look for signs of defects where observations cannot be taken while the boiler is in operation.

C-253. A record of each inspection shall be kept in a uniform manner so that any change of condition can be definitely compared especially with reference to thickness of scale, corrosion, cracks, etc.

Care and Management

C-254. The plant inspector shall note particularly any evidences of carelessness in the care and management of the boiler and its appurtenances.

C-255. The plant inspector shall demand immediate remedy of any unsafe conditions or undesirable practices he may uncover and shall report fully on the results of his inspection to the owners of the boiler plant, promptly.

C-256. The plant inspector shall be furnished a copy of all reports of inspections made by authorized inspectors and shall see that all recommendations in such reports are promptly and carefully carried to completion.

RULES FOR ROUTINE OPERATION

Putting Boilers in Service

C-257. Getting up Steam. In starting a new boiler or one that has been out of service for an extended period, see that the combustion chamber and gas passages are clean and in good repair. See that all clean-out doors are closed tight.

C-258. Operate and see that both inlet and outlet dampers are free and in good condition. Leave the back dampers open. Operate the stoker and draft fan to see that they are ready for service. Make sure that the grates are satisfactory and in place.

C-259. Examine the inside of the boiler and make sure that it is free from tools and foreign matter and that there is no one in the boiler; then close manhole openings.

C-260. See that blow-off valves, water column and water-glass drains, try cocks and feed valves are in good working condition and closed. Open vent valves.

C-261. By means of auxiliary feedwater connections, fill the the boiler with water to a level a little above the surface blow-off and then close the auxiliary feed connections. Open and close try cocks and blow-down valves on water column and water glass in order to make sure that these connections are not stopped up.

C-262. Draw off water through surface and bottom blow-off valves until the level of the water in the boiler is at the bottom of the water glass and then raise the level of the water to a point about 1/2 in. below the normal water line by opening the stop valve in the main feed line.

C-263. Ease up on the stem of the main stop valve without lifting the valve off the seat in order to make sure that the valve is not stuck.

C-264. Open valves to steam pressure gage.

C-265. If coal is used as a fuel, cover the grate with a thin layer of coal and start a light fire. Where pulverized coal, gas or oil is used as a fuel, make sure that the back damper is wide open, create light draft, with fan if necessary, place torch or fire near burner to insure quick ignition and start light fire by admitting fuel slowly.

C-266. If the boilers use oil as a fuel and the system is new or has been out of service for a considerable period, first clean and examine the strainers and remove, clean and examine tips and burners. If compressed air is available, blow out the oil supply lines with air. Place and adjust burners and tips and work the air registers to see that they are in good working condition. Close individual burner throttle valves.

C-267. Remove any spilled oil about burners, fronts and floor and see that there is no oil on the floor of the combustion chamber. Ventilate the boiler by opening draft gates and dampers.

C-268. If no steam is available for oil pump and burners, raise steam in boiler by wood fire. Remove any excess accumulation of water in oil tank. Have oil pumps warmed up ready for use. Open suction-line valves and pump oil to burners. If oil lines are equipped with air chambers, charge them with compressed air. Examine oil lines and equipment for leaks.

C-269. Light the center burner by holding hand torch near and just under tip or burner standing well clear to avoid possible flare back. If torch is snuffed out before oil is lighted shut off the oil and relight the torch. Always use the torch for lighting burners until the brickwork is intensely hot and even then if all burners are out. Next light the adjacent burners but be sure that there is an excess of draft before lighting additional burners. Do not permit the oil to impinge on the brickwork or parts of the boiler.

C-270. Test the steam coils in the heater for oil.

C-271. After starting a light fire and if the entire setting is new, the fire should continue until the brickwork is dried out thoroughly which in the average case takes several days; if the combustion chamber only has been renewed keep the fire going about 48 hours. After the usual week-end shut down, a light fire should be carried for about one hour. Only in extreme emergency should steam be raised in less than a half hour. Do not permit the fire to generate a steam pressure until about thirty minutes before cutting the boiler into the line.

C-272. In case of a new setting, ease up on buck stays and tie rods to allow for possible expansion of the brickwork. After water becomes heated, check the level of the water in the glass with try cocks and examine blow-offs for leaks. After steam has escaped through the vent valves for a few minutes, close the valves.

C-273. After brickwork is dried out and the boiler heated, begin raising the steam pressure slowly, especially in internally fired boilers where the circulation is sluggish. Keep the water level constant. When the steam pressure approaches the working pressure, examine the boiler for leaks, blow out the pressure gage connections and test the safety valve by hand. Blow down boiler to remove sediment.

C-274. If the boiler is equipped with a superheater of the indirectly fired type not constructed to withstand the intense heat during the firing up period, see that it is protected before lighting the fire by flooding or by closing dampers installed for the purpose.

C-275. Cutting In. Drain very thoroughly the steam connections between the boiler and the header or steam main. Where a non-return check valve or stop and check valve is not installed, the stop valve shall be opened very slowly and only when the pressure in the boiler is exactly the same as the pressure in the header. If the main stop valve has a by-pass, the by-pass should be used until the pressures are equalized. In any case the stop valve shall be opened very slowly and the operator should stand by for a few minutes after the stop valve has been opened wide; if any disturbance or hammer occurs in the boiler or in the pipe line, close the stop valve at once. If a non-return check valve or stop and check valve, as the case may be, is installed, open the stop valve when the pressure in the boiler is 10 or 15 lb. less than the pressure in the header, and let the non-return check operate automatically.

Firing Boilers

C-276. Uniform Firing. Aside from the standpoint of economy, the fire should be maintained as uniformly as possible in order to avoid excess combustion, undesirable variations in temperature and possible gas explosions.

C-277. Cleaning Fire. Fires should be cleaned at stated periods, if possible, and when boilers are operating at low rating as at noontime and just before peak loads. Avoid holes in fire and excessive draft while burning out the fire. Clean fires as rapidly as possible to minimize cold air in the boiler. Do not fire too heavily immediately after cleaning. Do not pile hot ashes and clinkers against boiler front, use care in quenching and remove ashes as soon as possible.

C-278. Banking Fire. Do not bank fires any more than necessary. When fires are banked, make sure that a continuous light current of air is passed through the boiler. This is usually accomplished by having the ashpit doors closed, the firing doors slightly opened and the back damper perforated or nearly closed.

Handling Boilers in Service

C-279. Water Level. The most important rule in the safe operation of boilers is to keep water in the boiler and as constantly at the proper level as conditions will permit. Never depend upon automatic alarms or feedwater regulators. Any inattention, other duties or reliance upon automatic devices cannot be accepted as an excuse for a boiler damaged by low water level.

C-280. The first duty on entering the boiler room is to ascertain whether the valves and connections between the boiler and water column are free and open especially when starting up in the morning after the fires have been banked over night. Then blow down the water column, noting the return of the water in the glass, and try the gage cocks until sure of the water level. This should be done at the beginning and end of each shift and also several times during the shift. Have the water column well lighted and keep the water glass clean. Do not allow steam to leak from the water column or its connections, as this will cause the water glass to show a false level.

C-281. If the level of the water is not visible in the water glass, try the gage cocks to determine whether the level of the water is above or below the water glass. If the level is below the water glass, stop the supply of fuel immediately and then the supply of air; close the dampers and ashpit doors. Close the feedwater valve and under no circumstances feedwater into the boiler. Haul the fire and, in the case of stokers or chain grates, keep them in motion with the fire doors open. Do not throw water on th

fire with fire or other hose. Do not open the safety valve or change the steam outlet valves or make any changes that will cause a sudden change in the stresses acting upon the boiler. Examine the bottom blow-off valves and repair them if they are found defective. Find the cause of the failure of the supply of water.

C-282. *Foaming and Priming.* If foaming occurs check the fuel supply and close the steam outlet valve long enough to determine the true level of the water in the glass. If the level of the water in the water glass is sufficiently high, blow down some of the water in the boiler and feed in fresh water. Use surface blow-off if any are installed. Repeat the alternate blowing-off and feeding several times, and if the foaming does not stop, draw the fire and continue the alternate blowing-off and feeding. When the boiler is sufficiently cooled off, empty the boiler and look for the cause of the foaming which may be caused by oil or other foreign matter in the feedwater or by scale solvent. Test safety valve and connections of water column and water glass for any choking or sticking. Determine positively the cause of foaming and adopt measures to prevent its recurrence.

C-283. *Oil in Boiler.* Watch carefully for any signs of oil in the feedwater heaters, water glasses and blowdowns. If a boiler becomes coated with oil or grease, shut down the boiler and clean it thoroughly. If the amount of oil is considerable, boil out in accordance with Par. C-311.

C-284. *Feedwater Treatment.* Execute carefully all instructions given for the treatment of feed water in your particular boiler room. Do not experiment with "home made" treatments or boiler compounds, unless advised to do so by a chemist experienced in feedwater treatment.

C-285. *Blowing Off.* Except where the amount and frequency of blowing down is determined by chemical analysis, blow down at least one gage every twenty-four hours. The amount of blowdown depends upon the number of hours per day the boiler is in service, the rate at which it operates and the kind of feedwater used. Blow down the boilers at a period in the day when the circulation of water in the boiler is slowest. Always open the cock first and the valve second; in closing, close the valve first and the cock second. Always open and close the blow-off valves carefully and slowly; if unusual effort is necessary to close the valve or cock, do not try to force them shut but empty the boiler and find the cause. In blowing down, open the cock or valve until it is half open and leave in that position until the water is blown down about $^1/_2$ in. in the water glass; then open the cock or valve wide open until the blowing off is completed. See that the valve shuts tight and remains tight. Repair all leaky blow-offs as soon as discovered. Use the surface blow-off frequently for a short period of time.

C-286. Where the water glass is not in view of operator blowing down a boiler, another operator shall be stationed where he can see the water glass and signal to the operator who is blowing down the boiler.

C-287. *Leaks.* When small leaks occur, locate their source and repair them as soon as boiler can be removed from service. If a serious leak occurs such as a leak along the longitudinal seams, shut down the boiler immediately by gradually reducing the steam pressure and have the boiler examined by an authorized inspector.

C-288. *Repairs.* Do not make any repairs upon a boiler, piping or auxiliaries while they are under steam pressure. Calking of pipes and joints and setting up of nuts and bolts under pressure to stop leakage must be prohibited.

C-289. *Removal of Soot and Ashes.* Soot should be dusted from the tubes once a day; whether a lance or soot blower is used, drain the steam or air-supply connections so that the steam or air is practically dry. Never use steam for dusting off tubes when the boiler is not under pressure. When a boiler is to be shut down, dust the tubes before the fire has died out and with the draft on after the boiler has been cooled, brush or scrape any hardened soot or deposit from the tubes.

C-290. Remove ashes frequently and do not permit the accumulation of any large amount of ashes in the ash pit, boilers, flues or base of stacks. Do not pile ashes against the furnace front and, when wetting down ashes, make sure that no water is thrown upon hot castings. Do not leave ashes banked about blow-off pipes as a protection.

C-291. When ashes are removed by a suction system, an explosion door shall be provided on the storage hopper. Where steam-jet ash conveyors are used, see that all operatives are warned against the water which may collect upon the top of the ashes in the hopper and may flow suddenly from the gate when the ashes are being removed. When necessary to bar through the gate to release clogged ashes, the operator shall be warned to stand sufficiently aside to avoid being burned by the hot ashes or water.

Care of Appliances

C-292. *Safety Valves.* Test the safety valves at least once a day by gently raising the valve off the seat by hand or, when practicable, test the valves daily by raising the steam pressure to the blowing pressure of the safety valve. If the valve sticks do not try to release it by hammering; drop the pressure in the boiler and clean the valve seat or correct any other defect that may be found. Repair or replace leaking safety valves as soon as discovered.

C-293. When a safety valve blows, note the pressure on the boiler steam gage and, if the stipulated blowing pressure varies more than 5 lb. from the pressure noted on the gage, test the gage. If the gage is found correct, adjust the safety valve.

C-294. Do not permit setting or adjustment of safety valves by any one but a competent person. Do not have the water in boiler above the highest gage cock when setting or adjusting the valve. When the spring becomes weak and must be screwed down to secure the stipulated blowing pressure, make sure that the spring is not screwed down so far that there is a restriction of the proper amount of opening of the valve as called for in Pars. 282 and 284 of the Rules for the Construction of Power Boilers.

C-295. Do not open the safety valve to reduce the pressure in the case of low water in the boiler.

C-296. Never set the blowing point of a safety valve above the authorized pressure of the boiler.

C-297. When making a hydrostatic test do not try to hold the safety valve closed by screwing down the spring; blank the valve, clamp the seat in place or use some other suitable method. Make sure that the safety valve is placed in good working condition after the hydrostatic test has been made.

C-298. Keep scale, dirt or other foreign matter from collecting between the coils of the spring. When running a wire in the drain hole in the escape pipe to ascertain if it is clear, be careful that the wire does not move scale that may fall over the drain opening when the wire is removed.

C-299. *Steam Pressure Gage.* Blow down the gage connections frequently and especially when checking the safety valve, raising steam in a boiler and when foaming occurs.

C-300. *Water Glass.* When a water glass has broken, remove the broken pieces and, with head turned away from the water column, slowly open the bottom valve to blow out any remaining pieces. Before inserting the new glass, see that the glass is of the exact length required and that the connections are in line. Insert the glass and set up the stuffing-box nuts taking care not to set them up too tight. Then warm the glass by opening the drain cock of the glass and with head turned aside, open the top valve slightly and let a small current of steam flow through the glass. Close the drain cock after the glass is sufficiently warmed, open the bottom valve slightly and when the level of the water in the glass has become stable, open the bottom valve wide and then open the top valve wide, all the while keeping the face turned to one side.

C-301. Water glasses must be kept clean. Do not clean a glass with waste or linty cloth; use cloth, free from lint and dirt, wound about a wooden stick. Do not use a metal rod that would scratch the glass and start a crack.

Handling Boilers out of Service

C-302. *Cutting Out.* To cut out a boiler, first cut off the supply of fuel. In a coal-fired boiler close ashpit and fire doors and close dampers. In an oil-fired boiler, continue the air supply until any oil on the floor of the combustion chamber is consumed and the gas passages are well ventilated; then close dampers. After the boiler ceases to require feed water and the non-return check valve, if any, on the steam line has closed, close the main steam stop valve. When possible blow off the tubes before the fire has died out. Fill the boiler to three-fourths of a glass.

C-303. Cooling Off. After the fires have died out, close all doors and open dampers. When the pressure has dropped to blowing down pressure (see Par. C-304), clean the furnace of all coal and ashes and permit the brickwork to cool for not less than two hours. When there is much sediment in the boiler, longer time must be allowed.

C-304. Emptying. After cooling off the setting, open the blow-off valves when the pressure in the boiler has been reduced to about 10 lb. if it is not feasible to empty the boiler at atmospheric pressure. When the boiler to be emptied is set in a battery, make sure the blow-off valves that are opened are on the boiler which is to be emptied. As soon as the boiler is empty, remove the manhole plates and covers of other openings.

C-305. Cleaning. Examine boiler frequently to determine how often the boiler should be washed. Wash more frequently when the boiler runs longer hours per day or at higher ratings, when feed water becomes foul or when scale solvents throw down scale.

C-306. Remove manhole and handhole plates, close feed valves, steam outlet valves and blow-off valves and hang sign on boiler to indicate that a man is working inside.

C-307. Use hose with considerable force or hand tools, if necessary, to remove scale. Disconnect blow-off pipe close to the boiler and run the water to waste. Horizontal-tubular boilers should be washed from below as well as from above. See that the water does not get on the brickwork of the combustion chamber.

C-308. After washing the boiler pass a light inside and see that the cleaning has been thorough and that no tools are left inside. If the boiler has been treated with kerosene in the feed water, ventilate the boiler; do not use a naked flame to examine the boiler.

C-309. Do not remove scale with kerosene if it can be done by any other means. If it is used, see that the boiler is dry and cool. Do not use kerosene in large quantities in a room where other boilers are in service unless special precautions are taken to keep the vapors from escaping into the boiler-room. Keep all lights away from the boiler except incandescent lamps enclosed in moisture-proof globes and guards.

C-310. Spray the inside of the boiler and, after allowing it to stand a sufficient length of time, wash thoroughly with hose and copious amount of water. Do not enter the boiler until it has been thoroughly ventilated. Also ventilate the boiler before entering it the next time that it is opened.

C-311. When boiler has been allowed to become heavily scaled or coated with oil it may be cleaned by boiling out with soda ash and kerosene. Fill boiler well above water line with water containing 50 lb. of soda ash and 5 gallons of kerosene to 1000 gallons of water. Close the boiler and start light fire sufficient to carry about 5 lb. pressure in the boiler. Continue boiling for two or three days, empty the boiler, then wash thoroughly and ventilate the boiler. Use the usual precaution against oil vapors.

C-312. When cleaning scale from tubes with mechanical hammer or cleaner follow the instructions given in Par. C-185.

C-313. Laying-Up. When laying-up a boiler for an extended period of time, follow the instructions given in Pars. C-152 to C-155, inclusive.

Second Revision of A.S.M.E. Boiler Code, 1923

A HEARING is held by the Boiler Code Committee at least once in four years, at which all interested parties may be heard, in order that such revisions may be made as are found to be desirable, as the state of the art advances. The year 1922 became the period of the second revision and the Boiler Code Committee held a Public Hearing in connection with the recent Annual Meeting of the Society in December, 1922, to which the membership of the Society and every one interested in the steam-boiler industry was invited to come and present their views.

For the convenience of every one interested, a printed schedule of the various proposed revisions had been published and distributed to all those who were invited to attend the Public Hearing and the opportunity was given thereat for the most careful consideration of all of the proposed revisions. As a result of the suggestions received at the Public Hearing, a number of modifications of the previously announced revisions were offered and in addition suggestions were received for still further revisions of the Code. All of these suggestions for modifications and new revisions have been carefully considered by the Boiler Code Committee and the result in modifications of revisions and additional revisions are here published.

It is the request of the Committee that these revisions be fully and freely discussed so that it may be possible for any one to suggest changes before the rules are brought to final form and presented to the Council for approval. Discussions should be mailed to C. W. Obert, Secretary of the Boiler Code Committee, 29 West 39th St., New York, N. Y., in order that they may be considered by the Boiler Code Committee.

The revisions here published are limited to the paragraphs appearing in the 1918 Edition of the A.S.M.E. Boiler Code, and the paragraph numbers refer to the paragraphs of similar number in that edition. For the convenience of the reader in studying the revisions, all added matter appears in small capitals and all deleted matter in smaller type in brackets.

In addition, there are here presented the revisions of the material specifications that have been approved by the Boiler Code Committee, to replace the specifications in the present edition of the Code, Pars. 23–178.

Modifications of Revisions

PAR. 250. REVISE FIRST TWO SENTENCES OF FORM GIVEN IN DECEMBER, 1922, ISSUE OF MECHANICAL ENGINEERING AS FOLLOWS:

250. A fire-tube boiler with tubes under 5 in. diameter shall have the ends of the tubes firmly rolled and beaded, or rolled, BEADED and welded at the firebox or combustion-chamber end, and rolled and beaded at the other end. In the case of tubes under $1^1/_2$ [$1^1/_4$] in. diameter, THEY [tubes] may be expanded by the Prosser method in place of rolling.

PAR. 308. ADD THE FOLLOWING TO THE REVISED FORM GIVEN IN THE JULY, 1922, ISSUE OF MECHANICAL ENGINEERING:

FOR PRESSURES NOT IN EXCESS OF 100 LB., RETURN CONNECTIONS OF THE SAME SIZE OR LARGER THAN THE SIZE HEREIN SPECIFIED MAY BE USED, AND TO WHICH THE BLOW-OFF MAY BE CONNECTED. IN SUCH CASE THE BLOW-OFF MUST BE SO LOCATED THAT THE CONNECTION MAY BE COMPLETELY DRAINED.

PAR. 318. ADD THE FOLLOWING TO THE REVISED FORM GIVEN IN THE AUGUST, 1922, ISSUE OF MECHANICAL ENGINEERING:

ON BOILERS HAVING MORE THAN 100 SQ. FT. OF HEATING SURFACE, THE FEED PIPE SHALL BE NOT LESS THAN $^3/_4$ IN. IN DIAMETER.

New Revisions

PAR. 301. REVISED:

Each steam-discharge outlet [over 2 in. in diameter] except safety-valve and superheater connections, shall be fitted with a stop valve [or valves of the outside-screw and yoke type], located as near the boiler as practicable. WHEN SUCH OUTLETS ARE OVER 2 IN. PIPE SIZE, THE VALVE OR VALVES USED ON THE CONNECTION SHALL BE OF THE OUTSIDE-SCREW AND YOKE TYPE.

MATERIAL SPECIFICATIONS

GENERAL RULES FOR INSPECTION AND TESTS

S-1. Inspection. At all times, while work on the contract of the purchaser is being performed, the inspector, representing the

purchaser, shall have free entry to all parts of the manufacturer's works which concern the manufacture of the material ordered. The manufacturer shall afford the inspector, without charge, all reasonable facilities to satisfy him that the material is being furnished in accordance with the specifications. Unless otherwise specified, all tests (except check analyses) and inspection shall be made at the place of manufacture, prior to shipment, and shall be so conducted as not to interfere unnecessarily with the operation of the works.

S-2. Rejections. *a* Rejections based on tests made by the purchaser under the provisions of the specifications shall be reported to the manufacturer within five working days from the receipt of samples.

b Material which shows injurious defects subsequent to its acceptance at the manufacturer's works will be rejected, and the manufacturer shall be notified.

S-3. Rehearing. Samples which represent rejected material, tested by the purchaser under the provisions of these rules, shall be preserved for two weeks from the date of the test report. In case of dissatisfaction with the results of the tests, the manufacturer may make claim for a rehearing within that time.

S-4. Ladle Analyses. *a* The manufacturer shall make an analysis of each melt of steel, from a test ingot taken during the pouring of the melts, to determine the percentage of carbon, manganese, phosphorus, and sulphur. The results of analysis shall conform to requirements, and shall be reported to the purchaser, or his representative.

Check Analyses. *b* The purchaser may make an analysis from finished material representing each melt. The chemical composition thus determined shall conform to the requirements.

Physical Tests. *c* The yield point shall be determined by the drop of the beam of the testing machine. For determination of the yield point the speed of the crosshead of the machine shall not exceed $^1/_2$ in. per minute when the elongation is taken in 2 in., nor exceed 2 in. per minute when the elongation is taken in 8 in. After the yield point has been passed the speed of the machine may be increased to not more than 2 in. per minute when the elongation is taken in 2 in., nor more than 6 in. per minute when the elongation is taken in 8 in.

SPECIFICATIONS FOR STEEL BOILER PLATE

Note: This specification is printed merely for information and is not in its final approved form. The Boiler Code Committee feels that additional protection should be secured in the case of firebox steel and has suggested to the American Society for Testing Materials and the Association of American Steel Manufacturers that an additional chemical check analysis from the top of the plate and possibly an additional tensile test also from the top of the plate should be provided for this class of steel. The replies of these organizations have not been received and the final form that this specification will take will depend upon the actions of these associations.

S-5. Classes. These specifications cover two classes of steel for boilers, namely: flange and firebox.

S-6. Process. The steel shall be made by the open-hearth process.

S-7. Chemical Composition. The steel shall conform to the following requirements as to chemical composition.

		Flange	Firebox
Carbon		Plates $^3/_4$ in. thick or under: not over 0.25 per cent	
		Plates over $^3/_4$ in. thick: not over 0.30 per cent	
Manganese	Plates $^3/_4$ in. thick or under	0.30–0.60	0.30–0.50
	Plates over $^3/_4$ in. thick	0.30–0.60	0 30–0.60
Phosphorus	Acid	Not over 0.05 per cent	Not over 0.04 per cent
	Basic	Not over 0.04 per cent	Not over 0.035 per cent
Sulphur		Not over 0.05 per cent	Not over 0.04 per cent

S-8. Check Analyses. As a substitute for check analyses in the general rules, the purchaser may make an analysis from a broken tension-test specimen representing each plate as rolled. The chemical composition thus determined shall conform to the requirements. For firebox steel, the purchaser may also make an analysis from a bend-test specimen representing each plate as rolled. The chemical composition thus determined shall not exceed the requirements by more than 10 per cent.

S-9. Tension Tests. *a* The material shall conform to the following requirements as to tensile properties:

	Flange	Firebox
Tensile strength, lb. per sq. in	55,000–65,000	55,000–65,000
Yield point, min., lb. per sq. in	0.5 tens. str.	0 5 tens str.
Elongation in 8-in., min. per cent (See Par. S-10*a*)	$\frac{1,500,000}{\text{Tens. str.}}$	$\frac{1,550,000}{\text{Tens. str.}}$

b Should the above rule for minimum allowable elongation give a value less than 25 per cent for firebox steel, the minimum allowable elongation shall be taken as 25 per cent, subject to the modification given.

c The tensile strength of the test specimen taken longitudinally from the top of the plate for firebox steel shall not exceed 70,000 lb. per sq. in.

S-10. Modifications in Elongation. *a* For material over $^3/_4$ in. in thickness, a deduction from the percentages of elongation specified of 0.125 per cent shall be made for each increase of $^1/_{32}$ in. of the specified thickness above $^3/_4$ in. to a minimum of 20 per cent.

b For material $^1/_4$ in. in thickness, the elongation shall be measured on a gage length of 6 in.

S-11. Bend Test. The bend-test specimen shall bend cold through 180 deg. without cracking on the outside of the bent portion, as follows: For material 1 in. or under in thickness, around a pin the diameter of which is equal to the thickness of the specimen; and for material over 1 in. in thickness, around a pin the diameter of which is equal to twice the thickness of the specimen.

S-12. Homogeneity Tests. For firebox steel, a sample taken from a broken tension-test specimen shall not show any single seam or cavity more than $^1/_4$ in. long in either of the three fractures obtained in the test for homogeneity, which shall be made as follows:

The specimen shall be either nicked with a chisel or grooved on a machine, transversely, about $^1/_{16}$ in. deep, in three places about 2 in. apart. The first groove shall be made 2 in. from the square end; each succeeding groove shall be made on the opposite side from the preceding one. The specimen shall then be firmly held in a vise, with the first groove about $^1/_4$ in. above the jaws, and the projecting end broken off by light blows of a hammer, the bending being away from the groove. The specimen shall be broken at the other two grooves in the same manner. The object of this test is to open and render visible to the eye any seams due to failure to weld or to interposed foreign matter, or any cavities due to gas bubbles in the ingot. One side of each fracture shall be examined and the length of the seams and cavities determined, a pocket lens being used if necessary.

S-13. Test Specimens. *a* Tension-test specimens shall be taken longitudinally from the bottom of the finished rolled material, and bend-test specimens shall be taken transversely from the middle of the top of the finished rolled material. The longitudinal test specimen shall be taken in the direction of the longitudinal axis of the ingot, and the transverse-test specimen at right angles to that axis. For firebox steel, an additional tension-test specimen shall be taken longitudinally from a top corner of the finished rolled material.

b Tension- and bend-test specimens shall be of the full thickness of material as rolled, and shall be machined to the form and dimensions shown in Fig. 1; except that bend-test specimens may be machined with both edges parallel.

(Fig. 1, A.S.M.E. Code [1918], page 13, to be inserted.)

S-14. Number of Tests. *a* One tension- and one bend-test shall be made from each plate as rolled. For firebox steel an additional tension test will be made from the top of the plate. Tensile strength only will be determined from this specimen.

b If any test specimen shows defective machining or develops flaws, it may be discarded and another specimen substituted.

c If the percentage of elongation of any tension-test specimen is less than that specified and any part of the fracture is outside the middle third of the gaged length, as indicated by the scribe scratches marked on the specimen before testing, a retest shall be allowed.

S-15. Permissible Variation. The thickness of each plate shall not vary under the gage specified more than 0.01 in. (The overweight limits are considered a matter of contract between the steel manufacturer and the boiler builder.)

S-16. Finish. The finished material shall be free from injurious defects and shall have a workmanlike finish.

S-17. Marking. *a* The name or brand of the manufacturer, the manufacturer's test identification number, class and lowest

tensile strength specified shall be legibly stamped on each finished plate in two places not less than 12 in. from the edges and on each butt strap near the center line not less than 12 in. from each end. Manufacturer's test identification number shall be legibly stamped on each test specimen.

SPECIFICATIONS FOR STEEL BOILER RIVETS

Note: This specification has not been approved by the Boiler Code Committee and is not in its final form, being printed for information only. An agreement has not been reached with the manufacturers of boiler rivets in regard to the tolerances for finished rivets. The tolerances as given in the specifications printed herewith are those which the Boiler Code Committee believe are reasonable. Some objections have, however, been raised to these tolerances by rivet manufacturers, and the Boiler Code Committee will take no final action on this specification until an agreement is reached as to what reasonable tolerances for the finished rivets should be.

A—Requirements for Rolled Bars

S-18. Process. The steel shall be made by the open-hearth process.

S-19. Chemical Composition. The steel shall conform to the following requirements as to chemical composition:

Manganese	0.30–0.50 per cent
Phosphorus	not over 0.04 per cent
Sulphur	not over 0.045 per cent

S-20. Tension Tests. The bars shall conform to the following requirements as to tensile properties:

Tensile strength, lb. per sq. in.	45,000–55,000
Yield point, min., lb. per sq. in.	0.5 Tens. Str.
Elongation in 8 in., min., per cent but need not exceed 30 per cent	$\frac{1,500,000}{\text{Tens. Str.}}$

S-21. Bend Tests. a Cold-Bend Tests. The test specimen shall bend cold through 180 deg. flat on itself without cracking on the outside of the bent portion.

b Quench-Bend Tests. The test specimen, when heated to a light cherry red as seen in the dark (not less than 1200 deg. fahr.), and quenched at once in water the temperature of which is between 80 deg. and 90 deg. fahr., shall bend through 180 deg. flat on itself without cracking on the outside of the bent portion.

S-22. Test Specimens. Test specimens shall be of the section of the bars as rolled. Tension- and bend-test specimens for rivet bars which have been cold-drawn shall be normalized before testing.

S-23. Number of Tests. *a* Two tension, two cold-bend, and two quench-bend tests shall be made from each melt, each of which shall conform to the requirements specified.

b If any test specimen develops flaws, it may be discarded and another specimen substituted.

c If the percentage of elongation of any tension-test specimen is less than that specified and any part of the fracture is outside the middle third of the gaged length, as indicated by scribe scratches marked on the specimen before testing, a retest shall be allowed.

S-24. Permissible Variation in Gage. The diameter of each bar shall not vary from that specified more than the amount given in the following table:

Diameters, In.	Variation in Diameter: Under, In.	Variation in Diameter: Over, In.	Out of Round, In.
Up to 1/2, inclusive	0.007	0.007	0.010
Over 1/2 to 1, inclusive	0.010	0.010	0.013
Over 1 to 1 1/4, inclusive	0.012	0.012	0.016
Over 1 1/4 to 1 1/2, inclusive	0.015	0.015	0.021
Over 1 1/2 to 2, inclusive	0.022	0.022	0.023

S-25. Finish. The finished bars shall be free from injurious defects and shall have a workmanlike finish.

S-26. Marking. Rivet bars shall, when loaded for shipment, be properly separated and marked with the name or brand of the manufacturer and the melt number for identification. The melt number shall be legibly marked on each test specimen.

B—Requirements For Rivets

S-27. Bend Tests. The rivet shank shall bend cold through 180 deg. flat on itself, as shown in Fig. 2, without cracking on the outside of the bent portion.

S-28. Flattening Tests. *a* The rivet head shall flatten, while hot, to a diameter 2 1/2 times the diameter of the shank, as shown in Fig. 3, without cracking at the edges.

b Three bend and three flattening tests shall be made from each size in each lot of rivets offered for inspection, each of which shall conform to the requirements specified.

(Figs. 2 and 3, A.S.M.E. Code [1918], page 18, to be inserted here.)

S-29. Permissible Tolerances. The diameter of the shank of finished rivets measured at any point between the fillet under the head and a point two-thirds of the length from the head to the end of the shank, shall not vary from the nominal diameter more than the amount given in the following table:

Diameters, In.	Variation in Diameter: Under, In.	Variation in Diameter: Over, In.	Out of Round, In.
Up to 1/2, inclusive	0.022	0.007	0.010
Over 1/2 to 1, inclusive	0.025	0.010	0.013
Over 1 to 1 1/4, inclusive	0.027	0.012	0.016
Over 1 1/4 to 1 1/2, inclusive	0.030	0.015	0.021
Over 1 1/2 to 2, inclusive	0.037	0.022	0.023

The dimensions of the rivet head shall not vary more than two per cent over or under, from those specified.

SPECIFICATIONS FOR STEEL STAYBOLTS

S-30. Solid or Hollow Staybolts. Steel for solid or hollow staybolts shall conform to the requirements for Boiler Rivet Steel specified, except that the tensile properties shall be as follows:

Tensile strengh, lb. per sq. in.	50,000–60,000
Yield point, min, lb. per sq. in.	0.5 Tens. Str.
Elongation in 8-in., min., per cent	$\frac{1,500,000}{\text{Tens. Str.}}$

The permissible variations in gage shall be as given in Par. S-32.

S-31. Seamless Tubing for Staybolts. *a* Seamless steel tubing for threaded steel staybolts shall conform to the requirements for Boiler Rivet Steel specified, with the exceptions as given herewith. This specification will not apply to stay tubes for locomotive boilers.

Chemical Composition. *b* The chemical composition shall conform to the requirements for Seamless Steel Tubes.

Physical Requirements. *c* The physical requirements shall be as follows:

Tensile strength, lb. per sq. in., minimum	48,000
Yield point, min., lb. per sq. in.	25,000
Elongation in 8-in., min., per cent	$\frac{1,500,000}{\text{Tens. Str.}}$

Tests. *d* Two tests from each 2500 feet of tubing may be made in absence of tests from each melt.

To insure sound and fine-grained structure, a special fracture test shall be made from at least each 2500 feet of tubing by cutting partly through the wall of the tube and breaking it off when removing the crop end. The fracture thus produced shall be fine-grained. This test will be used in place of the cold and hot quench bend tests specified.

e Ladle analysis will not be required.

f The marking requirement for rivet bars will not be required.

S-32. Permissible Variations in Gage. Solid or hollow bars for staybolts, not exceeding 1 1/4 in. diameter, which are to be threaded as rolled, shall be truly round within 0.01 in. and shall not vary more than 0.005 in. under or more than 0.01 in. over. All other bars for staybolts shall conform to the specified tolerances for Rivet Bars.

SPECIFICATIONS FOR STEEL BARS

S-33. Process. The steel shall be made by the open-hearth process.

S-34. Chemical Composition. The steel shall conform to the following requirements as to chemical composition:

Phosphorus	Acid	Not over 0.05 per cent
	Basic	Not over 0.04 per cent
Sulphur		Not over 0.05 per cent

S-35. Tension Tests. *a* The material shall conform to the following requirements as to tensile properties:

Tensile strength, lb. per sq. in.	55,000–65,000
Yield point, min. per sq. in.	0.5 Tens. Str.
Elongation in 8-in., min. per cent	$\frac{1,500,000}{\text{Tens. Str.}}$
Elongation in 2-in., min., per cent	26

S-36. Modifications in Elongation. For material over $^3/_4$ in. in thickness, a deduction from the percentages of elongation specified of 0.125 per cent shall be made for each increase of $^1/_{32}$ in. of the specified thickness above $^3/_4$ in.

S-37. Bend Tests. a Test specimen shall bend cold through 180 deg. without cracking on the outside of the bent portion, except as specified in section *b*, as follows: For material 1 in. or under in thickness or diameter flat on itself; for material over 1 in. to and including $1^1/_2$ in. in thickness or diameter around a pin the diameter of which is equal to the thickness or the diameter of the specimen; and for material over $1^1/_2$ in. in thickness or diameter around a pin the diameter of which is equal to twice the thickness or diameter of the specimen.

b The 1-in. by $^1/_2$-in. test specimen for bars over $1^1/_2$ in. in thickness or diameter shall bend cold through 180 deg. around a $^1/_2$-in. pin without cracking on the outside of the bent portion.

S-38. Test Specimens. a Test specimens shall be of the full thickness or diameter of material as rolled, except as specified in sections *b* and *c*.

b Test specimens for shapes and flats may be machined to the form and dimensions shown in Fig. 1, or with both edges parallel.

c Test specimens for bars over $1^1/_2$ in. in thickness or diameter may be machined to a thickness or diameter of at least $^3/_4$ in. for a length of at least 9 in.; or tension-test specimens may conform to the dimensions shown in Fig. 4. Bend-test specimens may be 1 in. by $^1/_2$ in. in section.

S-39. Number of Tests. a One tension and one bend test shall be made from each melt; except that if material from one melt differs $^3/_8$ in. or more in thickness, one tension and one bend test shall be made from both the thickest and the thinnest material rolled.

b If any test specimen shows defective machining or develops flaws, it may be discarded and another specimen substituted.

c If the percentage of elongation of any tension-test specimen is less than that specified and any part of the fracture is more than $^3/_4$ in. from the center of the gage length of a 2-in. specimen or is outside the middle third of the gage length of an 8-in. specimen, as indicated by scribe scratches marked on the specimen before testing a retest shall be allowed.

S-40. Permissible Variation in Gage. The diameter of each bar shall not vary from that specified more than the amount given in the following table:

Diameters, In.	Variation in Diameter Under, In.	Variation in Diameter Over, In.	Out of Round In.
Up to $^1/_2$, inclusive	0 007	0 007	0 010
Over $^1/_2$ to 1, inclusive	0 010	0.010	0 013
Over 1 to $1^1/_4$, inclusive	0 012	0.012	0 016
Over $1^1/_4$ to $1^1/_2$, inclusive	0 015	0 015	0 021
Over $1^1/_2$ to 2, inclusive	0 022	0.022	0 023
Over 2 to $2^1/_2$, inclusive	$^1/_{64}$	$^3/_{64}$	0 023
Over $2^1/_2$ to 3, inclusive	$^1/_{32}$	$^3/_{64}$	0 035

S-41. Finish. The finished material shall be free from injurious defects and shall have a workmanlike finish.

S-42. Marking. Bars shall, when loaded for shipment, be properly separated, and marked with the name or brand of the manufacturer and melt number for identification. The melt number shall be legibly marked on each test specimen.

SPECIFICATIONS FOR STEEL CASTINGS

S-43. Material Covered. These specifications cover two classes of castings, namely:

Class A, ordinary castings for which no physical requirements are specified;

Class B, castings for which physical requirements are specified.

S-44. Process. The steel shall be made by one or more of the following processes: open-hearth, electric-furnace, side-blow converter or crucible.

S-45. Heat Treatment. a Class A castings need not be annealed unless so specified, or unless the carbon content exceeds 0.30 per cent.

b Class B, castings shall be properly annealed, the treatment depending upon the design and chemical composition of the castings.

S-46. Chemical Composition. The castings shall conform to the following requirements as to chemical composition:

		Class A	Class B
Carbon		Not over 0.45 per cent	
Phosphorus	Acid	Not over 0 07 per cent	......
	Basic	Not over 0.06 per cent	Not over 0.05 per cent
Sulphur			Not over 0.05 per cent

(For Class B Castings Only.)

S-47. Tension Tests. a The castings shall conform to the following minimum requirements as to tensile properties:

Yield point, lb. per sq. in	29,250
Elongation in 2-in , per cent	$\frac{1,600,000}{\text{Tens. Str.}}$
Elongation in 2-in , per cent—not less than	24
Reduction of area per cent	$\frac{2,600,000}{\text{Tens. Str.}}$
Reduction of area per cent—not less than	35

The tensile strength shall be reported as information.

S-48. Alternative Tests to Destruction. In the case of orders including only castings not exceeding 150 lb. in weight, a test to destruction of one casting from each 100 castings or smaller lot may be substituted for the tension tests, at the option of the inspector. This test shall show the material to be ductile, free from injurious defects, and suitable for the purpose intended.

S-49. Test Specimens. a Tension-test specimens shall be taken from test bars cast attached to the castings where practicable. If the design of the castings is such that test bars should not be attached to the castings, the test bars shall be cast attached to special blocks of which a sufficient number shall be provided for each lot of castings. Test bars from which tension-test specimens are to be taken shall remain attached to the castings or blocks they represent through heat treatment and until presented for inspection. Test bars shall be provided in sufficient numbers to furnish the tests required.

b If satisfactory to the manufacturer and inspector, tension-test specimens may be cut from heat-treated castings instead of from test bars.

c Tension-test specimens shall conform to dimensions shown in Fig. —. The ends shall be of a form to fit the holders of the testing machine in such a way that the load shall be axial.

d Bend-test specimens shall be machined to 1 in. by $^1/_2$ in. in section with corners rounded to a radius not over $^1/_{16}$ in.

S-50. Number of Tests. a One tension test shall be made from each melt in each treatment charge, and from each casting weighing 500 lb. or over when specified.

b If any test specimen shows defective machining or develops flaws, it may be discarded; in which case another specimen from the same lot shall be substituted.

c If the percentage of elongation of any tension-test specimen is less than that specified and any part of the fracture is more than $^3/_4$ in. from the center of the gage length, as indicated by scribe scratches marked on the specimen before testing, a retest shall be allowed.

S-51. Retreatment. If the results of the physical test for any lot do not meet the requirements specified, such lot may be re-treated, but not more than twice. Retest shall be made as specified.

S-52. Workmanship. Castings shall conform substantially to the shapes and sizes indicated by the patterns and drawings submitted by the purchaser.

S-53. Finish Welding. a Castings shall be free from injurious defects.

b Defects which do not impair the strength of the castings may be welded by an approved process. The defect shall be cleaned out to solid metal, before welding, and when so required by the inspector, shall be submitted to him in this condition for his approval. When required by the inspector, important castings shall be heat treated after welding.

SPECIFICATIONS FOR BOILER RIVET, STAYBOLT, AND REFINED BAR IRON

S-54. Process. The iron shall be rolled from a bloom, slab pile, or box pile made wholly from reworked all-pig puddled iron or reworked knobbled charcoal iron. For rivet and staybolt iron the puddle mixture and the component parts of the bloom, slab pile

or box pile shall be free from any admixture of iron scrap or steel. Staybolt iron shall be double worked, i.e., twice piled.

S-55. Physical Properties and Tests. *a* The iron shall conform to the following requirements as to tensile properties:

	Rivet Iron	Staybolt Iron	Bar Iron
Tensile strength, lb. per sq. in., not over ...	52,000	52,000	53,000
Yield point, lb. per sq. in., not less than	28,000	29,000	28,000
Elongation in 8 in., not less than, Round Section	28 per cent	30 per cent	25 per cent
Reduction of area, not less than, ... Round Section	45 per cent	48 per cent	40 per cent

S-56. Cold-Bend Tests. Rivet Iron. *a* The test specimen shall withstand being bent cold through 180 deg. flat on itself, without fracture on the outside of the bent portion.

Staybolt Iron. *b* The test specimen shall withstand being bent cold through 180 deg. flat on itself in both directions, without fracture on the outside of the bent portions.

Bar Iron. *c* The test specimen shall withstand being bent cold through 180 deg. without fracture on the outside of the bent portion, around a pin the diameter of which is not greater than one-half the square of the thickness or diameter of the specimen.

S-57. Nick-Bend Tests. The test specimen when nicked 25 per cent around for round bars, and along one side for flat bars, with a tool having a 60 deg. cutting edge, to a depth of not less than 8 per cent or more than 16 per cent of the diameter or thickness of the specimen, and broken, shall show a wholly fibrous fracture.

Bend tests may be made by pressure or by blows.

S-58. Etch Tests. The cross-section of the test specimen shall be ground or polished, and etched for a sufficient period to develop the structure. For rivet and staybolt iron this test shall show the material to have been rolled from a bloom, slab pile or box pile and to be free from steel; for bar iron the structure shall be uniform and free from steel.

S-59. Test Specimens. Test specimens shall be of the full section of material as rolled.

S-60. Number of Tests. *a* All bars of a given grade and size shall be piled separately, sorted in lots of 100 each. Two bars shall be selected at random from each lot or fraction thereof and tested as specified; but only one of these bars shall be etch-tested.

b If any test specimen from bars originally selected to represent a lot of material contains surface defects not visible before testing but visible after testing, or if a tension-test specimen breaks outside the middle third of the gage length, the individual bar shall be rejected and one retest from a different bar will be allowed.

S-61. Permissible Variations in Gage. The diameter of each bar shall not vary from that specified more than the amount given in the following table:

Diameters, In.	Variations in Diameter: Under, In.	Variations in Diameter: Over, In.	Out of Round, In.
Up to 1/2, inclusive	0.007	0.007	0.010
Over 1/2 to 1, inclusive	0.010	0.010	0.013
Over 1 to 1 1/4, inclusive	0.012	0.012	0.016
Over 1 1/4 to 1 1/2, inclusive	0.015	0.015	0.021
Over 1 1/2 to 2, inclusive	0.022	0.022	0.023
Over 2 to 2 1/2, inclusive	1/64	3/64	0.023
Over 2 1/2 to 3, inclusive	1/32	3/64	0.035

The widths or thicknesses of flat bars shall not vary more than one per cent from that specified.

S-62. Finish. The bars shall be smoothly rolled and free from slivers, depressions, crop ends, seams and evidences of being burnt.

S-63. Marking. The bars shall be stamped or otherwise marked as designated by the purchaser.

SPECIFICATIONS FOR LAP-WELDED AND SEAMLESS STEEL AND LAP-WELDED IRON BOILER TUBES

Based upon A.S.T.M. Specifications A83–22T

(Comprises Pars. S-64–S-80)

SPECIFICATIONS FOR GRAY-IRON CASTINGS

Recent Developments in Balancing Machines

(Continued from page 355)

its synchronous speed. The armature to be balanced is driven by the belt *O*. The critical speed of the apparatus is about 1700 r.p.m. The speed of the armature while operating is 10,000 r.p.m.

The operation of this balancing machine is as follows: The armature is mounted in the machine and the carriage *E* is moved so that the pointer *S* is in one of the transverse planes in which the unbalance is to be corrected. The treadle *R* is pressed down, thus closing the switch *P* and releasing the brake *Q*. The rotation of the armature produces vibrations of the bed around the fulcrum axis; the amplitude is a measure of the weight to be applied at

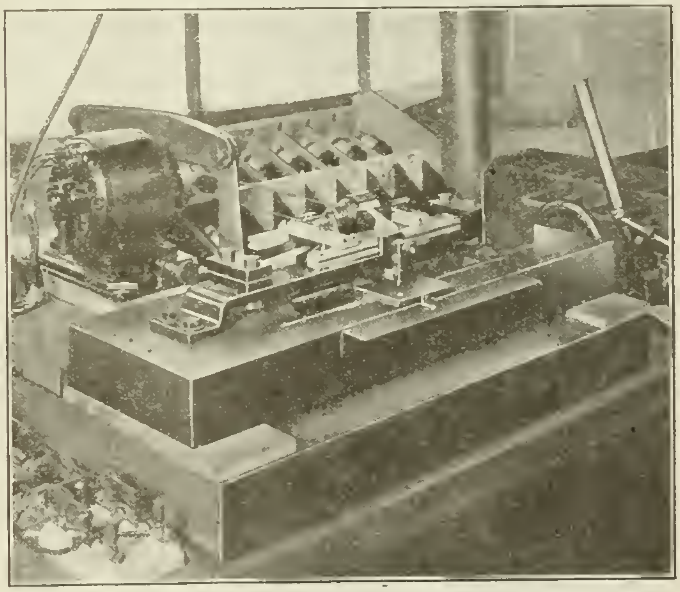

Fig. 6 Balancing Machine Slightly Modified

the other end of the armature. This weight is recorded by the vibrating reed. The treadle is then released, stopping the driving motor almost instantaneously. The recorded weight is applied at an arbitrary location and the armature is again rotated. The second amplitude will indicate if this arbitrary location is correct or not. Three to four trials usually locate the weight correctly. The carriage is then moved into the plane where the first weight was applied and the same procedure is repeated. The entire operation consumes but a few moments.

Fig. 6 shows the same machine slightly modified. The vibrating reed is attached to one end of the vibrating bed. As a result of this, the reed does not record the angular deflection of the bed in a uniform measure for all fulcrum locations. This variation was found to be negligible, however. The production of this machine is about 20 armatures per hour at the present time. It may be increased considerably as the operator gains in experience. The accuracy of the balancing result is ±0.00008 lb. at 3/4 in. radius, the two balancing planes being 1 in. apart.

Safety Code for Mechanical Power-Transmission Apparatus

A Code Now Proposed for General Adoption by the Industrial Accident Boards and Commissions of the Various States

In the November, 1920, issue of "Mechanical Engineering" the formation of a Sectional Committee to develop a national Safety Code for Mechanical Power-Transmission Apparatus was announced. This committee was organized under the Rules of Procedure of the American Engineering Standards Committee and has for its sponsors the International Association of Industrial Accident Boards and Commissions, The National Workmen's Compensation Service Bureau, and The American Society of Mechanical Engineers.

During the progress of the Sectional Committee's work a number of drafts of the code were prepared and passed upon by its 24 members. Later printed proofs were circulated to approximately 400 persons known to be interested in the development of this code. These included manufactures of this equipment, users of the equipment, and safety-code enforcement officers.

All the comments offered as a result of this circularization were carefully considered at a meeting of the full Sectional Committee and a revised draft of the code was subsequently prepared. This revised draft has now been formally presented to the three sponsor bodies for approval and adoption, actions which are obviously necessary before this safety code can be transmitted to the American Engineering Standards Committee for approval as a Tentative American Standard.

The following abstract of this code was prepared at the request of the A.S.M.E. Standing Committee on Safety Codes by Carl B. Auel, one of its members who is also one of that society's representatives on this Sectional Committee and is serving as its chairman.

The Safety Code for Mechanical Power-Transmission Apparatus, as it now stands, is the result of a very considerable amount of study over a period of many months. The Committee did not rely alone upon the judgment of its members, but had as well the benefit of the advice and experience of many experts, who willingly placed themselves at the service of the Committee in various ways.

Following the trend of more recent efforts in safety work, the code is an endeavor to combine the best, both with respect to theory and to practice; and, where these seemed occasionally at variance, decision was reached only after careful consideration as to which should be followed.

It is therefore reasonable to assume that while the code, as time goes on, unquestionably will undergo modification and improvement, it nevertheless in its present form offers adequate protection to the workers in industry.

Scope

This code applies to all moving parts of equipment used in the mechanical transmission of power, including prime movers, intermediate equipment and driven machines, excluding point of operation.

Note: The safeguarding of all connecting rods, cranks, flywheels, shafting, spindles, pulleys, belts (except flat belts one (1) inch or less in width or round belts one-half (½) inch or less in diameter), link belts, chains, ropes and rope drives, gears, sprockets, friction drives, cams, couplings, clutches, counterweights, revolving or reciprocating parts, up to but not including point of operation, also all bolts, keys, set screws, oil cups or similar projections, shall be included in and be in accordance with the provisions of the Mechanical Power-Transmission Code.

Interpretations and Exceptions

The purpose of this code is to provide reasonable safety for life, limb, and health. It should be liberally construed and applied by enforcing authorities to secure these results and in cases of practical difficulty or unnecessary hardship, exceptions from the literal requirements may be granted so long as equivalent protection is secured. Where specific devices or methods are mentioned in this code, other devices or methods which will secure equally good results may be used, subject to the approval of the enforcing authority.

Definitions

In order to clarify the text, it is prefaced by definitions of a number of the terms used; as, for example, the term "exposed to contact" is "interpreted as meaning that the location of any object is such that a person is liable to come into contact with it and be injured."

The code itself is divided into six parts, each with suitable subdivisions. These parts have to do respectively with prime movers, mechanical power-transmission equipment, starting and stopping devices, guard standards, operating rules, and discussion.

Prime Movers

This part of the code is very brief and offers no complications in the carrying out of its requirements, concerning itself simply with the guarding of flywheels, cranks, connecting rods, tail rods, and governor balls. As will be observed in this section, and, in fact, largely throughout the code, alternative methods of guarding have been presented wherever possible.

Flywheels located so that any part is six (6) feet or less above floor or platform shall be guarded in one of the following ways:

(*a*) With an inclosure of sheet, perforated, or expanded metal or woven wire.

(*b*) With guard rails placed not less than fifteen (15) inches nor more than twenty (20) inches from rim. When flywheel extends into pit or is within 12 inches of floor a standard toe board shall also be provided.

(*c*) When the upper rim of flywheel protrudes through a working floor it shall be entirely enclosed or surrounded by a guard rail and toe board.

(*d*) For flywheels with smooth rims five (5) feet or less in diameter, where the preceding methods cannot be applied, the following may be used: A disk attached to the flywheel in such manner as to cover the spokes of the wheel on the exposed side and present a smooth surface and edge, at the same time providing means for periodic inspection. An open space, not exceeding four (4) inches in width may be left between the outside edge of the disk and the rim of the wheel if desired, to facilitate turning the wheel over. Where a disk is used, the keys or other dangerous projections not covered by disk, shall be cut off or covered.

Note: This does not apply to flywheels with solid web centers.

(*e*) Adjustable guard to be used for starting engine or for running adjustment may be provided at the flywheel of gas or oil engines. A slot opening for jack bar will be permitted.

Cranks and connecting rods, when exposed to contact, shall be guarded in accordance with Part IV, Sections 40 and 41, or by a guard rail as described in Part IV, Rule 424.

Tail rods or extension piston rods shall be guarded in accordance with Part IV, Sections 40 and 42, or by a guard rail on sides and end, with a clearance of not less than fifteen (15) inches when rod is fully extended.

Governor balls six (6) feet or less from the floor or other working level, when exposed to contact, shall be provided with an enclosure extending to the top of the governor balls when at their highest position.

Mechanical Power-Transmission Equipment

As would be expected, this section, having to do with transmission equipment, constitutes the backbone of the code, shafting, pulleys, belts, ropes, gears, sprockets, chains, friction drives, keys and other projections, collars, couplings, and bearings, being treated in turn.

Shafting. Additional to the necessity of thoroughly guarding all exposed shafting when six feet or less from the floor or working platform, or unless at least fifteen feet above a driveway, particular emphasis is placed on the need for securing shafting, whether horizontal, vertical, or inclined, against excessive endwise movement.

Projecting shafting ends are not permitted, except when guarded by non-rotating caps or safety sleeves.

It is realized that the guarding of shafting in the regulation manner would involve an unnecessary expense if the rules were made universally mandatory. Exception has therefore been made in the case of shafting located in basements, used exclusively for power-transmission equipment, by the following provisions:

When belts, pulleys, and shafting are located in basements, towers, and rooms used exclusively for power-transmission equipment, the requirements for safeguarding may be waived if the following conditions are met:

1 The basement, tower, or room occupied by transmission equipment shall be locked against unauthorized entrance.

2 The vertical clearance in passageways between the floor and power-transmission beams, ceiling or any other objects, should not be less than five (5) feet six (6) inches.

3 The intensity of illumination shall conform to The American Engineering Standards Code for lighting of factories, mills, and other work places.

4 The footing shall be dry, firm, and level.

5 The route followed by the oiler shall be protected in such a manner as to prevent accident.

Pulleys. Pulleys are required to be guarded if any parts are six feet or less from the floor or working platform; but modification is made in this requirement when they serve as balance wheels, for example on punch presses, the code providing that:

Pulleys any part of which are six (6) feet or less from the floor or working platform shall be guarded in accordance with the standards specified under Part IV, Sections 40 and 42. Pulleys serving as balance wheels (e.g., punch presses) on which the point of contact between belt and pulley is more than six (6) feet from the floor or platform, may be guarded with a disk covering the spokes.

Guides are required to prevent belts leaving pulleys, unless the distance to the nearest fixed pulley, clutch, or hanger exceeds the width of the belt used. Overhanging pulleys, where there is no bearing between them and the outer end of the shafting, must be similarly provided with guides.

The use of pulleys with cracked or broken rims is forbidden, as in the use of composition or wood pulleys in locations where they would be subjected continually to the action of moisture.

Particular warning is given against operating pulleys at excessive speeds as follows:

Pulleys operating at a rim speed in excess of 4000 feet per minute shall be especially designed for the purpose and carefully balanced for the speed at which they are to operate.

Belts, Ropes, and Chain Drives. In the guarding of belts and ropes, the code states:

(*a*) Where both runs of horizontal belts are six (6) feet or less from the floor level, the guard shall extend to at least fifteen (15) inches above the belt or to a standard height except that where both runs of a horizontal belt are 42 inches or less from the floor, the belt shall be fully enclosed in accordance with Part IV, Sections 40 and 42.

Note: In power plants or power-development rooms a guard rail may be used in lieu of the above.

(*b*) Overhead horizontal belts, with lower part seven (7) feet or less from the floor or platform, shall be guarded on sides and bottom.

(*c*) Horizontal overhead belts more than seven (7) feet above floor or platform shall be guarded for their entire length under the following conditions.

1 If located over passageways or work place and traveling 1800 feet or more per minute, and

2 If center to center distance between pulleys is ten (10) feet or more, and

3 If belt is eight (8) inches or more in width.

For exception in case of flat belts 1 inch or less in width or round belts 1/2 inch, or less in diameter, see "Scope."

(*d*) Where the upper and lower runs of horizontal belts are so located that passage of persons between them would be possible the passage shall be either:

1 Completely barred by a guard rail or other barrier in accordance with Part IV, Sections 40 and 42.

2 Where passage is regarded as necessary there shall be a platform over the lower run guarded on either side by a railing completely filled in with wire mesh or other filler or by a solid barrier. The upper run shall be so guarded as to prevent contact therewith either by the worker or by objects carried by him.

In power plants only the lower run of the belt need be guarded.

(*e*) Overhead chain and link-belt drives, where the chain exceeds two (2) inches in width, are governed by the same rules as overhead horizontal belts and shall be guarded in the same manner as belts.

(*f*) American or Continuous System rope drives so located that the condition of the rope (particularly the splice) cannot be constantly and conveniently observed, shall be equppied with a "tell-tale" device (preferably electric-bell type) that will give warning when rope begins to fray.

(*a*) Vertical and inclined belts shall be enclosed by a guard conforming to standards in Part IV, Sections 40 and 42.

(*b*) All guards for inclined belts shall be arranged in such a manner that a minimum clearance of six (6) feet six (6) inches is maintained between belt and floor at any point outside of guard.

Vertical belts running over a lower pulley more than six (6) feet above floor or platform shall be guarded at the bottom in the same manner as horizontal overhead belts if conditions are such as stated in Rule 220-*c*, 1 and 3.

A cone-pulley drive with all parts of the lower cone pulley three (3) feet or more above the floor need not be guarded. Where any part of the lower cone pulley is less than three (3) feet from the floor, the pulley and belt shall be guarded in accordance with Part IV, Sections 40 and 42.

Gears, sprockets, and chains are to be guarded in accordance with the following specifications:

(*a*) A complete enclosure.

(*b*) A standard guard six (6) feet high extending six (6) inches above the mesh point of the gears.

(*c*) By a band guard covering the face of gear and having flanges extended inward beyond the root of the teeth on the exposed side or sides. Where any portion of the train of gears guarded by a band guard is less than six (6) feet from the floor a disk guard or a complete enclosure to the height of six (6) feet shall be required.

All sprocket wheels and chains shall be enclosed unless more than seven (7) feet above the floor or platform.

When frequent oiling must be done, openings with hinged or sliding self-closing covers shall be provided.

Friction Drives. Friction drives are treated much like gears:

(*a*) The driving point of all friction drives when exposed to contact shall be guarded.

(*b*) All arm or spoke friction drives and all web friction drives with holes in the web shall be entirely enclosed.

(*c*) All projecting bolts on fraction drives where exposed to contact shall be guarded.

Keys, Set Screws, Etc. The code states that:

All projecting keys, set screws, and other projections in revolving parts shall be removed or made flush or guarded by metal cover. This does not apply to keys or set screws within gear or sprocket casings or other enclosures, nor to keys, set screws or oil cups in hubs of pulleys where they are within the plane of the rim of the pulley.

It is further recommended that no projecting set screws or oil cups be used in any revolving pulley or part of machinery, even though they are within the limits stated in the above paragraph.

Collars and Couplings. Collars and couplings are required to be cylindrical in shape, and screws or bolts used in them must present no hazard.

Starting and Stopping Devices

Under this section are treated clutches, cut-off couplings, clutch pulleys, belt shifters, shippers, poles, perches, and fasteners.

Regarding the first of these items, the code provides that:

(*a*) Clutches, cut-off couplings or clutch pulleys having projecting parts, where such clutches are located seven (7) feet or less above the floor or working platform, shall be enclosed by a stationary guard constructed in accordance with these standards (the "U" type guard is permissible).

Note 1: Where clutches, cut-off couplings, or clutch pulleys are so situated within a machine or otherwise guarded by location, the application of this rule is within the discretion of the enforcing authority.

Note 2: In engine rooms a guard rail, preferably with toe board, will be permitted instead of the above, provided this room is occupied only by engine-room attendants.

Note 3: The use of a bearing support immediately adjacent to a friction clutch or cut-off coupling being recognized engineering practice, only self-lubricating bearings requiring attention at infrequent intervals shall be used in such locations.

An excellent caution in connection with belt and clutch shifters is contained in the following provision:

(*c*) All belt and clutch shifters of the same type in each shop should move in the same direction to stop machines, i.e., either all *right* or all *left*.

Belt shippers and poles are not recommended, nor are belt perches.

Perhaps no part of the code received greater attention than did belt fasteners, and a considerable number of belting experts, more particularly manufacturers of canvass and rubber belting, were invited to discuss this matter at a special meeting of the Committee. The following provision was finally adopted:

Belts which of necessity must be shifted by hand and belts within six (6) feet of the floor or working platform which are not guarded in accordance with the intent of this code shall not be fastened with metal in any case nor with any other fastening which by construction or wear will constitute an accident hazard.

Guard Standards

Under this section has been included materials for guard construction, designs of guards, and methods of manufacture.

Expanded metal, perforated or solid sheet metal, and wire mesh on a metal frame have been fixed as the standard materials for guard construction.

(*a*) Standard conditions will be secured by the use of the following materials: Expanded metal, perforated or solid sheet metal or wire mesh on a frame of angle iron or iron pipe securely fastened to floor or to frame of machine.

(*b*) All metal should be free from burrs and sharp edges.

(*c*) Wire mesh should be of the type in which the wires are securely fastened at every cross point either by welding, soldering or galvanizing, except in case of diamond or square wire mesh made of No. 14 gage wire, 3/4-in. mesh or heavier.

In the design of guards emphasis is placed on the desirability of making them with hinged sections or removable, where it is necessary to change belts, make adjustments, or oil parts.

Considerable space has been given to details of guard manufacture with information as to sizes of materials, clearances, etc. Illustrations are also used.

The code closes with a few of the more important rules in the care and operation of equipment and a brief discussion of the reasons leading to the adoption of certain features.

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

Résumé of the Month

A—Research Results

The purpose of this section of Engineering Research is to give the origin of research information which has been completed, to give a résumé of research results with formulas or curves where such may be readily given, and to report results of non-extensive researches which in the opinion of the investigators do not warrant a paper.

Fuels A3-23. How Steam Production Costs were Reduced in a Hand-Fired Return-Tubular Boiler Plant. See *Steam Power A1-23.*

Fuels A4-23. Value of Coke, Anthracite, and Bituminous Coal for Generating Steam in a Low-Pressure Cast-Iron Boiler. A series of steaming tests recently made at the Pittsburgh experiment station of the Bureau of Mines are described in a pamphlet known as Technical Paper No. 303. This paper was prepared by Messrs. John Blizard, James Neil, and F. C. Houghten.

The primary purpose of the tests was to determine the relative steaming values of coke, anthracite, and bituminous coal when burned in a low-pressure boiler, and fired by hand in fairly large quantities at a time.

A secondary purpose of the tests was to separate the heat losses, and to examine them carefully to determine the change in efficiency with the method of firing the fuel and manipulation of the draft dampers, with the rate of evaporation, and with the various fuels burned.

Other purposes may be mentioned, such as determination of the draft used, temperatures and composition of the gases in the flues, furnace, and combustion chamber, and other factors affecting the operation of the boiler.

Before these tests were completed, some special tests were run at the request of the Chamber of Commerce of Pittsburgh, to compare the steaming value and smoke emission of mixtures of coke breeze and Pittsburgh coal with those of the latter alone; results of these tests are also embodied in this report.

Address the Superintendent of Documents, Government Printing Office, Washington, D. C. Price per copy, 10 cents.

Industrial Management A1-23. How Steam Production Costs were Reduced in a Hand-Fired Return-Tubular Boiler Plant. See *Steam Power A1-23.*

Instruments and Apparatus A1-23. Testing of Barometers and Altimeters. This Circular of the Bureau of Standards, No. 46, describes the testing of mercurial and aneroid barometers at the Bureau and announces the fees which are charged for the various tests.

Address the Superintendent of Documents, Government Printing Office, Washington, D. C. Price per copy, 10 cents.

Machine Tools A1-23. Lathe Breakdown Tests of Some High-Speed Tool Steels. This report known as Technologic Paper No. 228 was prepared by H. J. French of the Bureau of Standards and Jerome Strauss of the U. S. Naval Gun Factory. In it, comparative lathe cutting tests are reported for about 25 brands, representing various compositions.

Important conclusions drawn from the described tests may be summarized as follows:

1 Breakdown tests, in which endurance of tools is determined under definite working conditions, are not satisfactory as the basis of purchase for high-speed tool steels.

2 In certain severe breakdown tests with roughing tools on 3 per cent nickel-steel forgings, in which high frictional temperatures were produced, it was found that the performance of commercial low-tungsten-high-vanadium and cobalt steels was superior to that of the high-tungsten-low-vanadium type and special steels containing about $1/4$ per cent uranium or $3/4$ per cent molybdenum. The average power consumption in all cases was practically the same.

3 Modification in test conditions, including small changes in tool angles but principally changes in cutting speed, more markedly affected the performance of steels containing cobalt or special elements, such as uranium or molybdenum, than that of the basic types (plain chromium-tungsten-vanadium steels).

4 The relatively poor endurance of the high-tungsten steels under severe working conditions was not observed in more moderate tests, made on the same test log with equal cutting speed and depth of cut but with reduced feed, in which the frictional temperatures produced were not so high. Also in these latter tests the performance of the cobalt steels was better than either the low- or high-tungsten steels.

5 Hardness determinations and examination of fractures indicate that the various types of commercial high-speed steel show differences in behavior under heat treatment and in physical properties which probably are of importance under moderate working conditions and might counterbalance slight advantages in performance.

The paper contains fifteen tables. Address the Superintendent of Documents, Government Printing Office, Washington, D. C.

Non-Ferrous Metals A4-23. Solders for Aluminum. Most of the metals commonly used in solders, except magnesium, are electropositive to aluminum, so that any metals used in making a soldered joint of aluminum act electrolytically in the presence of moisture accelerating the corrosion of the aluminum. Magnesium cannot be utilized because it disintegrates rapidly in the presence of moisture. Soldered joints of aluminum exposed to moisture should be protected by paint or varnish. Various compositions of zinc-tin and zinc-tin-aluminum solders give the best results. The tensile strength of a good aluminum solder is about 7000 lb. per sq. in. Those with higher tensile strength usually have such a high temperature of complete liquidation that they are unsuited for soldering purposes.

Circular No. 78 of the Bureau of Standards entitled, Solders for Aluminum, has recently been revised. It will soon be available from the Superintendent of Documents, Government Printing Office, Washington, D. C., at 5 cents a copy.

Steam Power A1-23. How Steam Production Costs were Reduced in a Hand-Fired Return-Tubular Boiler Plant. During the course of an investigation conducted by the fuel section of the Bureau of Mines, on a hand-fired return-tubular boiler plant, it was found that the average cost of fuel to produce 1000 lb. of steam was \$0.5287. Tests conducted after some simple changes had been made in the furnaces, and in the control of the boilers, showed the previous high cost of fuel per 1000 lb. of steam could be reduced to the reasonable figure of \$0.3540, or the equivalent of over 30 per cent saving in fuel cost.

These tests were made by A. R. Mumford, assistant fuel engineer of the Bureau of Mines, and consisted of a comparative study in the use of pea-size anthracite and bituminous coal without smoke. They involved experimental modifications of the setting, modifications in the method of control of the boilers, and improvement in the methods of firing. This last resolved itself into a comparative time study.

The total savings shown possible by the modifications introduced are approximately 900 tons of coal in an eleven-month period, and approximately \$12,500 in total fuel cost. Reports of Investigations, Serial No. 2455, U. S. Bureau of Mines, Washington, D. C.

Steel, Its Treatment and Products A1-23. Lathe Breakdown Tests of Some High-Speed Tool Steels. See *Machine Tools A1-23.*

B—Research in Progress

The purpose of this section of Engineering Research is to bring together those who are working on the same problem for coöperation or conference, to prevent unnecessary duplication of work, and to inform the profession of the investigators who are engaged upon research problems. The addresses of these investigators are given for the purpose of correspondence.

Instruments and Apparatus B2-23. Saybolt Universal Viscosimeter. A conference was held at the Bureau of Standards, November 14 with members of the American Petroleum Institute, as a result of which a committee of 5 members of the Institute was appointed to coöperate with the Bureau in expediting the more accurate standardization of the Saybolt universal viscosimeter.

The Institute and the Bureau are also coöperating with the Society of Automotive Engineers and the Interdepartmental Committee on Petroleum Products in the development of a numbering system for lubricating oils based on their viscosity.

Iron and Steel B1-23. Wear Tests of Steel. An investigation of the resistance to wear of steels has been in process at the Bureau of Standards for some time. During the past month a study has been made of the effect of keeping the surfaces of the specimens clean and free from all adhering abraded particles. A cloth buffing wheel, rotated at high speed by electric motor, has been used successfully for this purpose. It has been found that when the wearing surfaces are thus kept free of abraded metallic dust, the rate of wear drops to an almost negligible quantity compared with the rate when the wearing surfaces are not kept clean by the buffing wheel. Address Dr. Geo. K. Burgess, Director of the Bureau of Standards, Washington, D. C.

Lubricants B1-23. Saybolt Universal Viscosimeter. See *Instruments and Apparatus B2-23.*

Non-Ferrous Metals B2-23. Gases in Monel Metal. The Bureau of Standards has just completed determinations of oxygen and hydrogen in samples representing three phases of the deoxidation of monel metal. The samples were all from 50-lb. blocks cast during the progress of a regular heat. These samples represent (1) the metal at the time of tapping the furnace before the addition of any deoxidizers; (2) the above metal after the addition of ferro manganese in the ladel, and (3) the above metal after the further addition of magnesium in the ladle, that is, after all additions have been made. Both oxygen and hydrogen in the metal decreased rapidly with the progress of deoxidation. The finished metal, as represented by the last sample of this heat and

by samples of completely deoxidized metal from two other heats, contains from 0.002 to 0.005 per cent oxygen. All samples appear rather porous under a magnification of 100.

A sample of monel metal prepared as above, except that a portion of the deoxidation was carried out in the furnace rather than entirely in the ladle, showed no porosity, and no oxygen could be detected. A sample of monel metal from a Herault furnace heat, which had been completely deoxidized in the furnace, likewise was entirely sound and contained no oxygen. Of the five samples of finished monel metal examined the three which were deoxidized by addition of ferromanganese and magnesium in the ladle were porous and contained from 0.002 to 0.005 per cent oxygen, while the two which were deoxidized entirely or in part in the furnace were sound and contained no oxygen.

Paper B1-23. THE TENSILE STRENGTH OF PAPER. There are a number of devices for determining the tensile or breaking strength of paper, but the procedure in carrying out the tests has not been standardized; thus all sorts of combinations of width and length of the test specimen, rate of applying the load, and time during which the specimen is under stress, are in use.

A study of these various factors recently completed by the Bureau of Standards indicates that there is considerable difference in the amount of stretch when the factors are varied, but when only the strength is to be considered, the length of the specimen, within limits, is of negligible importance, while the strength is almost proportional to the width.

Paper B2-23. THE MULLEN TESTER FOR MEASURING THE QUALITY OF PAPER. What is known as the Mullen tester is used almost universally in this country for determining the bursting strength of paper, and on this factor is based to a large extent the measure of the quality of the paper. It often happens, however, that a sheet may be so made or so sized as to have a very high bursting strength and yet show up very poorly in a tearing or folding test.

The Bureau of Standards is working on a supplementary test employing two steel rollers which produce a crease in the paper under controlled conditions of pressure and time. The bursting strength is determined before and after such folding. The loss of strength under these conditions is an excellent indication of the brittleness of the paper. The method, however, must still be standardized. A report on this subject will be published in the near future.

Rope B1-23. TESTS FOR NEW DESIGN OF LARGE HAWSERS. Tensile tests were made during the past month at the Bureau of Standards on twenty-one samples of very large hawsers. The purpose of these tests was to determine the comparative strength of a new type of construction for manila rope as compared with the standard method of construction. In the new type the inner yarns of the strands are untwisted. The strands are made up of several outer layers of twisted yarns binding this inner compact mass of fibers; these strands being twisted in the usual manner to form the rope. The tests showed that in all cases the new type of construction increases the strength of the rope.

Steel, Its Treatment and Products B1-23. CARBURIZATION OF STEEL. An investigation of the effect of the quality of steel upon its carburizing properties, and particularly its hardening properties after carburization, was suggested to the Bureau of Standards by metallurgists as a problem of very considerable commercial importance. As soon as the necessary material (abnormal steels) can be obtained, the work will be started.

F—BIBLIOGRAPHIES

The purpose of this section of Engineering Research is to inform the profession of bibliographies which have been prepared. In general this work is done at the expense of the Society. Extensive bibliographies require the approval of the Research Committee. All bibliographies are loaned for a period of one month only. Additional copies are available, however, for periods of two weeks to members of the A.S.M.E. These bibliographies are on file at the headquarters of the Society.

Heat Transmission F1-23. HEAT EXCHANGERS. A bibliography consisting of two pages. Search No. 3717. Address the A.S.M.E., 29 West 39th Street, N. Y. C.

Machine Design F1-23. RING-OILING SYSTEMS. A bibliography consisting of one page. Search No. S 3683. Address the A.S.M.E., 29 West 39th Street, N. Y. C.

CORRESPONDENCE

CONTRIBUTIONS to the Correspondence Department of MECHANICAL ENGINEERING are solicited. Contributions particularly welcomed are discussions of papers published in this journal, brief articles of current interest to mechanical engineers, or comments from members of The American Society of Mechanical Engineers on activities and policies of the Society in Research and Standardization.

Methods of Calculating the Diameters of Open-Belt Speed Cones

TO THE EDITOR:

The following is submitted as a rational method for calculating the radii of open-belt speed cones.

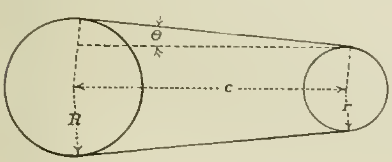

FIG. 1 DIAGRAM OF OPEN-BELT DRIVE

Let L = length of belt
c = distance between pulley centers
r = radius of smaller pulley
k = velocity ratio, whence
$R = kr$ = radius of larger pulley.

Then, referring to Fig. 1,

$$L = 2c\cos\theta + r(\pi - 2\theta) + kr(\pi + 2\theta)$$

$$= 2c\frac{\sqrt{c^2 - r^2(k-1)^2}}{c} + \pi r(k+1) + r(k-1)2\theta$$

$$= 2c\sqrt{1 - \left[\frac{r(k-1)}{c}\right]^2} + 2c\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)\frac{r(k-1)}{c}$$

$$+ 2c\frac{r(k-1)}{c}\sin^{-1}\frac{r(k-1)}{c}$$

Let $\frac{r(k-1)}{c} = u$; then, substituting in the preceding equation,

$$\frac{L}{2c} = \left[1 + (-u^2)\right]^{\frac{1}{2}} + \left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)u + u\sin^{-1}u$$

$$= 1 + \frac{1}{2}(-u^2) + \frac{\frac{1}{2}\left(-\frac{1}{2}\right)(-u^2)^2}{\underline{|2}}$$

$$+ \frac{\frac{1}{2}\left(-\frac{1}{2}\right)\left(-\frac{3}{2}\right)(-u^2)^3}{\underline{|3}}$$

$$+ \frac{\frac{1}{2}\left(-\frac{1}{2}\right)\left(-\frac{3}{2}\right)\left(-\frac{5}{2}\right)(-u^2)^4}{\underline{|4}} + \cdots$$

$$+ \left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)u$$

$$+ u\left[u + \frac{u^3}{2\cdot 3} + \frac{3u^5}{2\cdot 4\cdot 5} + \frac{3.5u^7}{2\cdot 4\cdot 6\cdot 7} + \frac{3.5.7u^9}{2\cdot 4\cdot 6\cdot 8\cdot 9} + \cdots\right]$$

or

$$\frac{L}{2c} - 1 = \left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)u + \frac{1}{2}u^2$$

$$+ \frac{1}{24}u^4 + \frac{1}{80}u^6 + \frac{5}{896}u^8 + \frac{7}{2304}u^{10} + \cdots$$

Let $\frac{L}{2c} - 1 = V$ and

$$u = AV + BV^2 + CV^3 + DV^4 + EV^5 + FV^6 + \cdots$$

Substituting the series in u for V in the series in V gives

$$u = A\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right) u + A\,\frac{1}{2}\,u^2 + A\,\frac{1}{24}\,u^4 \ + \ + A\,\frac{1}{80}\,u^6 + \cdots$$
$$+ B\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right) u^2 + B\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right) u^3 + B\,\frac{1}{4}\,u^4$$
$$+ B\,\frac{1}{24}\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right) u^5 + \cdots$$
$$+ C\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)^3 u^3 + C\,\frac{3}{2}\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)^2 u^4$$
$$+ C\,\frac{3}{4}\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right) u^5 + \cdots$$
$$+ D\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)^4 u^4 + D\,\frac{3}{2}\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)^3 u^5 + \cdots$$
$$+ E\left(\frac{\pi}{2}\ \frac{k+1}{k-1}\right)^5 u^5 + \cdots$$

Equating like coefficients,

$$A = \left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right) \qquad B = -\frac{1}{2}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^3$$

$$C = \frac{1}{2}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^5$$

$$D = \left[\frac{1}{24}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^5 + \frac{5}{8}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^7\right]$$

$$E = \frac{1}{48}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^9 - \frac{3}{8}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{11}$$
$$+ \frac{3}{48}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{13} + \frac{15}{16}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{15}$$

$$F = -\left[\frac{1}{80}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^7 - \frac{1}{48}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^9\right.$$
$$+ \frac{1}{16}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{11} + \frac{5}{96}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{15} - \frac{15}{16}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{17}$$
$$\left. + \frac{15}{96}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{19} + \frac{75}{32}\left(\frac{2}{\pi}\ \frac{k-1}{k+1}\right)^{21}\right]$$

Substituting these values in

$$u = AV + BV^2 + CV^3 + DV^4 + EV^5 + FV^6 + \cdots$$

where $u = \dfrac{r(k-1)}{c}$ and $V = \dfrac{L}{2c} - 1$, and letting $\dfrac{2}{\pi}\ \dfrac{k-1}{k+1} = w$,

$$r = \frac{c}{k-1}\left[wV - \frac{1}{2}w^3V^2 + \frac{1}{2}w^5V^3 - \left(\frac{1}{24}w^5 - \frac{5}{8}w^7\right)V^4\right.$$
$$+ \left(\frac{1}{48}w^9 - \frac{3}{8}w^{11} + \frac{3}{48}w^{13} + \frac{15}{16}w^{51}\right)V^5 - \left(\frac{1}{80}w^7 - \frac{1}{48}w^9\right.$$
$$\left. + \frac{1}{16}w^{11} + \frac{5}{96}w^{15} - \frac{15}{16}w^{17} + \frac{15}{96}w^{19} + \frac{75}{32}w^{21}\right)V^6 + \cdots\Big]$$

If $k = 1$, this equation reduces to

$$r = \frac{1}{\pi}\left(\frac{L}{2} - c\right)$$

The values of r given by this series may be calculated to any desired degree of accuracy by taking a large enough number of terms.

For values of angle θ up to four or five degrees the series converges very rapidly; the rapidity of convergence falling off, however, as the belt angle is increased.

The first two or three terms will generally be sufficient for cases with small belt angles; while the fourth should suffice for angles up to and including 10 or 11 deg. for θ.

In using this formula either the belt length should be calculated to fit a pair of pulleys at the start or some convenient belt length should be fixed upon and then the pulleys calculated to fit the belt.

The dimensions L, c, and r must, of course, always be taken in the same units.

W. H. Wise.

Missoula, Mont.

To the Editor:

In a correctly designed speed-cone drive the same belt will work in all positions with equal tightness. This is accomplished by so arranging the sum of the diameters that the length of belt required to pass over each pair of steps will remain constant. By comparing the formula for the exact length of a crossed belt [1] with that for the exact length of an open belt [2], it will be seen that in the former case the length is a function of the center distance and the sum of the diameters, while in the latter the length is a function of the center distance and the sum and difference of the diameters.

$$L = \frac{1}{2}(D+d)\left[\pi + 2\sin^{-1}\frac{D+d}{2c}\right.$$
$$\left. + 2\cot\left(\sin^{-1}\frac{D+d}{2c}\right)\right] \ldots\ldots [1]$$

$$L = \frac{\pi}{2}(D+d) + (D-d)\sin^{-1}\frac{D-d}{2c}$$
$$+ 2\,C\cos\left(\sin^{-1}\frac{D-d}{2c}\right) \ldots\ldots [2]$$

where

D = diameter of the larger pulley
d = diameter of the smaller pulley
c = center distance between shafts, and
L = length of belt.

Therefore, if the belt is to work with equal tightness when crossed, since the center distance is constant it is sufficient to so design the steps that the sum of the diameters of one pair shall equal the sum of the diameters of any other pair. In other words,

$$D_1 + d_1 = D_2 + d_2 = D_3 + d_3, \text{ etc.}$$

In the case of an open belt, however, not only the sum but also the difference of the diameters must be constant; this condition it is impossible to satisfy, hence there can be no direct solution.

Several excellent graphical methods have been devised. In practice, however, it is difficult to make a layout sufficiently accurate; very often the center distance is too long for the equipment on hand, so that a layout must be made to a small scale, and a very slight error will greatly affect the final results. None of the theoretical formulas known can be considered a convenient way of solving the problems because of their complexity and length.

The following is the method used by the writer in constructing a logarithmic chart which greatly simplifies the calculations of cone-pulley diameters. The formula for the length of an open belt is given by Professor Unwin as follows:

$$L = \frac{\pi}{2}(D+d) + 2c\left[1 + \frac{(D-d)^2}{8c^2}\right] \ldots\ldots\ldots [3]$$

which is very nearly the exact length. Let D_0 and d_0 be the diameters of one pair and D_1 and d_1 the diameters of any other pair of steps in the same cone; then, the length of the belt being the same,

$$L = \frac{\pi}{2}(D_0 + d_0) + 2c\left[1 + \frac{(D_0 - d_0)^2}{8c^2}\right]$$
$$= \frac{\pi}{2}(D_1 + d_1) + 2c\left[1 + \frac{(D_1 + d_1)^2}{8c^2}\right] \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

Solving for $D_1 + d_1$,

$$D_1 + d_1 = D_0 + d_0 + \frac{(D_0 - d_0)^2 - (D_1 - d_1)^2}{2\,\pi c} \ldots\ldots [5]$$

If D_0 and d_0 be the diameters of a pair selected to give the speed ratio $k = 1$, then $D_0 = d_0$ and $(D_0 - d_0) = 0$. Substituting this value in [5],

$$D_1 + d_1 = D_0 + d_0 - \frac{(D_1 - d_1)^2}{2\pi c} \qquad [6]$$

which means that for open-belt service the sum of the diameters of any pair of pulleys equals the sum of the diameters of a pair of mutually equal pulleys for the ratio $k = 1$ minus a correction (K) whose value is

$$K = \frac{(D_1 - d_1)^2}{2\pi c} \qquad [7]$$

Since the value $(D_1 - d_1)$ is unknown until $(D_1 + d_1)$ is found, an approximation must be used, which may be assumed as

$$D_1 - d_1 = (D_0 + d_0)\frac{k - 1}{k + 1} \qquad [8]$$

The value of the sum of the diameters $(D_1 + d_1)$ can now be found by solving [6]. In most cases the results thus obtained are sufficiently accurate for practical purposes. However, when the speed ratio k is large and the center distance very short, it is advisable to solve [6] a second time, substituting a closer approximation of $D_1 - d_1$, namely,

$$(D_1 + d_1)\frac{k - 1}{k + 1}$$

where $(D_1 + d_1)$ has the value as found in the first trial. This result is accurate enough for any condition met in practice.

The chart was evolved with the idea of eliminating as much as possible of the labor attached to calculating the correction number from Formulas [7] and [8]. For convenience in constructing the chart the expression for the correction number K can be written

$$K = \frac{\dfrac{(D + d)^2}{2\pi}}{\dfrac{1}{\left(\dfrac{k - 1}{k + 1}\right)^2} c}$$

The chart (Fig. 2) consists of four scales; the values on the scale representing the logarithm of the center distance c must be added to the value on the scale marked "Speed Ratio," which equals the logarithm of $1/[(k - 1)/(k + 1)]^2$, and the resulting logarithm should be subtracted from $\log (D + d)^2/2c$ on the scale marked "Sum Diameters." The remainder is the logarithm of the correction number and can be read on the fourth scale representing the correction number.

The procedure of calculating the correct diameters of any pair of steps for open-belt service can be best illustrated by an example. Given the diameters of a pair of even steps for ratio $k = 1$, each equal to 9 in.; center distance = 30 in.; speed of one shaft = 500 r.p.m.; speed of the other shaft = 100 r.p.m.

1 Add the diameters of the given even pair:

$$9 \text{ in.} + 9 \text{ in.} = 18 \text{ in.}$$

2 Express the speed ratio as follows:

$$k = \frac{\text{higher speed}}{\text{lower speed}} = \frac{500}{100} = 5$$

3 Set one point of a pair of dividers at 30 on the scale of Fig. 2 representing the center distance and the other point at 5 on the scale marked "Speed Ratio."

4 Keeping the above setting, place one point of the dividers at 18 on the scale marked "Sum Diameters;" the other point of the dividers will then indicate the first approximation of the correction number on the scale marked "Correction Number." In this example the first approximation equals 0.760.

5 Subtract this correction number from the sum of the diameters of the two even pulleys:

$$18 - 0.760 = 17.240$$

6 Keeping the same setting of the dividers as in (3), place one point at 17.240 on scale marked "Sum Diameters;" the other point will stop at 0.695, which is the second and closer approximation of the correction number.

7 Subtract this correction number (0.695) from the sum of the diameters of the even pair, then

$$S_K = 18 - 0.695 = 17.305$$

in which S_K is the corrected sum of diameters for the ratio $k = 5$.

8 The last step is to find the diameter of each pulley separately:

$$\text{Diameter of smaller pulley} = \frac{S_K}{k + 1}$$

$$\text{Diameter of larger pulley} = S_K - d$$

Then in the present example

$$d = \frac{17.305}{6} = 2.884 \text{ in.}$$

$$D = 17.305 - 2.884 = 14.421 \text{ in.}$$

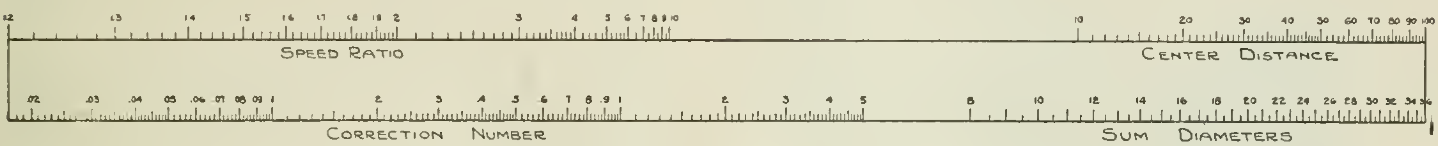

Fig. 2 Correction Chart for Use in Calculating Cone-Pulley Diameters

If the correction number is carefully read from the chart the final results will not vary on the average more than 0.005 in. from the most accurate mathematical calculations, and the whole procedure should not take over three minutes.

TABLE 1 CALCULATIONS OF THREE DIFFERENT CONE DRIVES

No.	c	k	$D_0 + d_0$	K from chart	S_K	D_1	d_1	L
1	40	1	32	.....	.....	.....	.....	130.266
	40	4	..	1.340	30.660	24.528	6.132	130.285
2	60	1	20	.....	.....	.....	.....	151.416
	60	3	..	0.256	19.744	14.808	4.936	151.417
3	30	1	18	.....	.....	.....	.....	88.274
	30	5	..	0.695	17.305	14.421	2.884	88.295

For the purpose of checking the accuracy of the chart, the diameters and the lengths of belts of three different cone drives have been computed, the results being given in Table 1.

David Turcott.

Beloit, Wis.

With Reference to the Discussion on High-Temperature and High-Pressure Steam Lines

To the Editor:

It has been called to my attention that as presented on page 294 of the May issue of Mechanical Engineering, the second paragraph of my closure to the discussion of my paper on High-Pressure and High-Temperature Steam Lines may be interpreted as an unfair criticism of Mr. Barrett, one of the discussors. Undoubtedly Mr. Barrett's discussion was prepared carefully and there was no desire on my part to pass on his engineering ability for which I have every respect. I desire to correct any different impression that may be derived from my closure.

Immigration Policy Places New Responsibilities on the Engineer

H. V. Coes

FROM all sides we constantly hear of labor shortage. The deflation period in 1921 seemed to indicate a large surplus of labor. As soon, however, as business began to revive, as it did the past year, the temporary surplus was immediately absorbed, and now one important industrial executive estimates the labor shortage in the United States at the present time at 600,000. The people of the United States have made up their minds that they are going to control the character of the raw material that is to make up their citizenship and their neighbors, and the present policy is to restrict immigration from those countries whose people are not readily assimilated. The shortage threatens to become permanent.

A study of our principal industries such as textiles or steel shows a continuous shift in the various nationalities engaged therein over a long period of years. The probable reason for it is that the second or third generation of a given group of immigrants will not do the work their grandparents did—they have advanced to a higher scale of living and the unskilled worker is recruited from a new group of immigrants. This substitution of labor, both male and female, has run through the nations of Western Europe and, in the last decade or two, has largely focused on those of Eastern Europe. How much farther it can go in the white race it is hard to say. It has reached a point in certain places where there has been considerable agitation for coolie labor. I doubt very much whether the United States will ever admit labor of that class.

It has been the policy of the United States for over seventy years to depend upon immigration to furnish the necessary unskilled labor for our industries. Last year the number of immigrants admitted to this country was approximately 360,000; pending legislation would limit the eligibles to 170,000. The vital question, then, is, can the country expand and prosper with such a limited supply of new labor? A glance at the following statistics may be of interest.

Year	Number of Immigrants	
1820	8,400	
1830	23,000	
1840	80,000	Period of industrial expansion
1854	420,000	
1862	72,000	
1905	1,026,000	

In other words, when the United States was an agricultural country we did not need large immigration. As our industries developed, however, our immigration rose very rapidly. It fell to a low point on account of the Civil War, but throughout that period we received a total of about 620,000. In the past century the United States has received 35,000,000 immigrants. They have not all remained here, however. For instance, from 1909 to 1923, 5,500,000 departed, while our gain in immigration during that same period was 5,125,000.

The question is asked, What interest has the engineer in a restricted immigration policy? The answer is that the engineer, appreciating his important function in developing and sustaining civilization, must provide workers of metal and wood to fill the ranks that have normally been recruited from immigrants. Opportunity awaits the grasping. Capital will be required, but will undoubtedly be forthcoming to furnish backing for the design and manufacture of machines and devices that are commercially practical for lessening the hand work of the world. The increasing material needs of the inhabitant of a modern civilized country means that industry must increase. The new personnel for an increased industry will not come from restricted immigration even though quotas be made net, taking into account emigration and immigration. New and better machines under the guidance of modern management methods form an important part of the solution of the problem of labor shortage. Providing the machines and the management methods is largely an engineering responsibility. In other words, the engineer and management must devise ways and means to release common labor from some of its present assignments and graduate it into the ranks of semi-skilled and skilled labor, substituting therefor mechanical appliances to do the work previously done by common labor. This substitution need not, in fact should not, be confined to the activities now performed by common labor, but similar substitution must be made all along the industrial path if we are to maintain our industrial supremacy.

H. V. Coes.[1]

Coast to Coast by Air

THE flight of Lieutenants John A. Macready and Oakley G. Kelly from Long Island to San Diego is primarily of interest as showing the progressive spirit governing the Army Air Service.

It is certainly no accident that at the time of this writing several world records are held by the Department, among others such important ones as the speed record, the endurance record, and now the non-stop distance flight. (The fact that for technical reasons this particular record cannot be homologated by the International Aeronautical Association, does not, of course, in any way affect its authenticity or value.) The coast-to-coast flight was a severe test not only of the plane and engine, but also of the training and personal ability of the men. Moreover it is not an isolated performance, a stunt. The same men have flown for other long distances, though not as great, of course, as that covered in the present flight. Other flights such as the one from Long Island to Alaska and particularly the recent flight to Porto Rico have shown that the Army Air Service is capable of what would have appeared to be only a few years ago unbelievable performances.

The machine used was a T-2 monoplane designed by Anthony G. H. Fokker and built by the Netherlands Aircraft Corporation to take the Liberty motor. The structural weight empty is 5100 lb. and the useful load for commercial operation is 3500 lb. The total wing area is 940 sq. ft. The maximum speed fully loaded is 105 miles per hour, and the ceiling approximately 11,000 ft.

In order to adapt the machine for the coast-to-coast flight certain changes were made. By the use of an extra tank in the cabin and an extra gravity tank in the wing, the total gasoline capacity was increased to some 735 gal. and the oil capacity to 30 gal. The total

[1] Chairman, Materials Handling Division, A.S.M.E.

weight fully loaded was thus increased to over 10,000 lb. An oil radiator was provided. Anti-leak compound with an appropriate pressure pump was carried for use in the radiator or water jackets in case of leak. A special tank was provided to catch overflow from the radiator or its expansion tank, so that the loss of water on a long trip was minimized. Spare batteries were taken along, as well as a spare glass tube for the gasoline level gage among other items. A second set of flying and engine controls were installed in the cabin, with a communicating door between the pilot and the cabin so as to facilitate interchange between the two men. A liding door was provided near the pilot in order to enable him to thrust his body right outside the plane.

The power plant was a Liberty engine, and it is stated that, with the exception of a short period at the beginning of the trip, it operated at about 90 per cent of its full power throughout the flight.

The present flight, as well as the flight from England to Australia by the Smith brothers in their Vimy biplane, has shown that highly experienced fliers can find their way even under adverse conditions by compass and dead reckoning. It has also shown, however, that it takes a highly experienced flier to do so, and that lack of ground markings is a serious obstacle to long-distance flight.

It may be a long time before flying from New York to San Francisco will become an every-day occurrence and a means of saving time for the ordinary busy man. Lady Carnarvon's attempt to reach her dying husband by air from England to Egypt, it may be said, failed mainly because of the extreme discomfort of long flight to those not accustomed to that mode of travel.

From a military point of view, however, the importance of the achievement of Macready and Kelly is very clear, and it is also of unquestioned significance as showing that while the number of planes available to the War Department is pitifully small for such a great country as ours, the men in the Department are capable of performing wonders even with what equipment they have.

Store Winter Coal Now!

ALL INDUSTRIES and individuals are asked to store a winter's supply of fuel during the summer months. The Coal Commission has pointed out that the storage of coal in this manner will even the demand for coal throughout the year, thereby rendering its production more economical and equalizing the demand for transportation. Secretary Hoover, in a letter to the Society, points out that the producing capacity and consuming demands of the country have advanced beyond our transportation facilities, and stresses the importance of both consuming and producing industries coöperating with the railroad managements to secure the most efficient operation of their lines. The transportation peak of the country occurs during October. It is extremely important, therefore, that coal be purchased and stored within the next three months so that the burden of moving this fuel will not be added to the difficult transportation period of the fall.

The importance of storing coal applies not only to the railroads, the public utilities, and the industries, but also to domestic users. The Storrs Plan of domestic coal storage was outlined in the May issue of Mechanical Engineering.

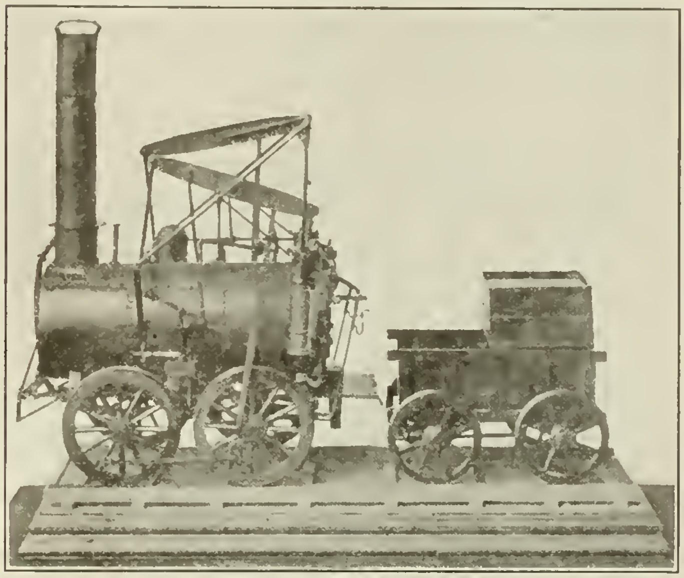
The American Engineering Council has appointed a committee to make a coal-storage survey and issue an authoritative statement covering the engineering, chemical, and economic factors involved in the storage of coal, and how they may be employed to relieve the present complex coal situation. It is hoped that this committee will report early in November, 1923.

The problem of coal storage is far-reaching and fundamental. It places a responsibility on each member of the Society to discuss the subject in his business and social contacts and arouse general public attention. The organized groups of the Society are mobilizing for duty. The Fuels Division is assisting the committee of the American Engineering Council, and in addition will hold a session at the A.S.M.E. Annual Meeting in December with papers on the storage of fuel. The Materials Handling Division is coöperating in the arrangements for this session. Each Local Section will be called upon by the American Engineering Council committee to assist in the survey.

Store winter coal now!

One Hundred Years of Transportation

THE centennial celebration of the Delaware and Hudson Company has served to recall the efforts of pioneers in creating a market for the "stone coal," as anthracite was then called, which was discovered near Carbondale, Pa., in 1799. There was doubt as to the ability of "stone coal" to burn on a grate. However, the war of 1812 cut off the normal supply of charcoal and the use of anthracite as a substitute was pushed. About this time William Wurts obtained a large acreage of coal lands near Carbondale and, with his brother Maurice, opened mines and attempted to market the product in Philadelphia. They were compelled to abandon this project to their competitors who were more advantageously located, and turned to New York for the outlet. So the Delaware and Hudson Company was organized to construct a canal connecting the waters of the Delaware and Hudson Rivers. A portion of



The "Stourbridge Lion," the First Steam Locomotive Run on Rails in America

the route from mine to market was over a range of mountains and a gravity railroad was built using inclined planes and stationary hoisting engines.

In 1829 four locomotives were imported from England for use on the gravity railroad. The *America*, built by George Stephenson, arrived on January 15, 1829, and the other three, built by Foster Rostrick, came in May. On August 8 one of the three, the *Stourbridge Lion*, was operated on a section of the track. The test convinced the engineers that the track would not stand the weight of the *Lion* or the side thrust of the wheels on curves. Rebuilding the road to withstand the stresses was considered but for various reasons was found to be impracticable, and the use of locomotives abandoned. The *Stourbridge Lion* was the first locomotive placed on any track outside of England and the first that ever turned a wheel on the Western Hemisphere. It was imported solely to transport and market anthracite.

In a country depending so completely on transportation as does the United States, the centennial of a pioneer transportation company is of great interest. Certainly we can have no accurate conception today of the courage of the pioneers who overcame the prejudices against anthracite and who conquered the physical difficulties of bringing the coal to market.

Transportation conditions a century ago were in at least one respect similar to those of the present day. Locomotives had been known for twenty-five years before the importation of the four engines by the Delaware and Hudson Company. The locomotive did not come into general use, however, until the demands for its services could be met commercially. Today the airplane, largely a war development, is waiting for commercial needs to require its unique transportation ability and to compel the expenditure of money for the research and development that will perfect it for commercial use.

Engineering in India

ENGINEERING projects of great magnitude are under way and under consideration in India, according to a report recently submitted to the Department of Commerce by Trade Commissioner Batchelder. It is estimated that nearly a million dollars is needed to carry out all the plans, among which are the following:

The Madras Presidency proposes to expend about $45,000,000 within the next five years, for irrigation, roads, and other public works. Bombay plans to spend $61,000,000 on irrigation alone, besides continuing the port-development works and the new schoolhouses required to carry out the terms of the new compulsory education act. The United Provinces need $30,000,000 within the same period for irrigation, forests, and other public works, while the Punjab has extensive plans for irrigation and hydro-electric plants requiring $140,000,000 before 1940.

Bengal has decided to build a $10,000,000 bridge across the Hoogly in Calcutta, and there will be further expenditures on the improvements of the port and for ameliorating the housing and congested traffic problems. The total desired for all these government and municipal public works cannot be less than $300,000,000. Besides, it is intended to spend about $500,000,000 in the next five years for new construction, repairs, and additional rolling stock on the government railways.

Some interesting communications concerning engineering in India have come during recent months from J. D. Rogers, representative of The Baldwin Locomotive Works at Calcutta. Mr. Rogers has spent some time in Africa—nearly three years in South Africa and later traveling in Portuguese East Africa and neighboring sections. His message to every American who has gone or expects to go into the foreign field of engineering is to remember that he represents not only some particular interest but the whole American engineering profession. Extracts from Mr. Rogers' letters follow:

India offers great opportunity for capital to be employed in development such as manufacturing, extension of irrigation, and making the great river system navigable. With proper expenditures of money the terror of the monsoons can be eliminated. There will be no suffering from either drought or flood. The Bengal government is to spend $2,000,000 on a canal at Calcutta. The engineer in charge tells me that all of his estimates are based on using American equipment, as we have solved the question of eliminating labor.

I have made a complete circuit of India; this means covering an area equivalent to about two-thirds of that of the United States. Travel here is very comfortable as the railway equipment is well adapted to the conditions. There are about 15,000 miles of broad-gage, 3 ft. 6-in. lines, and the same of meter-gage; this is supplemented by some 5000 miles of narrow-gage, 2 ft. 6 in. and 2 ft. Railways are not only vital in the economic development of India but are the means of distributing the food to the 350,000,000 people. Great famine funds which were provided by taxation are now being spent in further development, not only of railways but vast irrigation projects. At present the Punjab project is under way; it far exceeds anything ever undertaken in America and will make a barren desert as productive of cotton as our best southern states.

It is very gratifying to see the interest the railway men of India take in our American engineering. Just now there is a strong tendency toward our locomotive designs. I am here now in Delhi to discuss the standardization of locomotives with the Railway Board, the functions of which combine those of our Interstate Commerce Commission and the Railway Administration. They have to approve every policy of the Indian Railways, both engineering and financial. They are a very high-grade body of men, representative of the very best in India.

Conference of Women Engineers Held in England

SOME forty delegates convened by the Women's Engineering Society met at Birmingham University on April 12 and 13 in the first conference of women engineers ever held. The presidential address of Lady Parsons was followed by an outline of the history of mechanical engineering by Prof. F. W. Burstall, Dean of the Faculty of Science, Birmingham University. Professor Burstall discussed the social and ethical effects of scientific progress, stating that the human element must be the predominant issue in all matters of engineering development. He later conducted the delegates in an inspection of the engineering department of the University.

At an evening session on April 12 Miss M. Partridge, of M. Partridge & Co., domestic engineers, Exeter, read a paper based on her experience in electrical contracting work in country districts.

On April 13 a paper by Mrs. L. M. Gilbreth, whom illness prevented from being present as representative of The American Society of Mechanical Engineers, was read by Miss C. Haslett, secretary of the Women's Engineering Society. Her article was a brief exposition of the growth in the breadth of interest of the engineer, in his work, and in his field of influence.

Miss Entwisle, of the Metropolitan-Vickers Electrical Co., Ltd., Manchester, presented a paper entitled Some Considerations of Electrical Design. Mme. Laurent, who, with her husband, attended the conference as directors of the Ecole Technique Feminin de Paris, and as representatives of the French Government, gave a short lecture, illustrated with lantern slides, on the gradual development of women engineers in France. The convention closed with a trip to Stratford on Avon on April 14.

Dr. George K. Burgess Becomes Director of the Bureau of Standards

THE DIRECTORSHIP of the U. S. Bureau of Standards has recently been placed in the hands of Dr. George K. Burgess, who has been connected with the Bureau since 1903 and since 1913 has been chief of the Division of Metallurgy. His long association with the Bureau, and his intensive research work, particularly in iron and steel, make him well qualified for his new position.

Dr. Burgess was born in Newton, Mass., in 1874, received the degree of B.S. from Massachusetts Institute of Technology in 1896, held a fellowship there from 1898 to 1900, and obtained his Sc.D. from the University of Paris in 1901. He was instructor at the University of Michigan for one year, and at the University of California for two years, previous to entering the Bureau.

As a member of the National Research Council Dr. Burgess has been active in its committee work. He represents the Department of Commerce on the American Engineering Standards Committee and is this year's president of the American Society for Testing Materials.

Sir J. J. Thomson Visits America

SIR JOSEPH JOHN THOMSON, F.R.S., who has been a visitor in this country during recent weeks, was awarded the Franklin Medal at a special meeting of the American Philosophical Society in Philadelphia on April 10. He likewise received the John Scott medal and award of $1000. The subject of his address on this occasion was the possibility of a new form of water molecule.

Sir Joseph, for many years Cavendish Professor at Cambridge, and now Master of Trinity College, came here under the auspices of The Franklin Institute to give a series of lectures before that institution on The Electron in Chemistry. These lectures, with due regard to progress of science, may be said to be a continuation of those delivered by Lord Kelvin before the same body.

Sir Joseph was the speaker at the dedication of the Sterling Laboratory at New Haven on April 4, and on April 6 and 7 visited the Research Laboratory and the Schenectady Works of the General Electric Company, giving an informal talk to the laboratory staff and engineers and evidencing much interest in the work they are carrying on.

Mr. Dickinson of South Kensington Museum Visits the United States

H. W. DICKINSON, Assistant to the Director of the Science Museum at South Kensington, London, and Honorary Secretary and Treasurer of the Newcomen Society, visited New York, Washington, Philadelphia, Boston and Dayton during April and May.

Mr. Dickinson is keenly interested in the history of engineering and technology, developing interest in which is one of the important objects of the Newcomen Society. On his trip Mr. Dickinson was the guest of several groups of engineers who have displayed an appreciation of the value and importance of engineering history.

Mr. Dickinson was a speaker at the dinner celebrating the Centennial of the Delaware and Hudson Company on April 23. His topic was the early development of the steam engine.

The Engineer in Public Affairs

GANO DUNN was the presiding officer at the meeting, held May 8 in the Engineering Societies Building, devoted to the "Engineer in Public Affairs." The gathering was under the auspices of the New York Sections of the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, and the American Institute of Electrical Engineers. In addition there were present representatives of the Society of Municipal Engineers, Society of Automotive Engineers, American Society of Heating and Ventilating Engineers, the American Society of Safety Engineers, the Taylor Society, the Society of Illuminating Engineers, and the New York Society of Architects. The speakers of the evening were Admiral John Keeler Robison, Engineer in Chief of the United States Navy, and Frank Jewett, president of the American Institute of Electrical Engineers and Chairman of the Engineering Division of the National Research Council.

Mr. Dunn opened the meeting in the following well chosen words:

> Engineers have inscribed in this Temple of Engineering, in the great library that crowns our building and the efforts of many years, the legend, "Engineering is the art of organizing men and controlling and directing the forces and materials of nature for the benefit of the human race." Now, when we come to discuss the Engineer in Public Affairs, that discussion necessarily turns our attention rather more toward the side of engineering that has received more attention in late years than ever before, the side of the engineer's generalship, the side of the engineer's organizing capacity, the side of the engineer's human contacts. There has never been a time when the demand for the education of engineers in the humanities as well as in the sciences and the technologies has been as great as it is today. There never has been a time when the demand for the education of engineers in English, in literature, in the fine arts, has been as great as it is today. The reason is an appreciation, not only on the part of engineers themselves, but on the part of those with whom they work, that an engineer must be an all-around man before he can reach the heights of engineering. The groping and straining towards a larger part in national affairs that have been concomitant with the development of the national and other engineering societies in the last twenty years has been due to the feeling within engineers themselves that their places as citizens are more and more responsible as every day goes on.
>
> For my own part I think there has been a waning of opinion in engineering circles that has overemphasized the desirability, if not the appropriateness, of a certain extreme degree of participation of engineers in public affairs. On the other hand, the increasingly essential relation of engineering works and structures, engineering operations, engineering conceptions, and even engineering terms and habits in the daily life of the people of the United States, has been so marked that engineering of itself has been taking a greater and greater part in public affairs, and if the engineer cannot keep pace with his subject, then he certainly is unworthy of the name.

In introducing Admiral Robison, Mr. Dunn paid a tribute to the engineering service of the United States Navy and read the following engineering creed sent to Admiral Robison when he was appointed Engineer in Chief of the Navy and which served to inspire him in no small degree:

> The idea of devotion to duty as a measure of worth, of worth as a measure of happiness, and of service as the proper aim of each of us, I believe to be true. Particularly do I believe that lasting happiness is found only through the medium of unselfish service. The thought of self in service, no matter how big the service, runs counter to nature's laws of compensation. Self-glorification and contentment of spirit are not found on the same trail.

Admiral Robison pointed out that the opportunity facing engineers in public service must be grasped that the common weal of the whole mass of humanity may be accomplished. Originally all engineers in public service were civil engineers. The word "civil" is a derivation meaning a man who is a "builder for the state." Today there are many specialized branches of engineering but the basic reason for the existence of any kind of engineer is that he is a builder for the state. Admiral Robison then told of the remarkable work being carried on in the engineering department of the Navy. He emphasized the fact that, if the shores of this country are to be kept unpolluted by war, the ships or our Navy must be able to take any desired position and take it first. The ships must move far enough and stay there long enough. The ability to do this is an engineering problem. The task of moving a fleet between two points involves reliable machinery and plenty of fuel. Increasing the fuel radius of the individual vessels and installing machinery of greater reliability and economy was emphasized by the Admiral as important steps in increasing the mobility of the ships. The preparation of detailed instructions in the use of fuel and the enforcement of these instructions proved to be a considerable factor in reducing the expenditures for fuel by 32.03 per cent per knot under way and 49.7 per cent per day in port.

Admiral Robison also told of the great work the United States Navy had accomplished as a humanitarian agency. In closing he emphasized the tremendous importance of the spirit of service which is not peculiarly naval. He said they are but representatives of the noblest profession in the world, builders of things and of character.

In introducing Mr. Jewett, Mr. Dunn called attention to the fact that the meeting of the evening had been organized by the Federated American Engineering Societies and that representatives of all branches of the profession were present. Mr. Dunn expressed his views about the F.A.E.S. in the following words:

> The Federation is, up to date, the result of the outgrowth and the embodiment of those things in engineers which they feel can be done better united than separate.
>
> The Federation is going through a period which confronts bodies in similar circumstances in other realms. The details of its operations and accomplishments must be ultimately that nice balance between strong opposing forces upon which the health of an organization always depends. The history of our own country illustrates that: at the beginning it was almost impossible to form the federation which was called the United States of America. Even our own New York did not sign the Declaration of Independence until three or four months after the Fourth of July.
>
> Now, while in the ranks of engineers there is not today that agreement which many of us would like to see, I think if we all stand off a distance and look, we will get a perspective that will be of great value. I hold these principles to be self-evident, that engineers cannot continue to go on as entirely separate and distinct organizations, that there is something in the human side of all the engineering branches that needs contact with other branches, and that there is an as yet undeveloped force and power among engineers as a profession that, if properly united, polarized and made to pull all one way, can speak for engineers, can represent them, and can make them a force in the community that they have not as yet been made.
>
> Now, these things being so, it is not a question of whether or not engineers shall federate; they are already federated; this meeting tonight illustrates it. It is only a question of the details that that federation shall take, and, therefore, I think we can pay no greater tribute to the engineers as a profession than by adopting the confident belief that some kind of federation is a necessity, and that some kind of useful, successful, and effective federation is absolutely bound to come.

Mr. Jewett in his address further emphasized the belief that some sort of joint organization of engineers is necessary and that an effective federation should be developed in the future.

Los Angeles Regional Meeting

THE highly successful Los Angeles Regional Meeting on April 16 through 18, 1923, was reported in brief in the May 7 issue of the A.S.M.E. News. We received the corrected stenographic report of the excellent dinner addresses and the discussion at the technical session too late to give the proper space in this issue. They will be used in later issues of Mechanical Engineering.

Engineering Index and Library Combine to Serve Engineer

REFERENCE was made in the preceding issue of Mechanical Engineering to statements by Prof. W. Trinks in regard to technical literature. The paucity and inadequacy of engineering libraries in the country to which he calls attention need not be a serious problem for engineers in country districts if the following points are noted.

Back of The Engineering Index for 1922, which has just been issued, is the Engineering Societies Library of New York, from which may be obtained, at a nominal cost, photostatic reproductions of the text of any article indexed.

Some thirty per cent of the periodicals indexed in this volume are in foreign languages. The Library will furnish translations of articles from any of these. The list of bibliographies in this volume is more extended than in preceding years. Mr. Raymond Brown of the Library Staff assisted in the compilation of this list.

The Engineering Index is not an exhaustive guide to the engineering literature of the world but it does index what are considered the leading articles on the newest developments of the year. The services of the Engineering Societies Library are prompt and efficient. The combination should be of unequalled value to engineers, engineering students, and research workers everywhere.

Engineering and Industrial Standardization

Standardization of Mathematical and Graphical Symbols and Abbreviations

A RECENT conference held in New York under the auspices of the American Engineering Standards Committee revealed sentiment among engineers, scientists, government officials, business-paper editors and industrial executives emphatically in favor of the unification of technical and scientific abbreviations and symbols.

It was agreed on all sides that the standardization of abbreviations and symbols would result in inestimable mental economies. The present situation with respect to the use of abbreviations and symbols in engineering, scientific, and other technical fields is comparable to a language which has degenerated into a multiplicity of dialects, each of which has to be translated for the users of the others. Abbreviations and symbols constitute an ever-growing and important part of the language of engineers, scientists, industrial editors, and other technical men. The use of one symbol or abbreviation for several different terms and the use of several different symbols or abbreviations for one meaning are, however, at present causing a great deal of confusion, misunderstanding, and often serious errors.

The conference was called upon requests from the American Institute of Electrical Engineers, The American Society of Mechanical Engineers, and the Association of Edison Illuminating Companies to consider abbreviations and mathematical symbols, but after some discussion of the subject it was thought desirable to include as a part of the project the graphical symbols which are used in engineering drawings, diagrams, and the like, for representing instruments and apparatus and their components.

It was agreed that the coöperation of foreign standardizing bodies should be sought in the development of the work. The importance of international uniformity in symbols is great on account of the international character of much engineering and scientific work, and the importance of reference books and periodicals in foreign languages.

The work will go forward under a Sectional Committee organization developed in accordance with the rules and procedure of the American Engineering Standards Committee.

Recent Progress in Standardization of Particular Interest to Mechanical Engineers

Walkway Surfaces. The American Engineering Standards Committee has invited the American Institute of Architects and the American Society of Safety Engineers to act as joint sponsors for the proposed safety code on walkway surfaces.

Petroleum Products and Lubricants. Standard methods of testing petroleum products and lubricants will be developed by a sectional committee organized under the sponsorship of the American Society for Testing Materials as a result of recent action by the A.E.S.C.

Flash Point of Volatile Flammable Liquids. The A.E.S.C. has approved as "Tentative American Standard" the standard method of test for flash point of volatile flammable liquids submitted by the American Society for Testing Materials. The A.S.T.M. has been appointed sponsor for this standard, and in this capacity will publish the standard and direct any revision of it that may later be necessary.

Radio Apparatus. Sponsorship for radio standardization has been assigned by the American Engineering Standards Committee to the Institute of Radio Engineers and the American Institute of Electrical Engineers, jointly. This action was taken in accordance with the recommendations of the large representative conference called by the Bureau of Standards.

Safety Code for Forging Industry. The formulation of a national safety code for the forging industry will be undertaken immediately as a result of the decision of a conference of the principal organizations interested in the subject recently held in New York on the call of the A.E.S.C., under whose procedure the code will be developed.

The conference by resolution requested that the code include the hazards of drop forging and other hammer forging, as well as all hazards peculiar to the forging industry and associated with the machines used in the industry whether or not they occur at the point of operation. The same resolution suggested that the code do *not* include the hazards of cold extrusion of non-ferrous metals, or hydraulic presses, except as the Sectional Committee may find it desirable to include small types of the latter and that the inclusion of hot pressing, bulldozing, and other forging operations, such as those of bolt-heading and rivet-making machines, be left to the discretion of the Sectional Committee.

Colors for Traffic Signals. Forty-two men, representing the manufacturers and users of traffic signals, federal and state governmental departments, associations interested in the prevention of traffic accidents, and representatives of the general public, are now at work on the drafting of a national code on the proper colors for traffic signals, which it is expected will not only cut down the annual loss of life through traffic accidents, but will eliminate any of the existing irritations to motorists and to the operators of steam and electric railways.

This work is being carried on under the auspices of the A.E.S.C. whose approval of a code or standard insures its ultimate acceptance and observance throughout the country. The Sectional Committee drafting this code is made up of seven representatives of the manufacturers of traffic signals, nine representatives of the purchasers of such equipment, three representatives of the users of traffic signals, twelve representatives of governmental bodies, five technical specialists, and six insurance representatives. The American Engineering Standards Committee is composed of seven departments of the U. S. Government, the principal technical, industrial, and engineering societies, and individual business concerns interested in standardization.

Six Electric-Railway Rail Standards. The A.E.S.C. has approved as "American Standard" six of thirteen specifications covering the design of steel rails and their accessories, which have been submitted by the American Electric Railway Association, one of the pioneers in industrial and engineering standardization. Considerable progress has been made in the consideration of the remaining specifications.

The specifications which have been approved cover the design of the following: Nine-Inch Girder Grooved Rail; Seven-Inch Girder Grooved Rail; Nine-Inch Girder Guard Rail; Seven-Inch Girder Guard Rail; Joint Plates for Seven-Inch Girder Grooved and Girder Guard Rails; and Joint Plates for Nine-Inch Girder Grooved and Girder Guard Rails. Some of these specifications were adopted as standard by the A.E.R.A. as far back as 1907. The extent to which they have come into general use is indicated by the fact that one of the principal manufacturers of steel rails reports that approximately 79 per cent of his total tonnage of girder rails shipped to electric railways during 1922 was A.E.R.A. standard. This same company reports that during the past seven years 62 per cent of its total tonnage of electric-railway girder rails was A.E.R.A. standard.

Code on School Lighting. The lighting, building, education, health, and social agencies of the country have joined hands in an effort to develop a nationally accepted code for school lighting which will correct the conditions partially responsible for the defective vision of 10 to 20 per cent of the school children. The A.E.S.C. has appointed the American Institute of Architects and the Illuminating Engineering Society joint sponsors for a Code on School Lighting. The sponsors will organize a representative sectional committee to formulate the code and will provide for the publication of the code after it has been approved by the A.E.S.C.

Standardization in Denmark. The A.S.M.E.'s correspondent in Berlin reports as follows: "According to the Danish newspaper *Ingeniören* Nr. 2 of January 13, 1923, the Standardization Committee of that country held a meeting on December 12, 1922,

at which the question of coöperation with other national standardization committees was discussed. During this discussion it was pointed out that if it is a question of coöperating with one country, that country would most likely be Germany, as working with England is impossible on account of the inch system of measures in use there. A complete adherence to German standards may, however, easily lead to dependency; the more so as there is hardly any Danish export of industrial products to Germany."

Although it may readily be admitted that the German standards will be worked out perfectly, it is on the other hand almost certain that small Denmark will have no influence on such standardization. It was finally agreed, therefore, to strive for the creation of Inter-scandinavian Standards by Finland, Norway, Sweden, and Denmark.

Ice-Cooled Domestic Refrigerators. The American Institute of Architects has requested the A.E.S.C. to arrange for a national conference of all interests involved to consider the desirability and feasibility of establishing standards for ice-cooled domestic refrigerators both as to size and cooling per pound of ice melted. The American Institute of Architects is prompted to make this request by the belief that it is both desirable and feasible to establish a standard rating for domestic refrigerators, based upon thermal conductivity. There are, of course, many other features of design and construction affecting refrigerator efficiency which should be considered. There is today no criterion for ice-box efficiency by which either the public or the architectural profession may judge of values in terms of ice economy and food preservation. There is a wide variation in the chilling effect of the melting of a pound of ice in the various types and makes of domestic refrigerators now on the market. Some of them are practically worthless. Not only are they wasteful of ice, but they also constitute a menace to health in that they do not preserve the food placed in them.

Sizes for U. S. Flags. Most every one assumes when they buy a flag that it is an exact replica of "Old Glory." True, it has 13 stripes and 48 stars, but the size may be one of several hundred that do not conform to Government standards. On October 23, 1922, flag manufacturers met in conference with representatives of the Army and Navy, and others interested, to determine upon a method for establishing flag sizes which would be comparatively few in number and, moreover, would conform to the standards acceptable to our Government. An executive order by President Wilson in 1916 set up 12 sizes as standards for United States flags, and it is upon the basis of this, together with a survey by the manufacturers, that a subsequent conference is contemplated for the final adoption of national standards for flag sizes.

The Late Dr. Schuyler Skaats Wheeler

A LEADING inventor and engineer in the electrical field, Dr. Schuyler Skaats Wheeler, died suddenly of angina pectoris on April 20, 1923, in the sixty-third year of his age. Dr. Wheeler was born in New York and was graduated from Columbia University in 1881. After a few minor connections he became a member of the staff of Thomas A. Edison, and for three years was engaged in installation work. From 1886 to 1888 he was connected with the C. & C. Motor Co., which he helped to organize.

In 1888, the Crocker-Wheeler Company, of New York and Ampere, N. J., was formed with Dr. Wheeler as president, a position which he occupied up to the time of his death. This company was the first in the world to manufacture small electric motors, and during the past thirty-five years has installed more than 1000 electric drives designed by Dr. Wheeler.

Dr. Wheeler was an organizer and founder of the United Engineering Societies, and was a member of the national, civil, electrical, and mechanical engineering societies. He was for a time president of the American Institute of Electrical Engineers, to which he gave the Latimer-Clark library, said to be the largest collection of rare electrical books in existence. He became a member of The American Society of Mechanical Engineers in 1899.

Water-Power Resources of Canada

WATER power is one of Canada's most basic and valued natural resources. The capital invested in this development, well over half a billion dollars, makes it also one of her greatest single industries. The Water Power Branch of the Canadian Department of the Interior has for the past three years been collecting and analyzing data, and in a recent report presented some of its results.

The known available water power in Canada is 18,255,000 hp. for conditions of ordinary minimum flow and 32,076,000 hp. under a flow of estimated maximum development, that is, dependable for at least six months of the year. These estimates have been made on the basis of 24-hr. power at 80 per cent efficiency. The ordinary minimum flow is based on the averages of the minimum flow for the lowest two consecutive seven-day periods in each year over the period for which records are available. The estimated flow for maximum development is based upon the continuous power indicated by the flow of the stream for six months in the year.

The Interior Department believes that these are conservative estimates since an analysis of existing water-power plants scattered from coast to coast, concerning which complete data are available as to turbine installation as well as satisfactory information regarding stream flow, gives an average machine installation 30 per cent greater than the six-months'-flow maximum power. Applying this to figures quoted above indicates that the present recorded waterpower resources of Canada will permit a turbine ininstallation of 41,700,000 hp.

The total capacity of the water wheels and turbines installed is 2,973,759 hp. or 338 hp. per thousand population. Canada's position is second only to that of Norway in the per capita utilization of water power.

In the central-station industry in which there is an installed turbine capacity of 2,204,486 hp., 1,556,956 hp. is installed in privately owned stations and 647,530 hp. in publicly owned stations.

Pulp and paper manufacturing is a typical and preëminent Canadian industry with a future of almost unlimited prosperity ahead of it, the result of two natural advantages of almost equal moment, namely, an abundant supply of growing pulpwood and cheap accessible motive power in large quantities. The importance of cheap power lies in the fact that it takes practically 100 hp. to produce one ton of paper per day. It is not surprising, therefore, that the motive power used in this industry is almost altogether restricted to hydraulic energy and that Canada's premier advantage and position in the pulp and paper field rest on adequate and abundant water power well distributed among extensive forest reserves.

Water power is operating 113 pulp and paper mills in Canada, 664,805 hp. being employed. Of this total, 482,228 hp. is actually installed in connection with the mills and 160,577 hp. is purchased from hydroelectric central stations.

The innovation of the electric drive is having a marked and favorable influence on pulp and paper manufacturing processes. It makes possible the centralized operation of fewer and larger mills receiving power from several power sites, together with the further advantages of uniform speed and better control in grinding, thus lessening costs of operation, construction, and shipping. Of the 484,228 hp. actually installed in pulp and paper mills 183,311 hp. is used in the electric drive, besides which there is 160,577 hp. of hydroelectric energy purchased from central stations, thus bringing the total horsepower that is employed in the electric drive up to 343,888.

The water power now developed in Canada represents an investment of over $620,000,000. In 1940, should the rate of growth in installation during the past fifteen years be continued, this investment will have grown to over $1,100,000,000. The present development represents an annual equivalent of 26,700,000 tons of coal, which, valued at $10 per ton, represents $267,000,000. In the year 1940 these annual figures will, with the foregoing assumption, have become 50,000,000 tons and $500,000,000, respectively.

Meetings of Other Societies

American Society of Civil Engineers

The river and harbor problems of the lower Mississippi was the general subject under discussion at the spring meeting of the American Society of Civil Engineers held at New Orleans, April 18–20, 1923. A number of the eleven papers presented at the two technical sessions dealt with navigation control and operation, and the others with flood control. Maj. L. H. Beach, chief U. S. Corps of Engineers, described the work of the Engineers' Corps on the Lower Mississippi, A. L. Dabney, consulting hydraulic engineer, the success of the levees during the flood of 1922, and L. H. Parmelee, consulting engineer, Helena, Ark., the high-water fight at Old Town, Ark., in 1922.

The economic location of jetties was discussed by Henry C. Ripley, consulting engineer, Detroit, Mich., and river control by John Klorer, city engineer of New Orleans. Transportation on the Mississippi River was the subject considered by two speakers, M. J. Sanders, manager of the International Mercantile Marine and the Frederick Leyland Company, Ltd., New Orleans, La., and the Hon. Joseph E. Ransdell, U. S. Senator from Louisiana. The former took up the question of the revival of commercial transportation, and the latter spoke on the economics of transportation.

The port problem was also the subject of two papers, presented by John F. Coleman and Samuel M. Young, both of whom are associated with the Board of Port Commissioners, New Orleans. Elliott J. Dent, Lt-Col., U. S. Corps of Engineers, presented a paper entitled The Mouths of the Mississippi River.

John R. Freeman, a past-president of the society and now consulting hydraulic engineer, Providence, R. I., pointed out the necessity of an experimental hydraulic laboratory for the solution of river problems. Mr. Freeman discussed the present state of knowledge of river hydraulics, described the few experimental laboratories of the kind sought, and the suggested design for the one proposed in Senator Ransdell's bill presented at the last session of Congress.

An all-day excursion by steamer to points of interest in New Orleans Harbor, Inner Harbor Canal, and Lake Pontchartrain gave the members an opportunity to study conditions for themselves. The trip covered the entire harbor frontage of the Mississippi River on both sides.

Previous to the meeting the Board of Direction held a two-day session. Among the items of business transacted was the authorization of a committee of five to confer with other national societies looking toward coöperation in matters of interest in public affairs; the approval of the recommendations for Government reorganization, particularly of those tending to divorce civilian engineering activities of the Government from engineering duties which are under military control; and the acceptance of two grants from Engineering Foundation, one of $1000 for the investigation of concrete and reinforced-concrete arches, and the other of $4000 for the investigation of steel columns.

The next meeting, on the subject of highways, will be held in Richmond, Va., sometime in October.

Society of Industrial Engineers

The major subject of the tenth annual convention of the Society of Industrial Engineers, held in Cincinnati, April 18 to 20, 1923, was the effective management of the moderate-sized plant. Prof. Joseph W. Roe, president of the society, who spoke on Three Phases of Management: Financial, Sales, and Production, at the opening session, stated that although the large plant had a great advantage over the small one in the field of purchases and sales, in actual production the small plant could frequently compete with the large one on even or on better terms.

Speaking at a meeting of the educational group of the society on Economics and the Smaller Plants, Ernest F. Du Brul, general manager of the Machine Tool Builders' Association, presented figures from the Census of Manufacturers, 1919, which he believes verify statistically the economic principle that the division of labor is an economic benefit, not only in increasing product per man but also in increasing profit until a point of maximum efficiency is reached. Mr. Du Brul therefore advocates the concentration of industry in larger establishments.

Meetings of the production and personnel groups were also held, Chester B. Lord, industrial engineer, National Automatic Tool Co., Richmond, Ind., addressing the former on Production Control Systems for the Special Order Shop, and J. J. Davis, Paine Lumber Co., Oshkosh, Wis, the latter group.

Chief among the general sessions was that given over to a discussion of workers' participation in management. The workers' side was presented by John P. Frey, editor of the *International Molders' Journal;* the employers' side by Charles R. Hook, general manager, American Rolling Mill Co., Middletown, Ohio (read in his absence by M. E. Danford, of the same company); and the engineers' side by John Calder, consulting engineer, Lexington, Mass. Daniel Bloomfield, Boston, editor of *Industrial Relations*, gave a summary of surveys of 500 plans of employee representation made by him during the past few years.

Mr. Frey attributed 81 per cent of the waste in industry to management, 9 per cent to labor, and 10 to subsidiary causes. He believed that the only way waste could be eliminated was for the management, the efficiency engineer, and the workmen to get together to discuss and handle the various problems.

Mr. Hook's paper described the organization and functions of an advisory committee system in force in his organization for many years. He emphasized the importance of a proper understanding of the motives actuating the management of the business, and pointed out the benefits to be derived from a coöperative scheme which builds confidence and satisfaction on both sides.

Mr. Calder spoke for an organized representation allowing the worker a voice in the management where it touches him most closely. "Most workers," he stated, "want to count in management solely when their personal interests are concerned, and he is a wise manager who begins industrial relations there."

American Gear Manufacturers' Association

Progress in the standardization of gears, as evidenced by reports presented at the seventh annual meeting of the American Gear Manufacturers' Association, held in Cleveland, April 19–21, 1923, is indicative of a great deal of study and a fine spirit of coöperation on the part of the members of the standardization committees. One of the most important of these reports was that of the bevel- and spiral bevel-gear committee concerning a new system of bevel gears which has been worked out at the Gleason Works, Rochester, N. Y. The proposed system was adopted by the association as recommended practice for future design.

B. F. Waterman, chairman of the general standardization committee, summarized the work of the various sub-committees. He advocated that the recommendation of the worm-gear committee, which tended to eliminate the great diversity of hob sizes necessitated by the variance in customers' specifications, be tried out for six months, after which definite action might be taken. He announced a recommendation to be submitted by the metallurgical committee, covering the heat treatment of A.G.M.A. steels, and a forthcoming report on the nomenclature of gears. The proposed tentative American standards which have been submitted include gears and pinions for electric railroad service, gray-iron industrial spur gears, specifications for forged and rolled steel for gears, specifications for cast steel for gears, and specifications for brass and bronze for gears. During a general discussion of various phases of standardization, it was urged that the association should standardize tooth curves, that inspection should start with tooth curves, and that tooth forms for large-sized bevel gears should be standardized.

The report of the association's representatives on the A.S.M.E. research committee on gears stated that the special gear-testing machine designed by Wilfred Lewis had been found to warrant development, and that Ralph E. Flanders, of the Jones & Lamson Machine Co., had been authorized to solicit subscriptions from those interested in this research work.

Among the technical papers presented was one on Grinding and Measuring Involute Gear Teeth, by E. J. Lees, Lees-Bradner Co., Cleveland; one by Wilfred Lewis describing the special gear-testing machine of his design; one on Tooth Forms of Automobile Gears after Cutting, Hardening, and Grinding, by K. L. Hermann,

of the Studebaker Corpn., emphasizing that quietness depends upon the accuracy with which gears are cut; and one by S. P. Rockwell, metallurgical engineer, of Hartford, Conn., who was appointed metallurgist for the association. Mr. Rockwell dealt with the determination of grade of steel by observation of the characteristics of the spark when the sample is held against an abrasive wheel, and gave actual demonstrations to show the difference in the spark produced in the grinding operation with the use of samples of different carbon analysis.

Industrial relations, labor shortage, and cost accounting were among other subjects discussed at the meeting. Geo. L. Markland, Jr., of the Philadelphia Gear Works, was elected president to succeed F. W. Sinram, who has held the office since the formation of the organization in 1917. Mr. Sinram was elected honorary president for life.

Progress of Coal-Storage Campaign

One of the first companies to follow the lead of the Connecticut Company in aiding employees to secure their full supply of coal early in the season is the Adirondack Power & Light Co., of Schenectady, N. Y. Upon receipt of the outline of the Storrs Plan from the Federated American Engineering Societies, this company, of which C. S. Ruffner is general manager, sent a communication to all its employees which read in part as follows:

> In districts where this company sells coke from its gas plants a plan will be published offering special inducements to employees and to the public to purchase coke for their next winter's requirments, for delivery during the period from April 1 to September 1.
>
> For all districts there will be made arrangements whereby any employee may submit by April 15 an estimate of his winter fuel needs; the list of such individual orders will be placed with any dealer selected by a committee consisting of the resident manager and two other employees who desire to purchase fuel by this plan. Delivery to be made at the dealer's convenience any time before September 1. When delivery is made the company will, if requested by the employee, pay the dealer in fullf or fuel delivered, and will be reimbursed by deducting that amount from the employee's salary thereafter in equal installments in each of the next four months after delivery. The company will not buy and sell the fuel but will only guarantee cash payments to the dealer, and will carry the account for the employee as above stated.
>
> Under this plan fuel can be purchased at the best possible price, deliveries can be scheduled advantageously, dealers will be influenced to deliver the maximum amounts early in the season, and employees who have been accustomed to buying coal in small lots during the period of highest prices can make substantial savings and be assured of a sufficient quantity of coal when needed and without severe burdens of prepayment. Employees will be encouraged to enlarge their storage facilities to hold their whole winter's requirements.
>
> Nearly 170 employees of the company (about 10 per cent of the total number) have already ordered coal and coke amounting to over 800 tons, the orders being placed with local dealers at current prices.

The Westinghouse Electric & Manufacturing Co. reports that it is making a study of the plan which will be put into operation if found feasible for their organization. Other companies are desirous of developing their own plans, based upon the Storrs Plan.

Meanwhile the F.A.E.S. Committee on Coal Storage has been organizing. Those who have already accepted appointment on the committee are: W. L. Abbott, chief operating engineer of the Commonwealth Edison Co., Chicago, chairman; P. F. Walker, dean of engineering, University of Kansas; S. W. Parr, professor of applied chemistry, University of Illinois; H. Foster Bain, Director of the U. S. Bureau of Mines, and L. E. Young, Union Light Power Co., St. Louis.

The chairman of this committee has had large experience in the successsful storage of coal, having collaborated with Dr. Stock in much of his pioneer work. Professor Parr and Mr. Young had also worked extensively with Dr. Stock in developing ways and means of effective storage of coal. Professor Parr has a national reputation as a coal chemist. Mr. Young has had wide and responsible engineering experience and is also accomplished in accounting and economics. Dean Walker is especially familiar with the transportation and industrial conditions that will enter into this study. Dr. Bain, as Director of the Bureau of Mines, is in intimate touch with all that the Government has done with this subject.

A bibliography of the subject is already in course of preparation, as well as a compilation of data and records that have already been made by other organizations that will relate to this subject in various ways.

LIBRARY NOTES AND BOOK REVIEWS

American Petroleum Refining. By H. S. Bell. D. Van Nostrand, New York, 1923. Cloth, 6 × 9 in., 456 pp., illus., diagrams, $5.

The first American book exclusively devoted to refining. Discusses the manufacturing process, the arrangement of refineries, the apparatus and treatment used, the storage and transportation of oil, etc. Intended to give the fundamental information needed by those about to erect refineries or by those engaged in the industry who wish a picture of it as a whole.

Automotive Repair. Vol. 3, For Battery Service Men; vol. 4, For Tire Service Men. By J. C. Wright. John Wiley & Sons, New York; Chapman & Hall, London, 1923. Cloth, 6 × 9 in., vol. 3, 387 pp.; vol. 4, 305 pp.; illus., tables, $3 each.

These two volumes complete this extensive work on the repair of automobiles by presenting methods for repairing tires and batteries. They follow the plan of the earlier volumes in giving for each job, first, an outline of the necessary operations, then the materials, tools and parts required and, finally, a detailed description of the method. The reasons for each operation are also given. The directions are clear and practical, and cover almost every emergency that can arise.

Die Dampfturbinen. Vol. 1; Theorie der Dampfturbinen. By Const. Zietemann. Walter de Gruyter & Co., Berlin and Leipzig, 1923. Boards, 4 × 6 in., 150 pp., diagrams, $0.25.

The first portion of a three-volume work on steam turbines which is intended to give not only the theory and thermal calculations, but also practical information on design and construction, and an account of present practice. The work is designed as a concise introduction for students and practicing engineers.

The present volume is concerned chiefly with theory. The fundamental laws of heat, the properties of steam and its flow through orifices are explained. The utilization of the energy of steam in turbines, including methods of reducing speed, is next considered, and this is followed by a discussion of losses in the turbine, efficiency, and power. The final section treats of steam, heat, and fuel consumption.

Elektrotechnik. Vol. 4; Die Erzeugung und Verteilung der Elektrischen Energie. By Immanuel Hermann. Walter de Gruyter & Co., Berlin and Leipzig, 1923. Boards, 4 × 6 in., 138 pp., illus., diagrams, $0.25.

One of a series of small volumes giving an outline of electrical engineering in greatly condensed form. The present volume is concerned with the generation and distribution of electricity and discusses in five chapters power plants, methods of distribution, switch apparatus, distributing networks, and the cost of electric power.

Elements of Applied Physics. By Alpheus W. Smith. First edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 483 pp., illus., diagrams, $3.

Prepared for students who are primarily interested in the practical applications of physics, this book has been written with their training and habits of thought in mind and includes those topics that they can assimilate thoroughly. A large number of illustrations of the applications of physics to engineering and every-day life are given in an effort to stimulate the student to recognize the universality of physical laws and to find in them the explanation of every-day experiences.

Flussigkeitsbehalter. Rohren, Kanale. Vol. 5, Handbuch fur Eisenbetonbau. By F. Emperger. Third edition. Wilheim Ernst & Sohn, Berlin, 1923. Paper, 7 × 11 in., 409 pp., illus., diagrams, tables. $3.24.

Volume 5 of Emperger's well-known handbook has reached the third edition. It contains two chapters, one upon tanks for liquids, the other upon pipes, open conduits, aqueducts, and canal bridges. The first of these chapters has been entirely rewritten by Dr. Löser, Dr. Grun and Dr. Lewe. It now includes the experience resulting from the extended use of concrete tanks for many purposes since the appearance of the second edition in 1910. The composition of waterproof concrete, waterproofing compounds and paints, and the chemical effects of various liquids are discussed in detail. Similar detailed attention is given to the statics of tank construction, where an attempt is made to set forth modern methods of calculation in an easily understood form and to illustrate them by numerous examples. The chapter on pipes and conduits has been thoroughly revised by F. Lorey, in the light of recent experience and modern structures.

Four Lectures on Relativity and Space. By Charles Proteus Steinmetz. First edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 126 pp., diagrams, plates in pocket, $2.

In these lectures the extensive use of mathematics has been avoided. Dr. Steinmetz has attempted to give the layman and the engineer who is not an expert mathematician a general knowledge and understanding of the new ideas of time, space, the laws of nature and the characteristics of the universe which the relativity theory has deduced, and of the researches on which the theory rests.

Gas und Wasserversorgung der Gebaude. By Wilhelm Schwaab. Walter de Gruyter & Co., Berlin and Leipzig, 1923. Boards, 4 × 6 in., 121 pp., illus., $0.25.

The purpose of this little volume is to give those interested in gas and water installations in buildings a concise bird's-eye view of the subject. The first division of the work treats of gas, describing its manufacture, the method of distributing it and of installing the piping in the building, and its use for lighting, heating, etc. The second section of the work discusses the water supply in a similar way.

Handbook of Business Correspondence. By S. Roland Hall. McGraw-Hill Book Co., New York and London, 1923. Fabrikoid, 5 × 8 in., 1048 pp., illus., $5.

A small encyclopedia for advertisers and for business men generally, by an experienced manager of sales. Describes the organization of a mail-sales division, methods of caring for dictation, processes for printing and reproducing letters. Gives advice on the composition of letters for various purposes—selling, collecting, adjusting, etc.,—or to various kinds of people, and illustrates this advice by numerous models.

Handbook of Steel Erection. By M. C. Bland. First edition. McGraw-Hill Book Co., New York and London, 1923. Fabricoid, 4 × 7 in., 241 pp., tables. $5.

A pocketbook for engineers and contractors. Section one reviews briefly the ordinary methods for erecting bridges, buildings, standpipes and other structures. Section two, on equipment, contains numerous examples illustrating the design of ordinary appliances and data for finding the wheel and outrigger loads of locomotive cranes and derrick cars. Section three gives the detailed computations for several representative problems in the erection of bridges and buildings. Section four consists of mathematical tables.

Heizung und Luftung. Vol. 1; Das Wesen und die Berechnung der Heizungs- und Luftungsanlagen. By Johannes Körting. Walter de Gruyter & Co., Berlin and Leipzig, 1922. Boards, 4 × 6 in., 139 pp., diagrams, $0.25.

A concise guide for students of heating and ventilation. Deals with theoretical principles, rather than practical details.

History of the Theory of Numbers. Vol. 3, Quadratic and Higher Forms. By Leonard E. Dickson. Carnegie Institution of Washington, Washington, D. C., 1923. Paper, 7 × 10 in., 313 pp., $3.25.

The third volume of this exhaustive history treats of the arithmetical theory of forms and is concerned mainly with general theories rather than with special problems and special theorems. The investigations here in question are largely those of leading experts and deal with the most advanced parts of the theory of numbers. Many of the papers are so recent that all previous reports and treatises are entirely out of date. Every effort has been made to make the list of references complete.

Industrial Furnaces. Vol. 1. By Willibald Trinks. John Wiley & Sons, New York; Chapman & Hall, London, 1923. Cloth, 6 × 9 in., 319 pp., diagrams, $4.50.

This volume deals with the fundamental principles that underly all industrial heating operations and furnace design, and with those applications which are independent of the kind of fuel or energy supply. The principal subjects discussed are the heating capacity and fuel economy of furnaces, heat-saving appliances in combustion furnaces, furnace strength, and durability, and the movement of gases in furnaces. A succeeding volume will treat of specific applications of furnaces.

The book is based on articles published in the *Blast Furnace and Steel Plant* and the *American Drop Forger*, revised and expanded.

Industrial Organic Chemistry. By Samuel P. Sadtler and L. J. Matos. Fifth edition. J. B. Lippincott Co., London and Philadelphia, 1923. Cloth, 6 × 9 in., 691 pp., illus., diagrams, tables, $8.

The fifth edition of this well-known treatise follows the general plan of the preceding ones, but it has been thoroughly revised and to a considerable extent rewritten. Within a single volume of moderate size, it takes up a number of the more important industries or groups of industries based upon organic chemistry, and shows the existing conditions in them. This is done in language that can be understood even by those who are not specially trained in chemistry.

In taking up the several industries, the raw materials are first enumerated and described. The processes of manufacture are then outlined and explained, and the intermediate and final products are characterized. The analytical tests and methods used to control the processes or to determine the purity of the products are then given. A bibliography is appended to each chapter.

Industrial Organization. By Malcolm Keir. Ronald Press, New York, 1923. Cloth, 6 × 9 in., 421 pp., $2.75.

The author of this work believes that many persons find economics difficult and uninteresting because they have little conception of the complex industrial order by which the ordinary necessaries of life reach the consumer or of the complete organization of our national business life. This interesting volume is intended to supply such a background of facts about our industrial organization, to present a picture in perspective of the interlocking factors of our industrial life, and thus to make it possible for the reader to understand and appreciate theoretical economics.

Nickel. By F. B. H. White. Isaac Pitman & Sons, London and New York, 1923. (Pitman's Common Commodities and Industries.) Cloth, 5 × 7 in., 118 pp., illus., tables. $1.

A brief account of the occurrence of nickel, the methods for recovering and refining it, and the uses of the metal and its alloys. Written in simple style and intended for readers who are not specialists, but who wish general information.

Printing Telegraph Systems and Mechanisms. By H. H. Harrison. Longmans, Green & Co., New York and London, 1923. (Manuals of telegraph and telephone engineering.) Cloth, 6 × 9 in., 435 pp., diagrams, $7.

Intended as a reference book for designers of telegraph machinery and as a textbook for those engaged in telegraphy, this book is a comprehensive study of the principles and mechanisms which are involved in p inting telegraphs and a history of the development of the art.

Railroad Freight Transportation. By L. F. Loree. D. Appleton & Co., New York and London, 1923. Cloth, 5 × 8 in., 771 pp., illus., diagrams, map. $5.

All of the functions of a railroad arise from and focus in transportation. As they have become highly specialized, the functions of each department have found exposition in many books. But no book has been written immediately concerned with transportation, the reason for the existence of the railroads. It is the purpose of

this book to assemble in reasoned order all of the phases of loading, distribution of cars, movement of engines and trains, handling of men, the features of permanent way and shop plant, the organization through which they are controlled, and the accounting made of their activities—as they are related to transportation. It is concerned with all that enters into freight transportation.—*Preface.*

SEWERAGE: The Designing, Constructing and Maintaining of Sewerage Systems and Sewage Treatment Plants. By A. Prescott Folwell. Ninth edition. John Wiley & Sons, New York; Chapman & Hall, London, 1922. Cloth, 6 × 9 in., 477 pp., illus., diagrams, tables, $4.

Intended as a reference book for city engineers and as a textbook for students. The present edition has been revised to include new developments since the publication of the eighth edition, while at the same time the space devoted to methods that are disappearing has been reduced. The volume includes a list of all the plants for treating sewage in the United States.

THERMODYNAMICS AND THE FREE ENERGY OF CHEMICAL SUBSTANCES. By Gilbert Newton Lewis and Merle Randall. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 653 pp., tables. $5.

The authors have attempted to meet the needs of three classes of readers: first, the beginner who wishes to learn what thermodynamics is and what kinds of problems in physics, chemistry and engineering can be solved by its aid; second, the reader who looks for the philosophical implications of such concepts as energy and entropy; third, the investigator who seeks the specific thermodynamic methods which are applicable to the problem of pure or applied science which he has attacked and the data required for its solution. The book is not a textbook in the ordinary sense of the word, although the authors trust that it will be useful in advanced chemical courses. It is designed rather as an introduction to research and as a guide to anyone who wishes to use thermodynamics in productive work.

WAVELENGTH TABLES FOR SPECTRUM ANALYSIS. By F. Twyman. Adam Hilger, London, 1923. Cloth, 6 × 9 in., 106 pp., tables, 7s. 6d.

This book is a collection of wave-length tables intended for use in the laboratory and containing only matter essential for this purpose. It is of a convenient size and weight. It includes standard wave-lengths from 2375 to 8495 I.A., the persistent and sensitive lines of most of the elements arranged under the names of the elements, and the most persistent and sensitive lines rearranged in order to wave-lengths. There is also a list of wavel-engths useful in the determination of stellar radial velocities. The values are from the most competent authorities and the source of each is carefully indicated.

Important to A.S.M.E. Members Interested in Stress Analysis

AT THE 1922 Annual Meeting, under the auspices of the Railroad Division, an extremely valuable paper dealing with stresses in locomotive frames was presented by R. Eksergian. The paper gives a lengthy and complete discussion of the analytical methods to be followed in determining stresses in locomotive frames.

In view of the fact that there was a great wealth of material presented at the last Annual Meeting and that the Committee on Publication and Papers was compelled to reduce the size of Transactions to the minimum, it was decided to omit Mr. Eksergian's paper from the annual volume, but to print pamphlet copies of the complete paper with the discussion on it, and supply copies to members who might desire to have them. The number of copies printed will be limited to the number of requests for it received before September 1. Requests for this pamphlet should therefore be sent to the Secretary's office before that date.

A synopsis of the paper follows. Members of the Society are requested to study this carefully and determine whether the subject-matter would be of value in their work. It may be stated that the analytical methods developed by Mr. Eksergian should prove of value to all engineers engaged in the study of stresses howsoever set up.

SYNOPSIS OF R. EKSERGIAN'S PAPER ON STRESSES IN LOCOMOTIVE FRAMES

This paper is essentially a preliminary analysis of the major reactions brought on a locomotive frame, as well as of the nature of frame action as regards variation of bending moment, shear, etc., for differently supported types of frames.

A careful analysis has therefore been made of the various methods of equalization, spring design, and the nature of cab supports in electric locomotives. This is followed by a section dealing with the dynamics of the steam locomotive, where the variation of torque and a quantitative investigation of the various oscillations are discussed in detail. Further, a careful analysis of the variation of side-rod loads and journal-bearing loads is included. The succeeding section deals with electric-locomotive drives and the major reactions brought on the frame. This section includes the dynamics of the electric side-rod drive, which discussion augments the previous one on side-rod loads in steam locomotives. The next section discusses the dynamics of braking, its change in load on the equalization and the reactions brought on the frame. In this section is included a brief discussion of bumping loads and dynamical loads on the drawbar.

For a more quantitative investigation of the effects of vertical loads the bar frame has been approximately treated as a continuous beam under equalizer-applied loads and boiler supports, and the variations of bending, shear, etc., for the U. S. Standard Pacific locomotive are computed in detail in Appendix No. 1. Following this is a careful analysis of the stresses resulting from longitudinal loads due to traction, etc.

Finally, the nature of the lateral reactions and the dynamics of lateral oscillations on entering a curve, etc., are discussed, a short recapitulation of the static reactions while on a curve being also given.

A brief outline of methods of analysis coördinating with future experimental work is discussed in Appendix No. 2.

U. S. Navy Crane Ship No. 1

(Continued from page 341)

ends of a cross-shaft supported in bearings in the housings. This shaft is driven by two 110-hp. General Electric type M.B. No. 107 motors to which it is geared by two reductions of spur gearing and one herringbone reduction. The motor shaft is between the motors and is driven by separate pinions meshing with a single gear. A flexible coupling connects the pinions to the motor, and each pinion is provided with a magnetic disk brake.

The upper screws thread through nuts attached to the crane jibs while the lower nuts are carried in the back stays. All nuts are trunnion mounted, and the lower nuts are so arranged that their trunnion bearings are rigidly locked in position when the jib is raised off the cradle; but as the jib is lowered to its seagoing position, these bearings unlock automatically and the nuts slide off so that no possible tension or compression can be set up in the screws due to weaving of the ship. All of the movements of this mechanism are supplied with limit switches which prevent overtravel. A lever-operated band brake controlled from the operator's cab is attached.

The foregoing account is based on information kindly supplied to MECHANICAL ENGINEERING by the office of Rear-Adm. J. W. Beuret, Bureau of Construction and Repairs, Navy Department, Washington, D. C., officers of the League Island Navy Yard, Philadelphia, Pa., and by the Wellman-Seaver-Morgan Company Cleveland, Ohio, builders of the crane.

Discussion on Orifice Coefficients

(Continued from page 348)

the plane of the orifice the true pressure could be obtained at any geometrical point of the given pipe. Similarly, by extending the various curves on Fig. 5 the coefficient for any geometrical point close to or at the plane of the orifice could be obtained. He could see no reason why the most reliable position for pressure taps was in the plane of the orifice.

Mr. Hodgson had referred to the theory of dynamical similarity as applied to orifices in various sizes of pipes. Mr. Pigott had also referred to it, stating that Dr. Buckingham had predicted the characteristics of the orifices and the behavior of the jet at the various geometrical distances as found by the test. Obviously more tests would have to be run on various sizes of pipes before the validity of the geometrical similarity would be established.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 115-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AIRPLANE ENGINES

Wright. Wright-Navy Development Work Yields Great Increase in Engine Life, B. G. Leighton and R. M. Parsons. Automotive Industries, vol. 48, no. 17, Apr. 26, 1923, pp. 928–931, 2 figs. Changes in valves, valve seats, cylinder design and bearing metal multiply durability and render overhauls much less frequent. Results of tests completed on Wright E-2 model by Bur. of Aeronautics, Navy Dept.

AIRPLANES

Fokker. Fokker F 5 Commercial Transport. Aerial Age, vol. 16, no. 5, May 1923, pp. 218–219 and 232, 3 figs. May be flown as biplane or monoplane by simple expedient of attaching or removing lower wings.

ALCOHOL

Fuel. Alcohol Yields Higher Thermal Efficiency Than Other Fuels. Automotive Industries, vol. 48, no. 16, Apr. 19, 1923, pp. 876–877. Tendency to preignition is noted with 7 to 1 ratio; increase in water content up to 10 per cent is advantage especially under high compressions; no corrosion in engine. From interim report of Brit. Empire Fuels Committee.

AUTOMOBILE ENGINES

Tappet Lever, Positioning. Proper Positioning of Tappet Lever Lessens Valve Mechanism Wear, Glenn D. Angle. Automotive Industries, vol. 48, no. 17, Apr. 26, 1923, pp. 925–927, 9 figs. Correct layout with respect to end and axis of valve stem results in reduction of sliding motion; pure rolling action a prime requisite; question of material of secondary importance.

AUTOMOBILES

Citroën-Kegresse. Crossing the Sahara by Motor Car Engineer, vol. 135, no. 3511, Apr. 20, 1923, pp. 414–415, 9 figs. Account of journey across Sahara Desert and return of four Citroën cars mounted on Kegresse flexible tracks.

BELTING

Leather. How a Leather Belt Transmits Power, J. Edgar Rhoads and R. R. Tatnall. Am. Mach., vol. 58, no. 17, Apr. 26, 1923, pp. 629–631, 3 figs. Factors affecting power transmission; forces acting on belt; effect of centrifugal action on running belt; change in length, creep and slip.

BOILER OPERATION

Temperature and Draft Measurements. The Control of Boilers by Temperature and Draught Measurements, John B. C. Kershaw. Engineer, vol. 135, no. 3513, Apr. 27, 1923, pp. 437–441, 14 figures. Author directs attention to interdependence of tests results for CO_2, temperature and draft; and describes some of latest indicating and recording instruments for making latter type of measurements.

CARS, FREIGHT

Six-Wheel Truck. The Boyden Six-Wheel Coordinating Truck. Ry. Age, vol. 74, no. 20, Apr. 21, 1923, pp. 993–995, 6 figs. Designed to provide extreme flexibility in order to minimize curve resistance and flange wear.

CAST IRON

Hardness Control. Controlling Cast Iron Hardness, S. J. Felton. Iron Trade Rev., vol. 72, no. 19, May 10, 1923, pp. 1382–1383. Metallographic study showing different constituents indicates causes of hardness; control methods; close-grained iron not apt to be porous but has large internal shrinkage.

CENTRAL STATIONS

Birmingham, England. The Nechells Power Station of the Birmingham Corporation, W. Noble Twelvetrees. Engineering, vol. 115, nos. 2978, 2979, 2982, 2986, 2987 and 2989, Jan. 26, Feb. 2, 16, 23, Mar. 2, 23, 30 and Apr. 13, 1923, pp. 99–102, 136–137, 193–196, 227–228 and 238, 291–294, 353–356, 385–388 and 453–456, 101 figs. partly on supp. plates. Permanent generating station designed for ultimate capacity of 100,000 kw.; main power-house buildings comprises boiler and engine house and adjoining building, details of which are given.

CONVEYORS

Moist Fuels. Moist Fuels Present Unusual Conveying Problems, Zuce Kogan. Power Plant Eng., vol. 27, no. 9, May 1, 1923, pp. 461–463, 5 figs. Characteristics of various conveying systems which have been used with success around power plants.

CORROSION

Metals. Corrosion of Metals. Engineer, vol. 135, no. 3512, Apr. 20, 1923, pp. 412–413, 1 fig. Corrosion of industrial metals; influence of heat treatment; heat- and acid-resisting properties of certain nickel-chromium and nickel-chromium iron alloys; Monel metal; dry corrosion; stainless silver. Review of papers presented before joint meeting of Faraday Soc., Inst. of Metals and Manchester Met. Soc.

DIE CASTING

Dies. Design of Die-casting Dies, Charles Pack. Machy. (N. Y.), vol. 29, no. 9, May 1923, pp. 714–716, 2 figs. Discusses cause and elimination of blowholes in die castings; importance of proper venting; factors influencing cost of die casting; factors affecting life of dies.

DROP FORGING

Practice. Drop Forging Practice, Leslie Aitchison. Forging & Heat Treating, vol. 9, no. 4, Apr. 1923, pp. 176–181, 6 figs. Discusses principles which determine size of bar or billet to be used for manufacture of drop forgings; preliminary forging operations.

ELECTRIC FURNACES

Acid. Acid Electric Steel Furnace Operation, J. M. Quinn. Iron Age, vol. 111, no. 17, Apr. 26, 1923, pp. 1177–1179. Iron oxide a controlling factor; its reduction from acid slag; method of charging scrap.

ENGINEERS

Employment Service. Suggestions for An Engineering Employment Service, Morris L. Cooke. Eng. News-Rec., vol. 90, no. 19, May 10, 1923, pp. 830–831. Plan proposed for nation-wide paid service under auspices of Nat. Eng. Societies.

FLOW OF AIR

Measurement. The Measurement of Air Flow, R. O. King. Engineering, vol. 115, nos. 2990 and 2991, Apr. 13 and 20, 1923, pp. 456–458 and 481–482, 6 figs. Measurement of air flow by means of throttle plate with special reference to measurement of air supply to internal-combustion engines.

FLYING BOATS

Dornier Twin-Engined. The Dornier "Wal" Twin-Engined Flying Boat. Aviation, vol. 14, no. 17, Apr. 23, 1923, pp. 444–445, 7 figs. All-metal seaplane for long-range scouting and bombardment work has powerful armament.

FOUNDRIES

Methods and Equipment. Foundry Operates Efficiently, Pat Dwyer Foundry, vol. 51, no. 8, April 15, 1923, pp. 289–297, 16 figs. Practice and equipment at Ferro Machine & Foundry Co., for production of Automobile-engine cylinders. See also Iron Trade Rev., vol. 72, no. 17, Apr. 26, 1923, pp. 1225–1231, 9 figs.

GAGES

Inspection. Gage Inspection Methods, Fred R. Daniels. Machy (N. Y.), vol. 29, no. 9, May 1923, pp. 702–705, 8 figs. Use of high-grade measuring equipment for inspection of small tools.

GRINDING MACHINES

Automatic. Automatic Grinding Machines, Ethan Viall. Am. Mach., vol. 58, nos. 16 and 17, Apr. 19 and 26, 1923, pp. 577–580 and 613–616, 16 figs. Apr. 19: Types of machines; methods of holding and feeding work; kinds and speeds of wheels; stock removed and rate of production. Apr. 26: Centerless grinding; grinding tapered work on centerless machine.

HANDLING MATERIALS

Sugar Refinery. Materials Handling in a Modern Sugar Refinery, Homer L. Rank. Indus. Management (N. Y.), vol. 65, no. 5, May 1923, pp. 306–313, 11 figs. Describes methods and equipment employed in plant of American Sugar Refining Co. at Baltimore.

HELICOPTERS

Oehmichen-Peugeot. The Oehmichen-Peugeot Helicopter. Aviation, vol. 14, no. 15, Apr. 9, 1923, p. 399. Consists of framework of duralumin tubing, forming cross with unequal arms; stabilizing apparatus consists of gyroscope fixed to shaft of motor and turning at maximum peripheral speed of 130 m. per sec.; horizontal propulsion and control.

INDUSTRIAL MANAGEMENT

Executives, Duties of. The Ways and Means of the Chief Executive, John H. Williams. Taylor Soc.—Bul., vol. 8, no. 2, Apr. 1923, pp. 53–58. Discusses subdivision of duties and responsibilities on basis of function or personality of executive; lodging of final authority in committees or individuals; centralization or decentralization of authority; use of acummulated experience or of research as measure of accomplishment; meeting of conditions as they arise or seeking to forecast and prepare for them in advance.

Methods and Principles. Management Methods and Principles of Frank B. Gilbreth, Inc., K. H. Condit. Am. Mach., vol. 58, no. 18, May 3, 1923, pp. 665–666, 2 figs. Function of management engineer to reduce costs, raise wages, increase profits; seeing that workmen has material to work on; principles of blank-form construction.

Rate Setting. Setting Piece Rates by Formula, Chart and Slide Rule, Donald Ross-Ross. Indus. Management (N. Y.), vol. 65, no. 5, May 1923, pp. 301–305, 6 figs. Method worked out by author on certain specific rate-setting problems, but charts and slide rule described lends itself to wide variety of operations.

Routing Work in Foundry. Routing Work in the Steel Foundry, Larry J. Barton. Iron Age, vol. 111, no. 17, Apr. 26, 1923, pp. 1170–1172, 7 figs. System of records designed to prevent harmful leaks; orders filled completely and according to promise.

INTERNAL-COMBUSTION ENGINES

Exhaust Mufflers. Conquering the Noise, Hiram P. Maxim. Power, vol. 57, no. 17, Apr. 24, 1923, pp. 630–633, 7 figs. Results of experiments in developing silencer for firearms; describes construction of exhaust muffler.

IRON CASTINGS

Annealing. Critical Temperatures for Annealing Gray Iron, Emil Schuz. Forging & Heat Treating, vol. 9, no. 4, Apr. 1923, pp. 182–185, 6 figs. Influence of phosphorus and graphite on hardness; importance of pearlite; examples of cementite decomposition; procedure for determining critical temperature. Translated from Stahl u. Eisen, Sept. 18, 1922.

LABOR

Classification. Labor Classification and Pay-Roll Analysis, Carleton F. Brown. Taylor Soc.—Bul., vol. 8, no. 2, Apr. 1923, pp. 69–75 and (discussion) 75–77, 2 figs. Describes method tested, tried and found satisfactory by Corona Typewriter Co.

LOCOMOTIVES

Valve Gears. The Caprotti Locomotive Valve Gear. Engineering, vol. 115, no. 2991, Apr. 27, 1923, pp. 522–523, 17 figs. partly on supp. plate. Describes form of gear introduced on Italian State Railways, which is not worked by eccentrics or rods, but by revolving bevel-driven shaft.

MACHINE SHOPS

Ford River Rouge Plant. Ford Principles and Practice at River Rouge, John H. Van Deventer. Indus. Management (N. Y.), vol. 65, no. 5, May 1923, pp. 257–267, 15 figs. Machine-tool arrangement and parts transportation. Parts for 500 Fordson tractors and 8000 cylinder-block castings for Ford cars are machined daily.

MILLING CUTTERS

Stellite. Milling with Stellite Cutters, C. W. Metzger. Machy. (N. Y.), vol. 29, no. 9, May 1923, pp. 717–720, 6 figs. Directions for obtaining best results and highest efficiency in using stellite milling cutters.

OIL ENGINES

Solid-Injection. Solid-Injection Oil Engine Investigations in Sweden, Edvin Lundgren. Power, vol. 57, no. 18, May 1, 1923, pp. 666–669, 4 figs. Account of experimental work of Swedish Diesel designer in development of Hesselman solid-injection oil engine; particular emphasis is laid on fuel atomization tests.

PYROMETERS

Radiation. A New Radiation Pyrometer, D. Flir. Iron Age, vol. 111, no. 18, May 3, 1923, pp. 1302–1303, 7 figs. Portable instrument for measurement of high temperatures manufactured by Siemens & Halske, Berlin, Germany.

RAILWAY SHOPS

Economies. Suggested Economies for the Railroad Shop, L. S. Love. Iron Age, vol. 111, no. 19, May 10, 1923, pp. 1317–1319, 6 figs. What an Eastern line has done to expedite repairs by modifying practices and preparing for needs in advance.

SPRINGS

Oscillations and Fatigue. Oscillations and Fatigue of Springs, Joseph K. Wood. Am. Mach., vol. 58, nos. 2, 3 and 4, Jan. 11, 18 and 25, 1923, pp. 67–70, 113–117 and 155–158, 17 figs. Jan. 11: General cases of vibration; period equation derived with assumed constant load attached to spring; damped vibrations. Jan. 18: Period equations for springs without attached weight; values for helical and flexural springs; general period formula. Jan. 25: Internal friction as chief cause of fatigue; two resistances in hysteresis; overstrain and its practical uses.

STEAM POWER PLANTS

By-Product Power. Huge Savings Possible by the Use of By-product Power, Lewis J. Sforzini. Power, vol. 57, no. 17, Apr. 24, 1923, pp. 624–628, 7 figs. Possibilities of low-pressure turbine; advantage in use of steam engine or turbine for reducing pressures to points below 20-lb. gage when process-steam demand is spread over reasonable number of hours.

WAGES

Premium and Bonus Systems. Premium and Bonus Plans, H. K. Hathaway. Taylor Soc.—Bul., vol. 8, no. 2, Apr. 1923, pp. 59–65. Discusses straight piece-work, Halsey's premium, Emerson's bonus, and task systems; explains Gantt task and bonus system in detail which author believes, is best from standpoint of accomplishment in matter of high production and low cost, and as preventive of misunderstandings and mistrust that are at bottom of most labor troubles.

Walter F. Rittman

Sumner B. Ely

Frederick A. Gaby

Contributors to This Issue

Sumner B. Ely and **Walter F. Rittman**, co-authors of the leading article in this issue, are former business men now connected with the Carnegie Institute of Technology. Mr. Ely was born at Watertown, N. Y., in 1869, attended the public schools in Chicago, and received his M.E. from the Massachusetts Institute of Technology in 1892. Following graduation he worked as a machinist for various companies.

In 1897 Mr. Ely went into the drafting room of the Pressed Steel Car Co., at Pittsburgh, Pa. While associated with this company he went to Egypt to superintend the erection of the first lot of steel cars shipped there, and in 1902, a year after he became chief engineer of the American Sheet Steel Co., he was sent to Germany to study continuous sheet-rolling methods. The following year, when this company was merged into the American Sheet & Tin Plate Co., he became its assistant chief engineer, and later its chief engineer. In 1905, he organized the Chester B. Albree Iron Works Co., of which he became vice-president. It was not until 1916, after the death of Mr. Albree, that he disposed of his business interests and became assistant professor of commercial engineering at Carnegie.

Dr. Rittman was born at Sandusky, Ohio, in 1883, received his A.B. from Swarthmore in 1908, and entered the business world as chemist for the United Gas Improvement Co. of Philadelphia. In 1909 he opened an office in that city as consulting engineer. For seven years, from 1914 on, he was chemical engineer with the U. S. Bureau of Mines. He became head of the Department of Commercial Engineering at Carnegie two years ago.

Dr. Rittman received his Ph.D. from Columbia, and degrees in chemical and mechanical engineering from his alma mater. Both of these men are members of the A.A.A.S. the A.S.M.E., and other engineering and scientific organizations.

* * * * *

Julian C. Smith, author of the paper on power development in Quebec, was graduated from Cornell as a mechanical engineer in 1900 and began his business career as a draftsman with Wallace C. Johnson, consulting engineer of Niagara Falls, N. Y. Two years later he was made assistant engineer to Mr. Johnson at Shawinigan Falls, Quebec. In 1903 he became superintendent of the Shawinigan Water & Power Co. of Montreal, and was rapidly promoted to his present position of vice-president and general manager, and executive of all subsidiary companies. He is also president of a number of power and public service companies in Canada.

Mr. Smith is a member of the British Institution of Electrical Engineers, the Canadian Society of Civil Engineers, and the A.I.E.E. He was recently given the honorary degree of LL.D. by Queens University, Kingston, Ontario.

* * * * *

Frederick A. Gaby, who has been with the Hydro-Electric Power Commission of Ontario since 1907, its chief engineer since 1912, is a Canadian by birth and is about forty-five years old. He is a Toronto University graduate, year of 1903. Prior to his appointment to the Commission he was with the Canadian General Electric Co., the Toronto Niagara Power Co., and various companies handling electrical installation work.

Mr. Gaby is a fellow of the Royal Society of Arts and of the A.I.E.E., and a member of the A.S.C.E., A.S.M.E., E.I.C., and many other technical organizations in Canada and the United States.

* * * * *

G. G. Bell, who contributed an article on feedwater heating, was graduated from Toronto University in 1905 as an electrical engineer and took a special course in civil engineering two years later. The intervening time he spent in the engineering office of the Canada Foundry Co. of Toronto. From 1908 to 1910 he was engaged in structural drafting and design for the Canadian Bridge Company, Walkerville, Ont., and for a like period of time handled structural and hydraulic engineering for the Sawyer-Moulton Co., Portland, Me. Mr. Bell first became associated with the West Penn Power Co. in March, 1912. He is now manager of power development.

* * * * *

Herbert W. Croizer, with the assistance of J. D. Stigen and C. E. Nagel, tells about Diesel-engine progress on the Pacific Coast. These men are all good Californians now, whatever their nativity. Mr. Crozier was born and educated in that peerless state, being graduated from the University of California in 1899. For eight years he held various positions in electrical and constructional work. During the last fifteen years he has been mechanical and electrical engineer and manager of the San Francisco district for Sanderson & Porter, San Francisco.

For the past four years Mr. Stigen has been naval architect for the Standard Oil Co. of California. Previously he was connected with the Pacific Gas & Elec. Co., and the Union Branch of the Bethlehem Shipbuilding Co.

Mr. Nagel has been chief engineer of the Pacific Diesel Engine Co., Oakland, Cal., for the past three years. He was formerly assistant district supervisor of the Emergency Fleet Corporation at New Orleans, and for ten years prior thereto was state bridge engineer of Minnesota.

Coming A.S.M.E. Events

The Montreal Spring Meeting reported in this issue of MECHANICAL ENGINEERING is the last meeting until Fall. Then will occur the third regional meeting, to be held at Chattanooga, Tenn., October 23-24. The Annual Meeting will be held in New York, December 3-6.

Plans for the Chattanooga meeting include sessions on power, management, and welding. The Annual Meeting program is also well under way and an interesting four days is assured. The A.S.M.E. NEWS will contain the advance information about these events.

Power and Fuel Consumption of the Iron and Steel Industries of the Pittsburgh District

By SUMNER B. ELY[1] and W. F. RITTMAN,[1] PITTSBURGH, PA.

THE Carnegie Institute of Technology through its Commercial Engineering Department is conducting a major investigation of present power requirements and potential future power possibilities in the Pittsburgh district (1) with relation to the community and its development as a whole and (2) with relation to the various specific industries of the community.

The largest and most important industrial activity of the district is the production of iron and steel, and the first step has naturally been to make a detailed study of that industry with relation to its power requirements.

Some idea of the quantity of steam used by the steel industry within the 30-mile-radius circle around Pittsburgh can be had from the following interesting comparison with the Superpower Survey for the region between Boston and Washington lately published by W. S. Murray and others. If the boiler horsepower-hours as shown in the Pittsburgh power-study curve for the year 1920 [see curve (*b*), Fig. 2] are put into equivalent kilowatt-hours, it will be found that this figure is about two-thirds of the total kilowatt-hours for the same period as given in the Superpower Survey for the whole district covered by it.

The value of such a survey lies (1) in the importance of the Pittsburgh district as a factor in the nation's steel production, and (2) in the fact that the data will serve as a basis of comparison when corresponding data are collected for other steel centers. Furthermore, any development in the use of or in the creation of power for the steel industry is of vital concern to the other industries of the community, and, in fact, of interest even to concerns located within a radius of 100 miles or more from Pittsburgh. Finally, it was felt that a detailed study of power and fuel consumption in the steel industry in a district as important as that embraced by this investigation would give some indication as to the general trend of developments during the period covered, and there is good reason to believe that this expectation has been justified.

Points Brought Out by the Survey

The data presented show certain marked developments in the power phase of the steel industry. First, they reveal a greatly increased use of given equipment—expressed by the increased load carried by each unit of physical equipment; and secondly, a marked increase in cost of fuel for the development of power, as well as a period of inefficient fuel use coinciding with the war years. The curves drawn from data obtained in this survey indicate the volume and importance of power as a factor in determining steel production costs. A continuation of such curves will register changes in efficiency, while the accurate cost data obtained will undoubtedly be useful for future planning.

The Pittsburgh undertaking has taught a valuable lesson in regard to what might be called the art of making industrial surveys. It is obvious that the value of such a survey is primarily dependent on the ability of those making it to ascertain the facts which shall form the foundation of the deductions later made, and what is perhaps even more important, the ability to ascertain *all* the facts and not merely those easily accessible, and to express them in a comparable manner and in sufficient detail to enable one to obtain a clear insight into their significance.

In this connection it appeared early in the study that some of the institutions investigated either did not have the necessary facts properly collected or were reluctant to give detailed data as to their costs, fuel and power consumption, efficiency and so on, on the ground that their organizations might show up unfavorably in comparison with others, or that because of their size they would be accused of monopoly in their particular branch of the industry.

There was no way of compelling compliance with the request for facts, and even if there had been it would have been probably extremely unwise to have employed it. It was decided that the only way to collect the data was to obtain it from the individual companies, which meant that, speaking colloquially, the idea of the survey had to be "sold" to these companies, and that the various institutions involved had to be instilled with sufficient faith in the Carnegie Institute of Technology to entrust it with this confidential detailed information. This situation was met by a general agreement that no specific data referring to individual companies would be published and that all the data would be used only in combination so that only summation or overall figures would be shown.

In the spirit of confidence and mutual goodwill thus created it became comparatively easy to meet the next obstacle, namely, that different institutions used different units of measure and different ways of keeping records, which made interpretation difficult. This was done by the various parties involved joining about a common table and placing their respective engineers in conference for the common end. For instance, in the case of the public utilities, the data and trends were developed by engineers from the various utilities in counsel with the Carnegie Institute of Technology. There are indications that these conferences and the work done on the survey may lead to a greater completeness and uniformity of power- and fuel-consumption records in the steel industry of the

[1] Professors of Commercial Engineering, Carnegie Institute of Technology.

Pittsburgh district. Further, the work has effectually shown that the community or industrial inventory can be made only with the complete coöperation of the community and industry.

In general, it will be noted that the period covered by the curves presented is one of the most interesting in the history of our country, namely, that of the world war, but with a few overlapping years so that an idea of the trend is given and the distortion produced by the war indicated. Take for example the efficiency curve shown in Fig. 13 (*a*), which indicates how the efficiency of firing fuel varied during the war years and as what occurred in the Pittsburgh district is typical of what took place in most of the manufacturing districts of the United States it is not unreasonable to say that these curves in great measure reflect other manufacturing industries; so that by the study of these curves we can learn something, broadly speaking, of the condition of the whole country.

Again, a tendency to work equipment beyond its capacity is distinctly shown at the beginning of the war—possibly because additional equipment could not be obtained promptly—and later on an increase in equipment is evident. This undoubtedly reflects the general conditions then prevailing in most manufacturing industries, and while this agrees with general opinion, the curves provide a definite, concrete verification.

Furthermore it must not be forgotten that power is approximately proportional to production, and that the curves indicate in general the demand for steel and iron. The general rise in the price of fuel has not been confined to the Pittsburgh district, so that the percentage increase in the cost or price of fuel gives a fairly good idea of what happened throughout the United States, or the eastern half of it at least.

Defining the Pittsburgh District

The corporate limits of the City of Pittsburgh long ago proved inadequate to hold the manufacturing establishments and plants which now spread up and down its rivers and arteries of transportation. They are much more restricted than those of most metropolitan districts, but serve as the hub of the fifth major district of the country and embrace a population of over 1,200,000. The area selected for this study was that of the circle struck with a radius of thirty miles from the Pittsburgh City County Building as the center (see Fig. 1), because the people and the iron and steel plants comprised within it are intimately associated with and largely dependent upon the facilities of corporate Pittsburgh.

Summary of the Data Presented

Naturally a large number of sources of information are used in a study of this character. The various iron and steel interests of the community were most obliging in furnishing the data at their command. In addition, the authors were helped greatly by the Pennsylvania Department of Internal Affairs; by the Interior Department at Washington; by the officials of the American Iron and Steel Institute; and by the various technical journals and publications of the industry.

Table 1 presents the summation data covering the more important items entering into this study. To the business man the figures given in this table are valuable as covering the more important elements and relationships entering into the industry, but to the iron and steel engineer or the power engineer the detailed data and relationships are of equal if not greater interest. Column 1 shows the total gross tons of fuel, coal equivalent, used under boilers; column 2 the cost of this fuel, and column 3 the gross tons of ingots produced with this fuel. The three succeeding columns cover data derived from the first three columns. These data show that as the number of gross tons of steel ingots rose from approximately ten million in 1911 to thirteen million in 1920, the value of the fuel used under boilers increased from less than seven million dollars to more than twenty-nine million. On the other hand, the fuel used per gross ton of ingots produced increased only from 0.57 ton to 0.60 ton, and the value of fuel used per gross ton of steel ingots produced increased from $0.65 in 1911 to $2.27 in 1920.

The Rated-Capacity Curve, Fig. 2 (*a*), represents the boiler capacity of all the iron and steel plants in the District. The curve shows practically no increase in the installed boiler capacity during the years 1914 to 1917, but a tendency in that direction since 1918. In no case has the increase in boiler capacity been in proportion to the increase in production; in other words, increased producing capacity was attained largely by the harder and more efficient use of the existing equipment.

The Output Curve, Fig. 2 (*b*), gives, in boiler horsepower-hours, the total quantity of steam produced per year by the installed rated capacity shown by curve (*a*). By superimposing curve (*b*),

on curve (*a*), the extent to which greater utilization was secured from existing equipment becomes evident.

The Coal Used is shown in Fig. 2 (*c*), and is the tonnage actually fired under the boilers to produce the steam shown by curve (*b*) of the same figure. This curve appears to correspond closely with curves (*a*) and (*b*) in showing a fall in 1914 and then a greatly increased activity through 1920. A pronounced peak is evident during 1918. Personal investigation has developed the fact that much of this increase was not the result of efficient expansion. During that period fireman as a group showed a considerable labor turnover with resultant inefficiency in the use of a given volume of fuel, and considerable coal of less desirable character was used. Facts like these are not shown in the statistics but are of primary importance.

The Total Value of the Coal Used is shown in Fig. 3 (*a*). The rise in this curve from 1915 to 1918 is greater than the rise for the same period in the tonnage curve, Fig. 2(*c*), reflecting that the price per ton was advancing during the period—as might well have been expected from the demand at that time. The total amount of money paid for boiler coal during the year 1920 was in excess of $20,000,000.

The Price of Boiler Coal per gross ton throughout the period is shown in Fig. 4 and was derived by dividing the values of curve (*a*), Fig. 3, by the tonnage volume of curve (*c*) Fig. 2. The price variation during the period is vividly portrayed. A persistent upward tendency running from $0.955 in 1911 to $4.10 per gross ton in 1920 accords with the trend of all commodities during the period.

The Total Blast-Furnace Gas Used under boilers is shown in Fig. 5. In order to have a better basis of comparison, the cubic feet of a gas are expressed in terms of coal equivalent. The ratio used is 103 B.t.u. per cubic foot of gas to 13,500 B.t.u. per pound of coal.

Fig. 1 The Pittsburgh District Studied, which Embraces the Area Within a Radius of Thirty Miles from the City's Center

The Value of the Blast Furnace Gas Used, Fig. 3 (*b*), was estimated by valuing the quantities shown in Fig. 5. Considerable difference of opinion naturally existed as to what this value should be. A few years ago blast-furnace gas, being a by-product, was considered as of small value. Today, however, iron and steel manufacturers distribute a book charge for this gas, generally against the power plant, which is right and proper. The generally-agreed-upon value of the coal equivalent is $1.35 per ton, but in 1920 this figure was changed to $3.27. The weakness of such empirical assumptions is recognized, but so long as the basis of calculation is understood, each reader can revise the conclusions as he may see fit.

The Natural Gas Used under the boilers in the iron and steel industry is shown in Fig. 6 (*a*). The amount consumed was very small, and prior to 1918 was of such small volume as to be negligible.

The Cost of Natural Gas Used under boilers is shown in Fig. 6 (*b*), and during 1919 was only about $3000, an amount so small as to be of little importance in the total figures. The curves show that the average cost of the 18,000,000 cu. ft. used during 1919 was 18 cents per 1000 cu. ft. More natural gas probably would have been used by the industry had it not been for regulations exercised by the producers and distributors of natural gas by which domestic users were given priority.

The By-Product Tar Used as boiler fuel is shown in Fig. 7 (*a*), and, as in the case of the natural gas, was negligible when compared to the total fuel consumed. The tar is expressed in terms of coal equivalent on the ratio of one pound of coal containing 13,500 B.t.u. and one gallon of tar containing 168,000 B.t.u.

The Value of the Tar Used as boiler fuel is shown by curve (*b*) of Fig. 7.

In the Pittsburgh District considerable gas is generated by the by-product coke ovens for use in open-hearth furnaces. At Clairton alone more than 13,000 tons of coal are being coked daily in by-product ovens, and the capacity of this plant is now being doubled. While some of this gas is occasionally diverted to boilers because of shutdowns of furnaces and some is used for what is known as "regulator gas" to take care of slight shortages that may arise, the quantity is so small as to be negligible in the fuel totals for boilers under consideration.

The Total Quantity of Fuel Used under the boilers of the iron and steel manufacturers in the Pittsburgh District is shown in Fig. 8. The upper curve, which represents a summation of the coal, gas, and tar used, has much the same shape as that of the lower one, which covers coal only and is reproduced on a different scale from Fig. 2 (*c*). There was a decided upward trend in the fuel consumption of the industry from 1911 to 1920 which corresponded generally with the increase in iron and steel production during that period.

The Percentages of Coal and Blast-Furnace Gas Used for power purposes are shown in Fig. 9. The curve is based on the coal equivalent for blast-furnace gas as compared with the coal, and appears to be fairly constant in the ratio of 60 per cent coal to 40 per cent gas. This ratio is important because it shows that through the efficient use of the blast-furnace gases they can be substituted for 40 per cent of the coal which otherwise would be required.

The Total Value of All Fuels Used under the boilers of iron and steel manufacturers in the District is shown by Fig. 10. Comparing this curve with curve (*a*) of Fig. 3 which shows the same data for coal only, it will be observed that the proportion and trend in blast-furnace-gas consumption is such as not to materially change the slope of the curve. It clearly brings out the upward trend in the value of power fuel since 1911. Starting at about $5,250,000 in 1911 there was comparatively little change until 1915, when a marked increase occurred during the war years, with a decrease from 1918 to 1919 and a further considerable rise until the value reached more than $29,000,000 in 1920, or an increase of more than 500 per cent during the ten-year period.

The Value of a Unit of Fuel is shown in Fig. 11. This value comprises coal and blast-furnace gas, the natural gas and other fuels being negligible. The curve further shows the proportionate

(Note: Value given for a "gross ton" of blast-furnace gas is for the quantity of gas that will develop the same amount of heat as one gross ton of coal.)

values of coal and blast-furnace gas which go to make up the unit value. The unit taken is a gross ton, the blast-furnace-gas equivalent coal value being used as previously stated.

The percentage shown by Fig. 9 makes the blast-furnace-gas equivalent coal used not greatly less than the actual coal used, whereas the values in dollars show the blast-furnace gas to be valued at a much smaller figure than the coal. This is a question of bookkeeping as before stated. It would seem logical that blast-furnace gas should be given a higher value to make its variations more nearly correspond with the variations in coal prices. In this

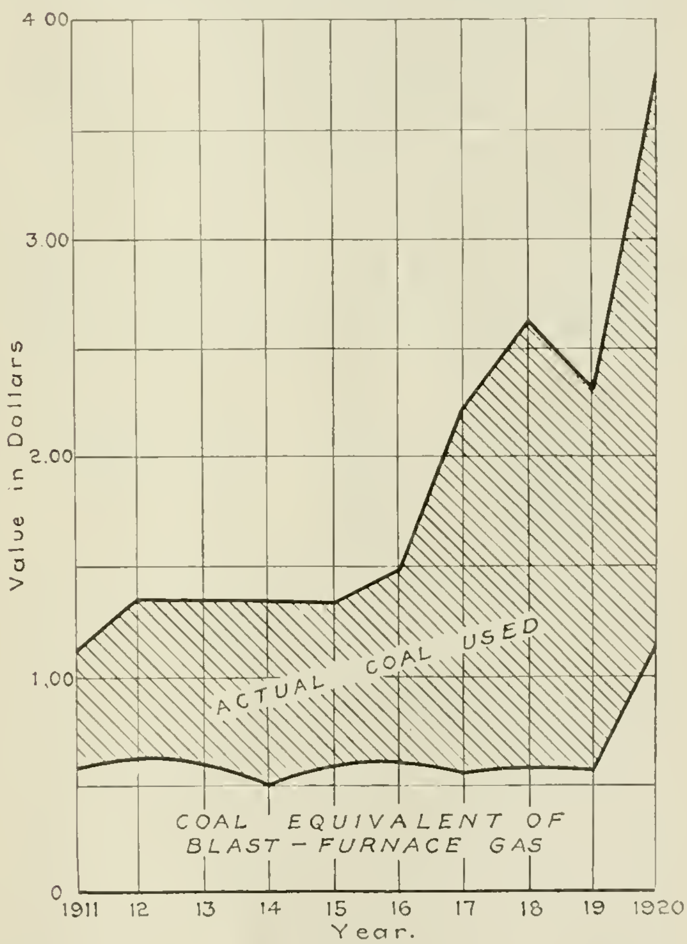

Fig. 11 Curve Showing Value of One Gross Ton of Fuel Used Under Boilers in All Steel Works of the Pittsburgh District
(Explanation: In 1916, e.g., one gross ton of average steam fuel consisted of 61 cents' worth of blast-furnace gas and 87 cents' worth of coal, making the fuel equivalent of one gross ton of coal cost $1.48. See note under caption of Fig. 4.)

study, however, it was considered advisable to follow more nearly the practices of the industry.

The Total Tonnage of Iron and Steel Produced in the Pittsburgh District during the years 1911 to 1920 is taken as the total weight of ingots produced during that period and is given in detail in Table 1, and expressed in the form of a curve in Fig. 12. These figures were

largely derived from the American Iron and Steel Institute for the later years, whereas for the earlier years a canvass was necessary to secure data covering each individual plant in the District.

It was considered advisable to use ingots as a basis of weights in connection with the production of the iron and steel plants, because it was deemed impracticable to use records of finished tonnages since the latter practice inevitably involves much duplication and confusion of data.

The curve as a whole shows a decided upward trend in keeping with the trend in general production. On the other hand, the ten-year period covered is probably too brief a one upon which to base conclusions as to the proportion of increase that the Pittsburgh District is responsible for in the industry as a whole.

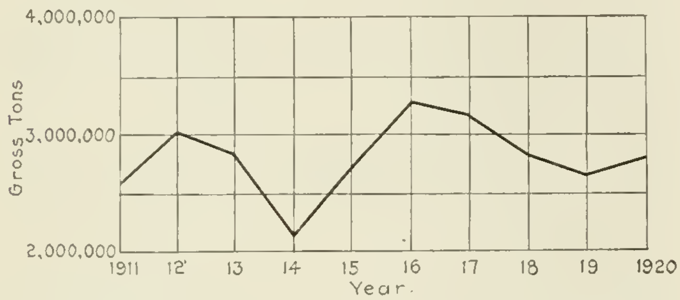

Fig. 12 Curve Showing Total Quantity of Steel Ingots Produced per Year in All Steel Works of the Pittsburgh District

The Quantity of Power Fuel per Ton of Steel is shown by curve (*a*) of Fig. 13. Variation in this curve resulted either from the use of less desirable fuels or variations in the efficient utilization of the fuels available. Details regarding the efficient use of fuels cannot be shown in general-data figures, but are worthy of special study.

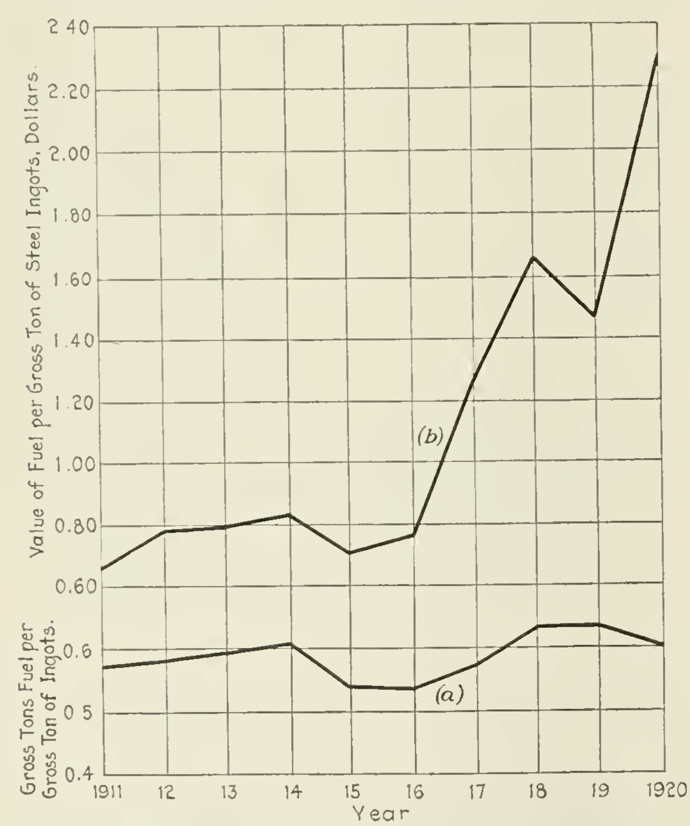

Fig. 13 Curves Showing (*a*) Quantity and (*b*) Value of Fuel (Coal plus Blast-Furnace Gas) Used Under Boilers per Gross Ton of Steel Ingots Produced in all Steel Works of the Pittsburgh District

The Cost of Power Fuel per Ton of Steel is shown by curve (*b*), of Fig. 13, which represents the data of curve (*a*) translated into dollars and cents and indicates how the price of fuel advanced during the latter half of the period. It will be noted that in 1911 the cost of power fuel to manufacture a gross ton of ingots was 65 cents, whereas by 1920 this same figure had mounted to $2.27, an increase of more than 300 per cent.

The data presented show two marked developments in the power phase of the industry: first, the increased load carried by each unit of physical equipment; and second, the marked increase in cost of fuel for the development of power. Many other equally interesting observations and comparisons can be made for the ten-year period, but because of the different viewpoints of those interested in the industry, the authors prefer to leave the wide variety of interpretations possible to such individuals or groups.

FROM the beginning the steel industry has had to depend on its own orgaization for its power, for at the outset there were no adequate sources of, or means of transporting to the plant, the large quantities required, and long before any knowledge of electrical generation and transmission it was recognized that the sources of power in the industry itself necessitated their utilization at the plant, so that we have today in every steel works a power plant, frequently in many units, generating in all of its several phases most of the power required to carry on the various operations from raw materials to finished steel products.

During comparatively recent years tremendous development has been made in the size, reliability, and control of electrical apparatus for steel-plant service, and in the generation and transmission of the power required for its operation. Its almost innumerable applications have been so general in character and large in total that in many cases the development of the plant's own power supply has not kept pace either in economy or size with the peak power demand, so that electric current frequently must be purchased to take care of these maximum-load periods. It is only natural to expect that still further applications of power, both electric and steam, will be made in the ever-constant development of the steel industry so that its power plant will ever become increasingly important.

Unfortunately, power does not appear on our cost sheets as a single total item, and we are apt to think of power costs only to the extent that they do appear as separate items of steam, electricity, water and air, not always remembering that power is the total of all of these, plus the additional power costs that are necessarily included in our cost-sheet figures, in raw materials for their handling, in partly worked materials, power for shops appearing as repairs, and many other auxiliary operations. The result is that the true cost of power is not generally fully appreciated, total power cost being defined as the cost of producing or purchasing all the energy for generating steam, electricity and blast-furnace blowing. In such a cost, waste heat must be accorded a value commensurate with the value of the fuel that would have to replace it if the waste heat were not available.

The author gives a tabulation of cost data taken from the cost records of three of the Bethlehem Steel Company's plants. This tabulation covers the period from Jan. 1, 1920, to Aug. 1, 1922, considered as representative. From this tabulation the importance of the power item in steel making appears plainly.

Any single cost item that stripped of all credits reaches the proportion of early one-fifth of the total plant payroll, or $5^1/_2$ per cent of the total sales value of all manufactured products, or twice the cost of all refractories, commands attention. How to reduce it, and the extent to which it can be reduced, constitute the real economic question.

In general, there are three points of attack on the problem after the cost analysis has been made; first, on the prime movers of mill and auxiliary drives; second, on the electric generating and blast-furnace blowing plants; and third, on the steam plants. For new installations there is little room for argument against electrification as showing the greatest economy. For existing steam-driven units practically every case will show a fair return on the investment by the substitution of electric drive, including the generating equipment.

In general, steelworks have not taken full advantage of the economies possible in connection with the operation of electric generating stations and blast-furnace blowing plants. (Abstract of paper read by E. F. Entwisle, Mem. A.S.M.E., before the *American Iron and Steel Institute* published in *The Iron and Coal Trades Review*, vol. 106, no. 2882, May 25, 1923, p. 784)

Hydroelectric Possibilities of Quebec

The Potential and Actual Hydroelectric Development of the Province of Quebec and Its Probable Rate of Growth in the Future

By JULIAN C. SMITH,[1] MONTREAL, CANADA

THE OBJECT of this paper is to present briefly the potential and actual hydroelectric development of the province of Quebec, and so far as may be done from the progress in the past, to estimate the probable rate of development of the hydroelectric resources in the future.

The province of Quebec comprises that vast stretch of territory lying east of the Ottawa River and north of the United States boundary line, bounded on the north by Hudson Strait, on the west by Hudson Bay, and on the east by Labrador. It is 2000 miles in width from north to south and 1350 miles from east to west, having an area of 706,804 square miles, or almost 25 per cent of that of the United States. The northern section is for the most part uninhabited, but the southwestern portion lying along the lower part of the Ottawa and St. Lawrence Rivers, and extending south to the American border and east to the Saguenay River, is an important and rapidly growing industrial section.

If we superimpose a map of the province of Quebec over a map of the eastern portion of the United States, Quebec will cover the states from the Atlantic Ocean west to Chicago including the Great Lakes, and from North Carolina to Canada, leaving some 200,000 square miles of the northern part of the province overlapping Canada.

The climate of Quebec is quite similar to that of northern New England. The winters are severe, and snow covers the ground from the middle of November to the end of March. The summers are warm and pleasant, and the precipitation, which is fairly evenly distributed over all seasons, averages about forty inches per year.

The Watersheds of the Province

Topographically the country north of the St. Lawrence River is divided into three great watersheds. South of the river and west of the town of Levis, which is opposite the city of Quebec, the country is a low-lying fertile plain; east of the town of Levis the land rises gently to between 1000 and 2000 ft., with elevations of nearly 5000 ft. in the Gaspé Peninsula. On this south side of the river there are no large waterpowers as the watershed is comparatively narrow and, although well watered, is traversed by only a few rivers of any magnitude.

The three great watersheds lying to the north of the St. Lawrence River are the south watershed, draining into the St. Lawrence River; the north watershed, into the James and Hudson Bays; and the east watershed, through Labrador into the Atlantic Ocean. Of these the south watershed, through which flow the tributaries of the St. Lawrence from the Ottawa to the Notashkwan, is the most important. The height of land dividing the north and south watersheds lies some 200 miles north of the St. Lawrence and runs roughly parallel to it. On either side of this height of land there is a vast plateau having a mean elevation of from 1200 to 2000 ft. which begins at the Ottawa with a width of some 150 miles and spreads out like a fan toward Labrador where it attains a width of 500 miles or more. The southern edges of this plateau are for the most part near the St. Lawrence so that the rivers which traverse it make their sharpest descent to sea level not far distant from the main river, and as a consequence much of the water power of this watershed is within easy reach of the industrial section of the province.

The north watershed is drained by many large streams flowing into James Bay, and when the development of the country has progressed far enough to permit their waterpowers to be utilized, enormous amounts of power will become available on the Nottaway, Rupert, East Main, and Kaniapiskau Rivers.

[1] Vice-president and general manager, Shawinigan Water and Power Co.

Presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Slightly abridged. All papers are subject to revision.

With regard to this northern watershed, although the area is large the precipitation is largely unknown, and the run-off also is largely a matter of speculation.

The east watershed is drained principally by the Hamilton River, on which is situated a water power estimated at 700,000 hp. at Great Falls, some 350 miles from the mouth of the river and 200 miles north of the St. Lawrence River at the west end of Anticosti Island.

The ultimate source of the water power of any country is the precipitation, and the total potential water power produced thereby may be estimated by calculating the potential energy of this precipitation in its descent from the highlands to the sea.

Potential Water Power of the Province of Quebec

To calculate the total potential water power of the province of Quebec we may superimpose a map of the precipitation upon a topographical map of the province and then divide the province into areas having the same average elevation and approximately the same precipitation. An estimate of the potential energy due to precipitation can then easily be made. The precipitation in inches per year at different points of the province is as follows:

Montreal	40	Shawinigan	37.61
Quebec	40.5	Chicoutimi	30
Brome	34.3	Anticosti Island	36
Father Point	33.58		

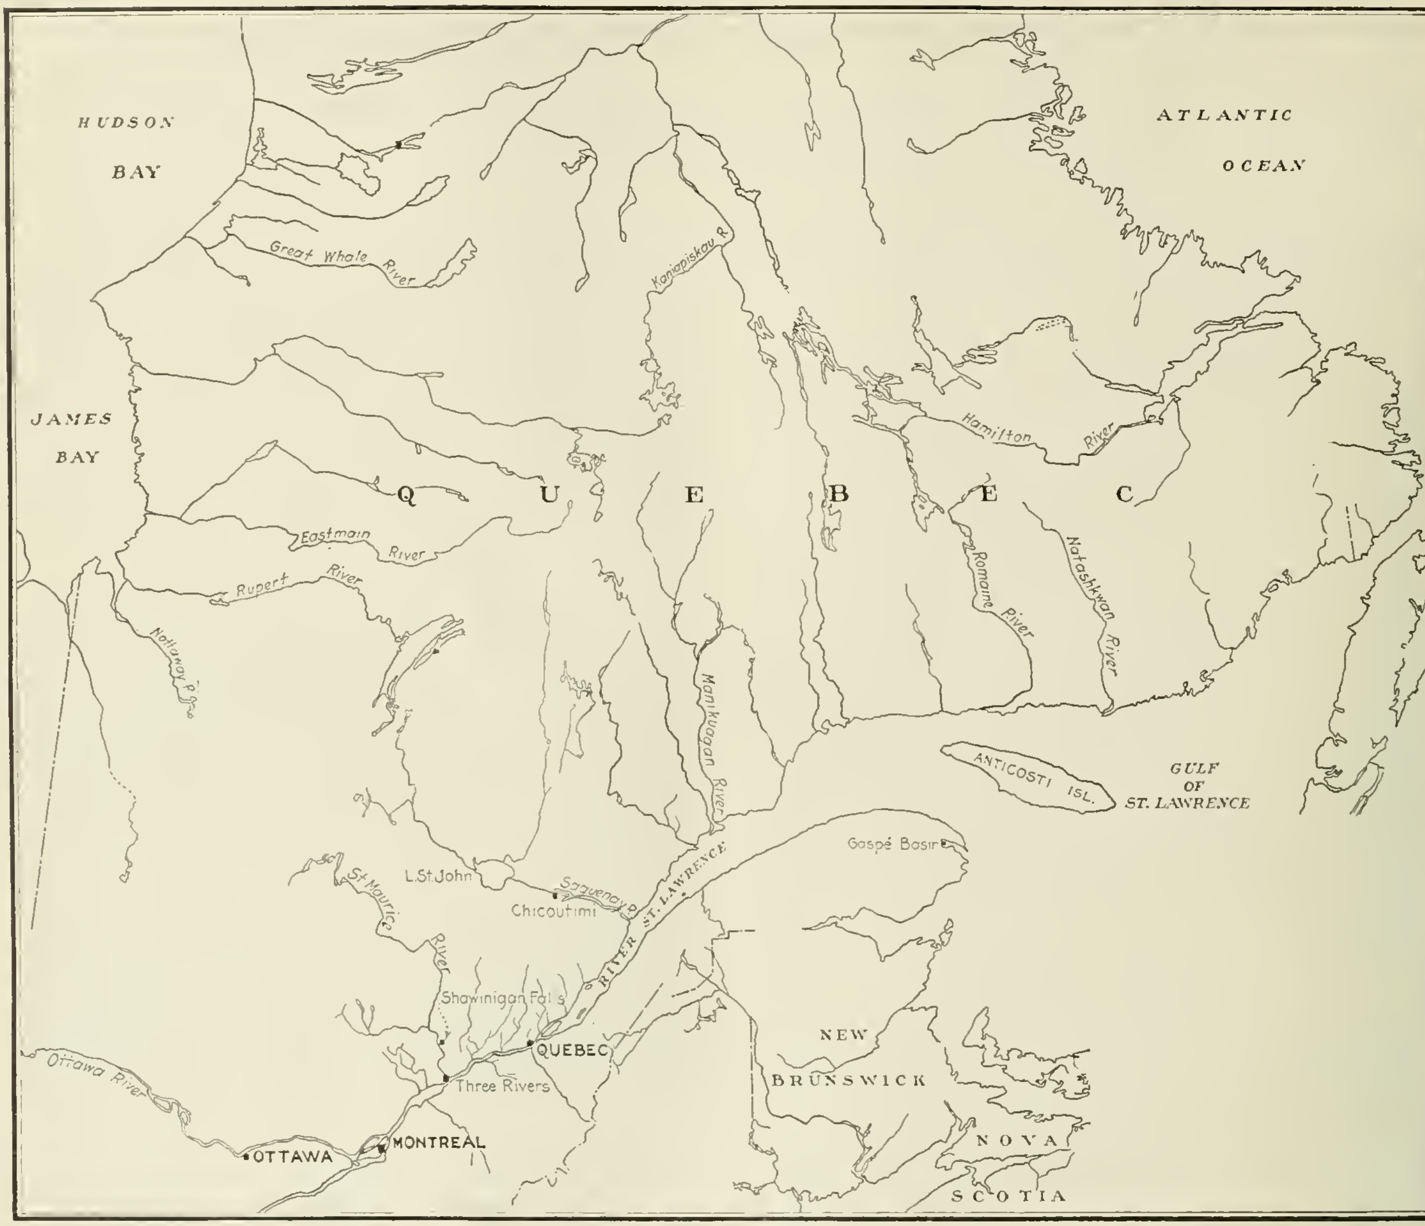
The total area of the province is as stated above roughly 700,000 square miles, of which for the present purpose we may neglect the triangular area cut off by a line drawn from the northern tip of Labrador to the southern end of James Bay containing some 200,000 square miles of snow-covered land, leaving a net area of 500,000 square miles. This area of 500,000 square miles may be divided into four plateaus of different elevations and slightly different rainfall, as follows:

Average precipitation per year in inches	Average elevation in feet	Area in square miles	Equivalent continuous power in kw.
40	1700	170,000	71,400,000
40	1000	220,000	92,400,000
35	500	100,000	18,350,000
40	300	10,000	1,260,000
		500,000	183,410,000

Mr. C. P. Steinmetz, in a paper read before the American Institute of Electrical Engineers in 1918, made a similar computation showing the potential water power from the rainfall in the United States between the thirtieth and fiftieth parallels of latitude and found that over an area of 2,970,000 square miles the potential power was 1000 million kilowatts of continuous power. Prorating the figures obtained above for the province of Quebec, the potential water power of the province due to the precipitation is about 10 per cent higher per square mile of area than the average potential water power of the United States.

It is of course obvious that this amount of power is not available because no water would be left for vegetation, and even were all hydroelectric developments carried out, no allowances have been made for losses due to seepage and evaporation.

If we average the figures for the various stations throughout the province, we arrive at an estimated run-off for the whole province of 18 in. per year. Substituting this figure for the total precipitation, we obtain a total of 88.7 million kilowatts of continuous power, and allowing an efficiency of conversion of 60 per cent from the stream to the distribution center, there remains 53 million kilowatts of continuous power as the maximum possible hydroelectric power which could be produced if during all seasons every drop of water which ran off the 500,000 square miles of territory considered were converted into hydroelectric power. This is of course an impossible condition, as there would be no flowing streams



Map of Quebec Showing Watersheds and Rivers

in the country but only lakes and canals connected together by penstocks discharging through turbines into those of lower levels.

In estimating the amount of power which is actually available we must obviously neglect the energy in the water falling on the upper plateau, which is lost in the first part of its descent from these highlands.

While it is impossible to state accurately the percentage of energy loss before the gathering together of water takes place, it may be conservatively estimated at 50 per cent on an average over the many steep and shallow valleys that go to make up the different drainage basins.

We must also subtract from the total of available energy all the energy consumed by friction of the banks and beds of the rivers and streams, which is sufficient to use up about one-half foot of head per mile on the average; and in addition we must consider as non-available all the energy contained in those portions of the rivers and streams and brooks where the fall is hardly greater than that necessary to produce the required flow of water through the channel. In this class will be included practically all the lower reaches of the main rivers and those tributaries which unite with them below the points of greatest descent.

As continuity of supply is an essential condition to all power service, due allowance must be made for the fact that while the precipitation is more or less equally distributed during the year, the run-off from the precipitation is most unequally divided among the different seasons. During the spring thaw the melting and running away of the accumulated winter snowfall produces flood conditions on all rivers and streams, raising the flow to as much as 20 to 100 times the minimum. The necessary waste of the greater part of the water reduces still further the quantity of energy which may be considered as available for industrial uses, even under ultimate conditions of development.

Combining the sources of lost energy enumerated we may assume that not more than 25 per cent of the 53 millions of kilowatts of energy contained in the total run-off could be converted into electric energy, and therefore that the actual potential energy of the province of Quebec is approximately thirteen to fifteen millions of continuous kilowatts.

In the present state of the art of the development and distribution of hydroelectric power, only those sites near industrial centers and at which water power exists in considerable quantities are capable of being developed. The theoretical available quantity of fifteen to eighteen million kilowatts of continuous power must therefore be very considerably reduced in estimating the quantity of power that is actually adaptable to industrial purposes. From recent surveys of the water powers of the province, and considering only those rivers on which water power is available in such quantities and in such locations as could be economically developed either now or in the near future, the quantity of actually available water power in the province is estimated at approximately 5.25 million kilowatts of continuous power, of which some 800,000 kilowatts have now been developed and utilized. There remains,

therefore, in the Province of Quebec as available commercial water power about 4.5 million kilowatts of continuous power or about 12 million horsepower at 50 per cent load factor.

The Quebec Streams Commission of the Province of Quebec, and the Water Powers Branch of the Department of the Interior at Ottawa, have published during the past several years valuable articles giving detailed information regarding the available water powers, and particularly those which can be developed within the next few years from an economic standpoint.

The Load Factor

The various amounts of power mentioned in this paper thus far have been described as "continuous power," which means that the flow of water producing this power is sufficient to provide the full quantity twenty-four hours a day, three hundred and sixty-five days in the year, and here the author proposes to digress for a moment from the main subject of the paper to discuss briefly the subject of "load factor," or the proportionate duration of use of power.

It must be borne in mind that no industry is able to make continuous use of the power which it requires, and that therefore no power company supplying power for industrial purposes is called upon to supply the total amount of contracted power all day every day in the year. The term "load factor" is used as a measure of the duration of use of power and is defined as average power divided by peak power. The load factors of the various industrial loads in Quebec differ considerably. For instance, paper mills operate a load factor of between 65 and 75 per cent, averaging more nearly 65 per cent; carbide and electrochemical plants operate at 85 to 90 per cent; cement mills at 80 to 90 per cent; and asbestos and mining industries at 45 per cent load factor. The load factor of a hydroelectric station supplying various industrial establishments and providing power and lighting service to communities will obviously be the average of the combined load factors of the various loads. Such a plant will therefore not require to use continuously the flow of its water which will produce maximum output. Provided sufficient water-storage capacity exists, the surplus energy that the normal flow of the river could produce may be stored in the form of water, but otherwise a certain portion of the available energy—which might be very great at certain seasons in the year—must be allowed to run to waste. In estimating the amount of energy available for industrial uses from the flow of the river at a given head, due consideration must therefore always be given to the storage capacity of the watershed and to the amount of regulation of flow which is possible with full utilization of the storage capacity.

TABLE 1 PRINCIPAL WATER-POWER DEVELOPMENTS IN THE PROVINCE OF QUEBEC

River	Location	Company	Available Head, ft.	Total Generating Capacity, hp.
In Operation				
St. Maurice	Shawinigan Falls	Shawinigan Water & Power Co.	150	195,000
	Shawinigan Falls	Northern Aluminum Co.	145	40,000
	Grand Mere	Laurentide Power Co.	84	160,000
St. Lawrence	St. Timothee	Quebec-New England Hydraulic Corpn.	50	21,000
	Cedars Rapids	Montreal Light, Heat & Power Co.	32	229,200
	Soulanges	Montreal Light, Heat & Power Co.	50	15,000
	Lachine Rapids	Montreal Light, Heat & Power Co.	14	13,000
Richelieu	Chambly	Montreal Light, Heat & Power Co.	...	31,000
Ottawa	Hull	Ottawa and Hull Power & Mfg. Co.	40	20,000
		E. B. Eddy Co. (private)	...	10,000
St. Francis	Drummondville	Southern Canada Power Co.	32	6,700
Montmorency	Montmorency Falls	Quebec Ry., Light, Heat & Power Co.	270	5,000
St. Anne	Seven Falls	Laurentian Power Co.	410	20,000
Under Construction				
Saguenay	Lake St. John	Quebec Development Co.	300	400,000[1]
St. Maurice	Gres Falls	Shawinigan Water & Power Co.	65	132,000
Ottawa	Calumet Island	Ottawa and Hull Power & Mfg. Co.	60	60,000

[1] A further 800,000 hp. will be developed later near the mouth of the river.

In plants where no storage capacity exists, the installation of sufficient generating capacity to consume the increased flow of water during the six high-water months becomes economically justifiable by the use of electric steam generators as an adjunct to the plant to make possible the utilization of the excess energy produced during these months by its conversion into steam. The ability to obtain a return from all the energy available at all times of the year will make possible the development of many power sites which, if dependent solely upon the sale of continuous electric power as such, might remain undeveloped.

Early Water-Power Developments

The earliest water-power developments in the province were the old seigniorial mills constructed by the French seigniors to grind the grain of their dependents. These little grist mills were in existence as early as 1650, and were almost always developed by the construction of a small canal which carried the water to an overshot or undershot wheel where the heads used varied from about five or six feet up to ten or fifteen feet.

The first hydroelectric development was the Montmorency plant near the mouth of the Montmorency River, seven miles below Quebec, built in 1895 and having an installed capacity of five 600-kw. generators.

This was followed in 1897 by the St. Narcisse plant on the Batiscan River, with an output of 750 kw. which was transmitted to Three Rivers over a two-phase 12,000-volt transmission line 18 miles long. This was the first high-tension line in the British Empire.

The Chambly plant on the Richelieu River, 17 miles from Montreal, was built in 1898 with four 2000-kva. machines, the output of which was transmitted to Montreal at 25,000 volts, three-phase; and in the same year the Lachine Rapids plant was put into operation with a maximum output of 10,000 kw., at certain times of the year only.

Principal Water Powers Now in Operation

The principal water powers now in operation in the province of Quebec may be divided as follows: Powers on the Ottawa River; powers on the St. Lawrence River, Province of Quebec; powers on the St. Maurice River; powers on the Saguenay River and its tributaries in the vicinity of Chicoutimi; and powers located on the south side of the St. Lawrence River, particularly on the St. Francis River and its tributaries.

The two great developments existing today in this province are located at Cedars Rapids in the St. Lawrence River, thirty miles west of Montreal, and on the St. Maurice River at Shawinigan Falls and Grand Mere. The third great power, which ultimately may eclipse these, is now being constructed on the Saguenay River just below the outlet of Lake St. John.

In addition to the developments enumerated in Table 1, which generate electricity for use in public-utility service or for industrial service in the neighborhood of power developments, there are a large number supplying power for grinding wood. These latter are widely scattered throughout the province, most of them having been built prior to 1910. The total amount of hydraulic power used directly for this purpose in the province has been stated by the Water Power Branch to be 162,825 hp. With the advent of the vertical turbine and the increase in the size of electrical generating units, it became in many cases more economical to develop the power in the form of electricity to be transmitted to pulp and paper mills built in favorable positions rather than to locate the mills at the site of the power development. The amount of hydroelectric power so used is stated to be 157,367 hp., making a total of 320,192 hp. of hydraulic turbines employed in the pulp and paper industry.

Difficulties Encountered in Water-Power Engineering

There are certain difficulties occurring in water-power engineering in this province which meet engineers in every locality where the climatic conditions are similar to those which obtain in its latitude. Ice troubles in the past have caused serious interruptions of service and reductions in the available amount of power. These troubles may be divided into two broad divisions:

a Ice troubles occurring in the power house itself, due to the presence of ice on the racks on the waterwheels

Hydroelectric Developments in Ontario

Present and Projected Developments of Hydroelectric Power in the Province of Ontario, Together With Particulars Regarding the Largest Single Hydroelectric Development in the World, the Queenston-Chippawa Installation

By F. G. GABY,[1] TORONTO, ONT.

THE province of Ontario is richly endowed with water powers, widely distributed over an area of over 400,000 square miles, and its surface waters drain both to the Atlantic and to the Arctic oceans. The water-power possibilities of the streams draining through the Great Lakes system to the Atlantic have been fairly well ascertained, but much remains yet to be known regarding the power possibilities of the streams draining through Hudson Bay into the Arctic. However, preliminary estimates which include Ontario's share in the water powers of her international waters have indicated a total of some 6,000,000 hp., of which about 1,300,000 hp. has already been developed.

The Chief Water Powers of Ontario and Their Strategic Situation

The power potentialities of the Niagara and St. Lawrence Rivers constitute a very large proportion of the available power in the watershed, tributary to Lake Ontario. There are nearly thirty sites, of which about one-half have been developed with an aggregate capacity of 50,000 hp., leaving undeveloped sites with an aggregate capacity of some 15,000 hp. Tributary to Lake Huron are water-power streams with an aggregate potentiality at known sites of nearly 300,000 hp., of which about 100,000 hp. is developed. Tributary to Lake Superior are water-power streams with an aggregate potentiality of about 300,000 continuous hp. About half of this total is on the Nipigon River, on which an initial development has been made for the municipalities of Port Arthur and Fort William by the Hydro-Electric Power Commission of Ontario. The outflow from Lake Superior through St. Mary River constitutes an important water-power site, which has been partially developed. In the extreme west of the province, the English and Winnipeg rivers, which flow into the province of Manitoba, have important water powers; in Ontario these powers aggregate over 250,000 hp.

Fig. 1 Map of Ontario, Showing Watersheds and Rivers

province. Next in importance is the Ottawa River and its tributaries. The power on the main stream, which constitutes part of an interprovincial boundary, is shared by the provinces of Ontario and Quebec. Under conditions of controlled flow, Ontario's share of the power available on the main stream, together with that on the tributaries in Ontario, aggregates about 700,000 hp.

Other important water powers are found in the Trent River watershed... There remain to be mentioned the water powers of the streams flowing from Ontario into James Bay and Hudson Bay. The more important of these streams from the viewpoint of water-power possibilities are the Mattagami, the Abitibi, the Missinaibi and the Albany Rivers. These streams have not yet been adequately appraised; the total water-power possibilities of known sites aggregate upward of 1,000,000 hp.

What, at the present time, however, is of much greater importance to the province of Ontario than its total water-power possibilities, is the fact that in its commercial centers where the greater proportion of the population resides, are situated the largest and most important water powers.

[1] Chief Engineer, Hydro-Electric Power Commission of Ontario. Mem. A.S.M.E.

Presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

Ontario has no natural supply of coal and has been compelled to import this necessity—both bituminous and anthracite—chiefly from the state of Pennsylvania. The rising cost of this fuel and the fact that manufacturers have been dependent upon outside sources for their supply, have been phases of the power situation in the province which have greatly stimulated, and which doubtless will continue to stimulate, the utilization of the water powers of the province along the lines of hydroelectric development.

Early Hydroelectric Developments in Ontario

The most important *early* hydroelectric development in the province of Ontario from the standpoint of magnitude and extensive transmission, was the plant at DeCew Falls. This plant takes its water from Lake Erie at the level of the upper reach of the Welland Canal at Allenburg. It is a high-head development (265 ft.) of about 50,000 hp. capacity. Current is generated at 2400 volts, 3-phase, 66 cycles, and transmitted at 44,000 volts. The main objective of this DeCew power was the city of Hamilton, in the industrial life of which it has played a most important part.

Niagara Falls. The three large hydroelectric plants at Niagara on the Canadian side of the river have often been described in print, but in view of the subject in hand, it is believed that a brief reference should be made to these developments because of their importance to the general hydroelectric economy of the province of Ontario.

In 1889 negotiations by a group of United States capitalists with the Queen Victoria Niagara Falls Park Commission eventuated in the formation of the Canadian Niagara Power Company—an ally of the Niagara Falls Power Company of Niagara Falls, New York. The water for this plant is drawn from the level of the upper river through an intake canal, and is thence distributed to the intake chambers at the head of each penstock. The penstocks pass vertically down an average depth of about 160 ft. to the turbines. The water finds its outlet to the lower level of the river in the gorge below the falls. The nominal installed capacity of this plant, including a spare unit, is 121,000 hp. The ground was broken for the tunnel on October 4, 1890, and the first commercial power was delivered to the Pittsburgh Reduction Company for the reduction of aluminum ore on August 26, 1895.

The next important development at Niagara was that of the Ontario Power Company, which commenced operation by the delivery of commercial power in 1905. This plant has its intake near the Dufferin Islands, above the falls. The water is conveyed a distance of over 6000 ft. to penstocks by means of underground conduits. The plant operates under an average effective head of about 180 ft. and its present capacity is a little over 160,000 hp. In 1917 the Hydro-Electric Power Commission acquired the whole of the assets, including the generating plant at Niagara Falls, of the Ontario Power Company. This plant is now operated by the Commission.

In 1903 the Electrical Development Company entered into an agreement with the Commissioners of the Queen Victoria Niagara Falls Park whereby the company was to utilize the waters of the Niagara River for the development of 125,000 e.hp. Its plant is situated above the falls and about midway between the headworks at Dufferin Islands of the Ontario Power Co. and of the Canadian Niagara Power Co. The plant operates under a head which varies from 130 to 145 ft., dependent upon river conditions. In 1922 the assets of the company, including the development just described, were acquired by purchase by the municipalities of the Niagara district, and the operation of the plant was placed under the jurisdiction of the Hydro-Electric Power Commission.

There is a demand for the total output of these Niagara plants which represented in their day the highest state of the art to which hydroelectric development had attained. The splendid service given by these installations under the exacting conditions of overload—especially during the period of the great war—reflects great credit upon the engineers and manufacturers responsible for their design and construction.

New Ontario Developments. In the Sudbury, Cockrane, and Cobalt districts of what is known as New Ontario there are several developments on the Metabitchawan, Montreal, Metagami, and Wahnapatie Rivers which aggregate approximately 60,000 hp. and are used for general municipal purposes and the operation of gold, silver, cobalt, copper and nickel mining properties in Northern Ontario. The pulp and mining companies have their own developments to the extent of 125,000 hp. located on the Abitibi, Spanish, Vermillion, Magnetawan and the Onaping Rivers, which they use for their own manufacturing purposes.

Systems and Power Developments of the Hydro-Electric Power Commission

Having now reviewed the outstanding features of hydroelectric development in the province of Ontario, we may next devote attention to some of the more interesting characteristics of the power developments which supply electrical energy to the various systems

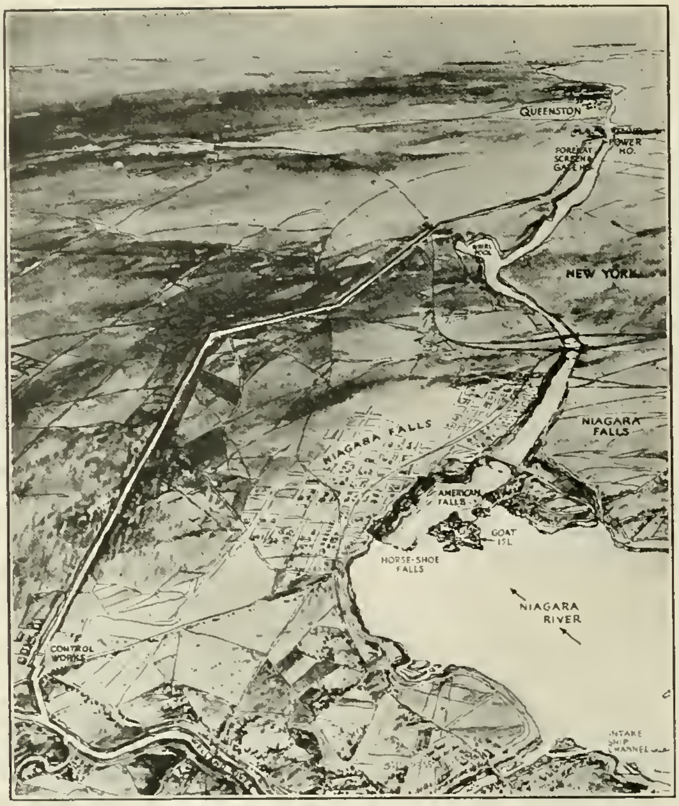

FIG. 2 THE QUEENSTON-CHIPPAWA DEVELOPMENT

of the Hydro-Electric Power Commission to which reference has just been made. In this connection special attention will be directed to certain features of some of the developments installed under the administration of the Commission.

From an initial investment in 1910 of some \$3,750,000 the operations of the Commission have extended until at the present time it administers properties to the value of approximately \$200,000,000 delivering upward of 625,000 hp. to 14 different systems in various parts of Ontario and serving 350-odd municipalities, the systems comprising some 3500 miles of transmission lines.

Transmission Voltages. The frequency employed is 25 cycles in the Niagara system and 60 cycles in all other systems. In the Niagara System the main high-tension lines are operated at 110,000 volts and are carried on steel towers. The secondary distribution from the main transformer stations to the various municipal and distribution stations is chiefly at 13,200 and 26,000 volts, although other voltages are employed. Outside of the Niagara system the only 110,000-volt lines are in the Thunder Bay district where about 70 miles of wood-pole line are operated at this voltage. The main transmission lines of the Severn, Eugenia, Wasdells, and Muskoka systems are operated at 22,000 volts; the St. Lawrence system and the Rideau system lines at 26,400 volts; the Central Ontario and Trent system lines at 44,000 volts—recently raised from 26,400 volts, at which some lines still operate—and the Nipissing system lines at 22,000 volts. Local distribution in the various systems is usually at 2200 and 4000 volts, the service voltages being 110, 220 and 550.

The extent of the hydroelectric developments by the Commission, both actual and conjectural are summarized in Table 1.

Storage. The rapidly increasing demand for electrical energy in all of the fourteen systems operated by the Commission has in some instances already used the available water supply, while in other systems it is only a matter of two or three years or even less, before practically all of the power available under existing conditions of water supply will be requisitioned. The Commission will be able in some cases to increase the supplies available by providing storage. Most of the drainage basins supplying existing developments are well furnished with lakes and reservoir possibilities. The potentiality of the storage available as well as the potentialities of remaining power sites are being investigated by the Commission's engineers, it being recognized that such storage as may economically be developed will be demanded at an early date.

THE QUEENSTON-CHIPPAWA DEVELOPMENT

It is now proposed to describe some of the important features of the largest development in Ontario, in fact, the largest single hydroelectric development in the world, namely the Queenston-Chippawa installation.

The Queenston-Chippawa development, which was placed in service on February 11, 1922, is the latest addition to the Niagara system operated by the Hydro-Electric Power Commission of Ontario. This development will have a normal operating head of 294 ft. to 305 ft. when the installation is complete, which is over 90 per cent of the fall between Lake Erie and Lake Ontario. The conservation of head effected by the reduction of hydraulic losses to a minimum and by refinements in the design of the various essential elements of the project as a whole, has resulted in the production of a power development which is believed to represent the best in modern engineering practice.

The plant when completed will consist of ten 60,000- to 65,000-hp. units running at 187.5 r.p.m. and generating power at 12 kv., three-phase, 25 cycles, which in turn is transformed to 110 kv. for transmission with an ultimate capacity of 575,000 to 650,000 hp.

A glance at Fig. 2 will indicate the relation of the various works comprising the development. Water is taken from the Niagara River about one mile above the falls, is conveyed through the improved section of the Welland River, a distance of $4^1/_2$ miles, thence by a canal $8^1/_2$ miles long to the forebay and screen house located on the Niagara River about one mile south of the village of Queenston. From the screen house, steel penstocks encased in concrete carry the water down the cliff to the power house, from which it passes to the Niagara River.

The Intake. On the Niagara River one of the great obstacles to securing continuity of service is the annual formation and flow of ice. In order to eliminate as far as possible interference of operation due to ice, a special form of intake has been provided.

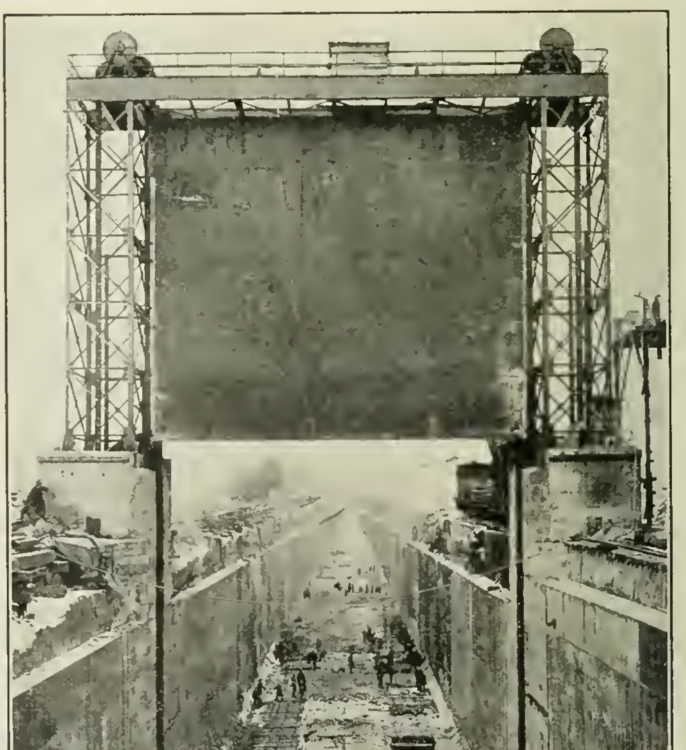

FIG. 3 CONTROL GATE AT UPPER END OF CANAL

The complete structure is approximately 1100 ft. in length and is made up of an entrance with lock gates for navigation, a bulkhead section, and the intake proper, the latter combining two forms of intake; the conventional or surface intake consisting of a concrete barrier or boom with fifteen openings each 18 ft. in width, normally having 8 ft. of submergence, which submergence however, can be

increased, by means of drop gates to any amount up to the full depth of water or 35 ft.; and the submerged intake consisting of gathering tubes or draft distributors, six in number and 675 ft. in length.

Control Gate. Fig. 3 shows the control gate located at the upper end of the canal, where the earth section merges into the rock section. This is the largest single-leaf, roller-type, motor-operated gate ever built. It is motor-operated by means of a worm drive connected to double hoisting gears on the top of the end towers. Roller chains pass over these gears connected at one end to counterweights and at the other to the gate. When raised to its full height it leaves a clearance of 14 ft. above the water level in the canal, which will permit the passage of patrol tugs throughout the length of the waterway.

The total pull on the two chains in raising the gate is 316,000 lb. The chains are made up of pairs of links 9 in. by $1^1/_4$ in. in cross-section, and rollers $4^1/_2$ in. in diameter. The speed of lift is 4.6 ft. per min., thus requiring 12 min. to operate the gate from closed to full open position.

Concrete Lining. Economic considerations prompted the lining of the canal with concrete averaging 20 in. in thickness. The height of the lining was fixed slightly lower than the profile of the water surface existing when the load conditions on the plant are a maximum and the Niagara River flow is a minimum. Thus at all times the lining will be protected by submergence against the action of frost.

Screen House. At the lower end of the forebay, and serving as a dam for the same, is located the screen house. This structure forms the entrance and the control for the penstocks. The entrance to each of the main penstocks is a modified bell mouth consisting of three openings 12 ft. 8 in. wide and 29 ft. high at the rack supports. These three openings gradually converge into one opening 16 ft. in diameter at the point of connection to the penstock. Immediately behind the curtain wall, steel-lined gate checks are provided to support structural-steel gates.

On account of the provision of Johnson valves at the lower end of the penstocks, permanent gates were not installed in the screen house at the entrances to the penstocks. Movable gates have been provided consisting of sectionalized leaves which can be dropped into checks in the piers by means of the 25-ton traveling crane in the screen house. Concrete piers divide the entrances to the penstock into three openings, and the drop gates for closing these openings are made in three sections.

Penstocks. From the screen house the water is carried to the turbines in steel-plate penstocks. The economical diameter for units 1 to 5 was determined to be 15 ft. and in order to simplify the field riveting the lower third of the penstock was made 14 ft. and the upper two-thirds 16 ft. This decrease in the diameter at the lower end permitted the use of plates $1^1/_4$ in. in thickness, which could be readily riveted in the field. The total weight of each penstock is 840,000 lb.

Each penstock ring is made up of two plates with longitudinal joints on the horizontal center line, the plates varying from $^1/_2$ in. at the top section to $1^1/_4$ in. in thickness at the lower section. These joints are all double butt joints, varying from double riveted at the top to quadruple riveted at the lower end. The circumferential joints are also single-butt, double riveted with the butt strap on the outside. The longitudinal joints are calked on the inside, but the circumferential joints are made watertight by electric welding. This type of circumferential joint gives a very much better alignment to the inside of the pipe than can be obtained with the usual outside and inside course with lap joints. In designing the penstocks a stress of 12,000 lb. per sq. in. was used, this figure being taken to provide for the exigencies of corrosion, fatigue,

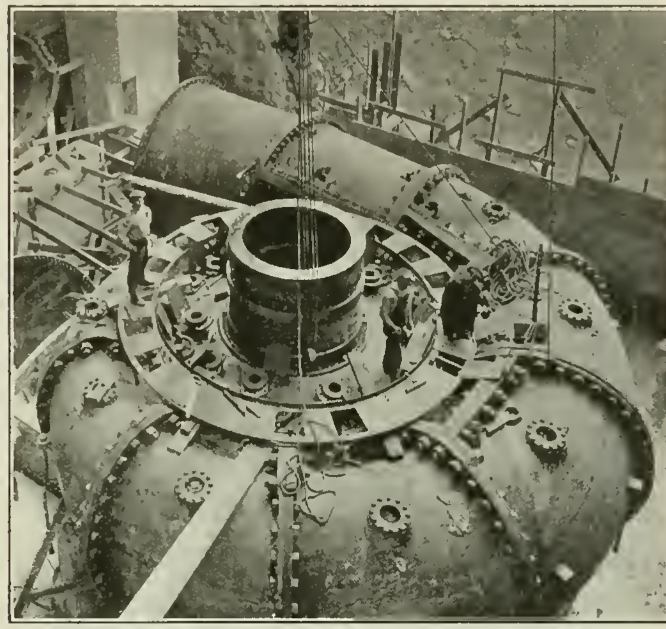

Fig. 5 Turbine Casing Erected in Place

suddenly applied loads, and other indeterminate or unknown contingencies. The internal pressure used for design purposes was taken to be the static head plus the pressure rise due to a complete closing of the turbine gates in $1^1/_2$ sec. This increase in pressure was taken as a maximum at the turbine gates and varying uniformly to zero at the racks.

The penstocks are covered throughout their entire length with a concrete envelope having a minimum thickness of 24 in., which protection will, it is believed, greatly increase the life of the steel pipes.

For discharging ice which may form on the canal and forebay, a chute has been provided at the south end of the screen house leading down the cliff and under the power house to the Niagara River. This ice chute is 10 ft. in diameter, made of reinforced concrete and provided at the upper end with a drop gate.

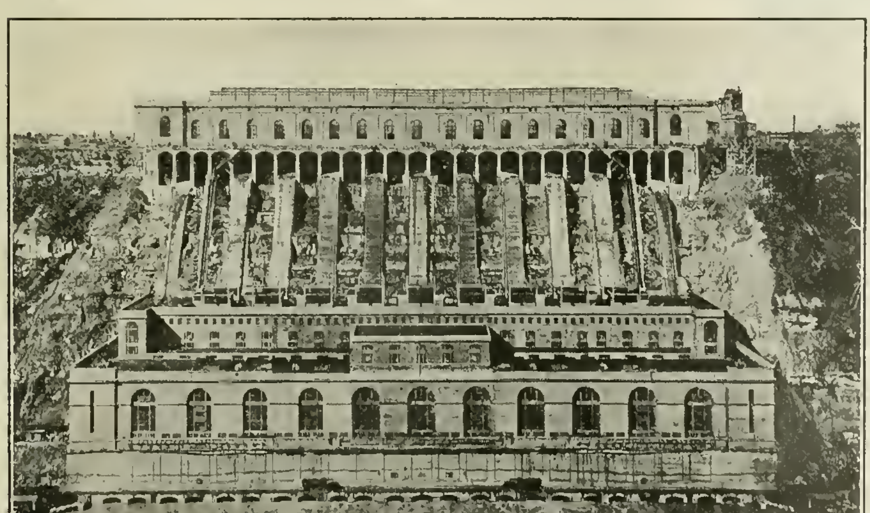

Fig. 4 View of Power House From the River

Generating and Transformer Station. The generating and transformer station (Fig. 4) is located below the escarpment and close to the river's edge. As will be observed, the station extends about one-half the distance to the top of the escarpment. The structure required to house five main units and the service equipment is 350 ft. long, and ultimately this length will be doubled. The substructure is of massive concrete construction carried down to rock foundations, and provides chambers and tunnels for housing and giving access to various kinds of apparatus. The superstructure consists of a structural-steel framework with reinforced-concrete floors and roofs, and concrete, brick, and tile walls and partitions.

Turbines and Governors. Turbines Nos. 1 and 2 are designed for 52,000 hp. and Nos. 3, 4, and 5 for 55,000 hp., all at 305 ft. head, the speed being 187.5 r.p.m. They are of the single-runner vertical

type, set in spiral cast-steel casings. The inlet diameter of the casings is 10 ft. In Nos. 1 and 2, manufactured by the Wellman-Seaver-Morgan Company, of Cleveland, the casings are divided into nine sections with a separate speed ring, while in Nos. 3, 4, and 5, manufactured by the Wm. Cramp & Sons Ship & Engine Building Company, of Philadelphia, the speed ring is cast integral with the casing and the whole divided into 12 sections. The weight of the casing and speed ring in Nos. 1 and 2 is 240,000 lb., while in 3, 4, and 5 it is 180,000 lb.

The runners are made of cast steel in one piece and provided with special renewable seal rings. Those for Nos. 1 and 2 are 125 in. in diameter, and those for Nos. 3, 4, and 5 are 121 in. in diameter.

The gate control is the usual double-regulating-cylinder type operating through rods to a shifting ring connecting to the individual gates through specially designed breaking links.

All parts of the turbines adjacent to rotating elements and to water passages subjected to high velocities are made of special steel and renewable. The main-journal guide bearing on each unit is of the water-lubricated lignum vitae type, such as has been used on all modern vertical-turbine plants. This type of bearing has been selected on account of its simplicity and low maintenance cost.

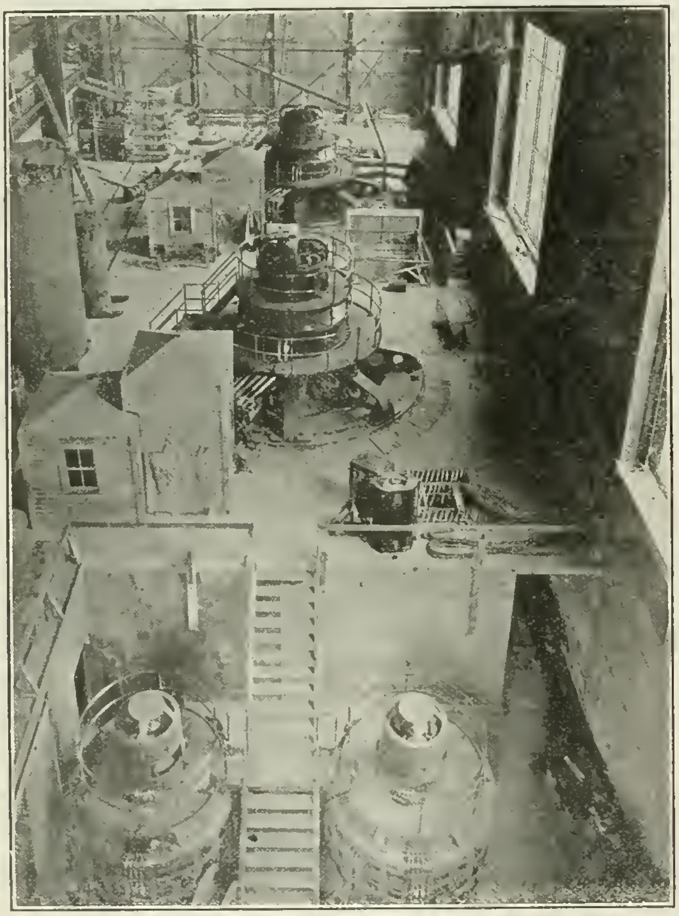

Fig. 6 Interior View of Generator Room

The draft tubes are all of the Moody spreading type except that of No. 1, which is a bent tube.

On account of the limitations in the use of water at Niagara the runners are designed to obtain their maximum efficiency at a point about 10 per cent below their maximum rated output, at which load for the most part they are operated. This condition required that the runners be larger than would normally be used and that the turbines be "gated back." With the gates full open actual tests have shown that the capacity of Nos. 1 and 2 is 60,500 hp. each, and of Nos. 3, 4, and 5, 65,500 hp. each, under 305 ft. head.

Exhaustive tests have been carried out on the units, using the Gibson "pressure-time" method for determining the discharge. The maximum efficiency obtained on each turbine was 93 per cent, exceeding, so far as is known, any figure heretofore recorded on a commercial operating turbine. Fig. 5 shows a turbine casing erected in place.

The governor actuator is set on the generator floor, the flyballs being driven by belt from the turbine shaft. The main valve is located adjacent to the turbine regulating cylinders, 35 ft. below the actuator. To meet the conditions of this layout the pilot valve is hydraulically coupled to a small piston valve which is mechanically connected to the pilot valve of the main dog valve. The hand-control stand is located on the generator floor and operates the regulating cylinders through the governor pressure system.

The governors are operated on the "central" type of pressure system. Two motor-driven centrifugal pumps, each delivering 500 imp. gal. per min., and located adjacent to two 3000-gal. sump tanks built into the concrete substructure of the power house, deliver the governor fluid at a pressure of 200 lb. per sq. in. to a header from which branches are connected to the governors through individual pressure tanks. The capacity of one pump is sufficient to operate five governors.

The fluid used in the governor system is filtered water in which is dissolved, 7 lb. potassium bichromate to every 1000 gal. water. This fluid does not corrode the valve seats and has proved satisfactory in service.

Service Turbines. The two service-turbine casings have a 30-in. inlet diameter and runners of 42 in. outside diameter. The gate mechanism is of the "outside" type, similar to the main turbine.

The governor is the "direct-connected" type, and the pressure liquid is ordinary lubricating oil. The flyballs are mounted upon the main turbine shaft, and the governor stand with self-contained pumping unit is placed on the turbine floor.

A band brake is furnished in order to assist in bringing the unit to a quick stop when necessary.

Johnson Valves. A Johnson valve is located on each penstock near the entrance to the turbine casing. The action of this type of valve has been frequently described in other papers. The control of the Queenston valve is made through the operation of three small Johnson valves which automatically adjust the flow into the central and annular chambers so that the main valve plunger cannot travel at a dangerous rate. The closing stroke is cushioned at the end, and in the opening stroke the plunger moves just sufficiently to permit the wheel case to be primed before completing its stroke. An emergency handle is located on the control stand on the generator floor by which an operator can close the Johnson valve in case of trouble. The valve can be opened only from the control located adjacent to the valve itself.

Acres Control Pedestal. For the purpose of the floor operation of each unit, a pedestal is erected adjacent to each generator. On this pedestal are mounted the pressure and vacuum gages for the turbine, signal light and loud-talking telephone from the control room, temperature indicators from the generator windings, oil- and water-flow indicators, a control for the air brakes, and the emergency closing control for the Johnson valve. An operator standing at the pedestal is in close communication with the control room and at the same time has under his hand the control of the turbine governor and Johnson valve. The signal lights operated from the control room call the floor operator to any unit desired.

Generators. The present five units are each rated at 45,000 kva., 80 per cent power factor, 12,000 volts, three-phase, 25 cycles at 187.5 r.p.m. They are capable of being operated continuously at 49,500 kva. with either voltage or current 10 per cent in excess of the rated values. The type is vertical (see Fig. 6) with direct-connected, shunt-field, commutating-pole, 250-volt, 150-kw. exciter. The overall efficiency of the generating units is slightly in excess of 97 per cent at 80 per cent power factor. The thrust bearing is designed to support a load of one million pounds, which is slightly more than the weight of the rotor plus the hydraulic thrust imposed by the turbine. Upper and lower guide bearings are provided, the latter on account of the length of shaft and to keep the generator a self-contained unit.

The overall diameter of these units is 25 ft., the diameter of rotor over pole faces being 18 ft. approximately. The shafts are 30 in. in diameter in the guide bearings and are provided with a flange at the lower end for bolting to a corresponding one on turbine shaft. The shafts are hollow with an 8-in.-diameter bore and are 30 ft. 3 in. in total length. The overall height of the generators

above the generator floor is 26 ft. 10 in., thus above the main floor only the top of the frame and the upper bracket, thrust-bearing housing, and exciter are visible (Fig. 6).

The weight of the complete generator is 1,400,000 lb. and that of the rotor, 615,000 lb. The largest piece to be handled by the cranes weighs 600,000 lb.

It was specified that there should be a thrust bearing at the top to carry the weight of the rotating part and the total thrust due to turbine at rated speed and at overspeed; that the rotor be capable of operating at an overspeed of 347 r.p.m. without injury to any part; also that provision for easy handling of various parts be made.

Contracts were placed with two manufacturers who used different methods in constructing the generators, the general difference being that one made use of a built-up laminated sheet-steel rotor rim mounted on a small cast-steel spider; of cast iron in the upper and lower bearing brackets; and of a Kingsbury thrust bearing to carry the rotating parts; while the other used a rotor consisting of seven cast-steel wheels shrunk on to the shaft; cast steel in the upper and lower bearing brackets; and a thrust bearing with stationary bearing plate supported on a large number of small springs. Both manufacturers used forged-steel hollow shafts of approximately the same dimensions, which were 30 in. in diameter in the guide bearings and had a forged half-coupling at the lower end.

The steel forgings and steel and iron castings were required to meet the specifications of the American Society for Testing Materials. With reference to the steel castings, particularly those of large section such as are used in the cast-steel rotor wheels, attention is drawn to the advisability of not depending entirely on small test pieces attached to the casting to determine if the annealing has been properly carried out. It is the practice of the Commission on these large rotor castings to require that test pieces taken from 4-in. by 4-in. blocks 12 in. long cast on the outside and underside of the rim meet the specification requirements, also that core-drill samples be taken from the rim at the ends of the arms and if possible from between the arms, these samples being tested and examined to determine the quality of the metal.

The two types of bearings provided are interchangeable in the housings as constructed. In the Kingsbury bearing the shaft is supported on the thrust bearing by a nut threaded on the upper end of the shaft. The nut rests on a thrust collar which rests on the runner plate of the thrust bearing. The runner plate is of cast iron with a very highly finished surface, being true to 0.0002 in.

The stationary bearing surface consists of six babbitted sector-shaped shoes, each mounted on a support on the head of a jack screw so that it is free to tilt.

The maximum diameter of the runner plate is 69 in. The total area of the shoes is approximately 2500 sq. in., so that the unit pressure is 380 lb. per sq. in.

In running, a wedge of oil is dragged between each shoe and the runner plate, the shoe tilting sufficiently to accommodate this wedge, so that the rotor floats on a film of oil.

The friction losses in this bearing at normal load and speed are approximately 90 hp. Lubricating oil is circulated at the rate of about 4 gal. per min. between the purifying system and the bearing housing.

In the spring type of bearing the thrust is taken from the shaft to a cast-steel thrust collar by means of a shear key in a groove in the shaft. The groove is 3 in. wide and the shaft 29 in. in diameter. The thrust collar rests on a runner plate of cast iron 69 in. in diameter and is attached by two 2-in. dowel pins to prevent relative rotation. The carefully finished surface of the runner plate runs on a stationary steel ring with a babbitted surface, which in turn is supported on a nest of over 700 steel spiral springs. The babbitted ring is split in one place radially to give flexibility and the surface is radially grooved to allow oil to reach the rubbing surfaces. The unit pressure is about 265 lb. per sq. in. of bearing surface at 960,000 lb. total downward thrust. Total loss in the bearing is about 125 hp.

Growth in Demand for Hydroelectric Power

The first five units of the Queenston-Chippawa development are now in operation and the other units are being installed as rapidly as possible, and when completed the Commission will have a generating capacity for the Niagara District of over 900,000 hp., including the Toronto Power Co. and the Ontario Power plants.

Since 1910 the demand for "Hydro" service from the Commission has grown from an output of 750 hp., taken by 10 urban municipalities, to one of 628,000 hp. (of which 75,000 hp. is exported) taken by 250 municipalities and 97 townships supplying 335,000 consumers.

Realizing as it does the large amount of time—often several years—that must elapse between the initiation of a new, extensive water-power development and its being brought to the stage where commercial power can be delivered, the Hydro-Electric Power Commission has always been compelled to take early action on behalf of municipalities for the creation of new sources of supply for electrical energy. It has sometimes required a good deal of courage on the part of the officers of the Commission to incur heavy financial outlay years in advance of the actual demonstration of markets to absorb electrical output, but, in no instance, has its judgment eventually been found to have been in error.

At the present time, all evidence points to the fact that by the end of the year 1926 the existing provisions made for the supply of electrical energy to municipalities will be fully taxed and no spare power will be available. The output of the Queenston-Chippawa plant will have been absorbed. The Commission has considered the possibility of producing further power at Niagara Falls, but the chairman of the Commission, Sir Adam Beck, has stated from the public platform that he believes that it would be more profitable for all concerned to turn to the St. Lawrence River for the next large hydroelectric development.

Power on the St. Lawrence River

The province of Ontario shares with the state of New York the water power in the international stretch of the St. Lawrence River extending from Prescott to the international boundary. In this portion of the river there is a possibility of developing upon a conservative basis about 1,600,000 hp., of which 800,000 hp. would belong to Ontario. For several years the Commission has been conducting special surveys and investigations with the view of determining the best means of developing the international reach of the river in the joint interests of power and of navigation.

The International Joint Commission has had the problem of the most efficient development and utilization of the St. Lawrence river in the joint interests of navigation and power referred to it for report. The Commission reported about a year ago to the International Joint Commission in detail on the development of the St. Lawrence, but, so far as is known, the two governments interested—the United States and the Dominion of Canada—have announced no decision respecting the development.

This international stretch of the river is a feature which must be considered in its relationship to the larger project of dealing with the Great Lakes route to the sea. The necessity for additional power in Ontario is urgent; but this can be dealt with at once without making any improvements to the St. Lawrence River for navigation purposes, except in so far as they affect the power works contemplated.

Rates Charged for Electrical Energy

One of the basic principles upon which the Hydro-Electric Power Commission of Ontario operates is the furnishing of electrical energy to consumers *at cost.* Time and again, it has been stated that the rates for light and power resulting from the efforts of the Commission were much less favorable than those prevailing in other places. However, the author wishes to state that nowhere in the world over such extensive areas do communities and citizens obtain electric power and light at such low rates as prevail throughout the hydro municipalities in the province of Ontario, namely, from 1.5 to 3.1 cents per kw-hr. for residence and commercial service, and from $13.26 to $25.14 per hp-year for power service.

The secret of the phenomenal growth of the operations of the Commission lies in the fact that as the trustee and agent of coöperating municipalities it has made available to them electrical energy *at cost,* which they have then distributed and vended to their individual consumers at *as near cost as possible.* Moreover the Commission has made its distribution of energy to small municipalities and to rural districts, and the demand of these small municipalities aggregates a substantial load. Electrical energy, once a luxury, has now become a common commodity of the people.

Discussion on Papers on Hydroelectric Powers in Canada

THE preceding papers, Power Development in the Province of Quebec, by Julian C. Smith, and Development of Hydroelectric Power in Ontario, by Frederick A. Gaby, were presented at the first power session of the Spring Meeting, held on Tuesday morning, May 29. Prof. A. G. Christie was presiding officer. Mr. Smith's paper was presented by P. S. Gregory, one of his associates.

F. Darlington,[1] who opened the discussion on these papers, gave emphasis to a statement by Mr. Gaby, pointing out that economic operations were rapidly extending the application of power and that it was most important that the supply should keep pace with the need. He referred to certain features of the power industry that were international in their scope, such as the increased centralization and unification of power service by interconnecting and expanding existing electric systems. This he characterized as the greatest forward step that could be taken to put cheap and dependable power within reach of all. He stated that it was not enough to have a huge power plant at Niagara Falls or on the St. Lawrence or in the Pennsylvania coal fields, for while power confined to these places might be used in factories or electrochemical works located at the source, its more general use and broader application must be through wide distribution to industrial and social needs. Only by wide distribution from the best natural power resources, could the public be properly served.

Of the two basic resources for power generation—fuel and water—one was conserved by saving it, the other was lost if it was not used; but where both were available the best conservation was achieved by using them to supplement each other. Then also, whichever source of power was used there must be great generating plants and power-transmission systems, and conservation required that the fullest possible use should be made of these structures.

All the conditions for conservation and high economy were enhanced by interconnections between electric systems to combine the loads into big blocks and permit the use at all times of the most economical available source of power; and when new generating plants were built always the most efficient source of power within the area of the interconnected system could be used, whether it was a water power or a steam plant at a coal mine, or at tidewater or elsewhere.

In this connection Mr. Darlington called to mind the idea sometimes erroneously held, that if any given electric company had the cheapest source of power within practical transmission distance, such a company would have little or nothing to gain by tying in with other less fortunately situated concerns. This, he said, was radically wrong, even from a purely selfish point of view, for the more economical a generating plant might be, the more important it was that the fullest possible use should be made of it, and interconnection in great superpower systems brought opportunities for the fullest use of the most efficient plants, with corresponding economy and conservation. For example, a superior coal-mine plant, say in Pennsylvania, would gain much by interconnection with a New England, New York, or New Jersey superpower system, or still more by interconnection with the St. Lawrence, for by such means it would secure a fuller use of its plant, and a relay or breakdown connection for use in case of emergency.

Mr. Darlington referred to a statement made by Mr. Smith that the powers of Quebec would be fully utilized in 29 years, urging conservation through the best utilization of both water power and steam power by coördination and interconnection with United States resources.

John R. Freeman,[2] paid a tribute to the foresight of the Canadian Water Power Branch in studying the water-power resources long in advance of demand and seeing that each was developed to the best of its possibilities. They had mapped everything out before it had any real commercial value and had surveys on record so that when there was development there should be no tendency to make use of the best and leave the rest. The work of the Water Power Branch of the Dominion Government, he said, was model for the whole world, and there had been little appreciation of the magnificent work that it had been doing for twenty years not only in surveying water-power sites but also in the actual building of storage reservoirs.

Mr. Freeman referred to his early days in water-power work, fifty years ago, when he was with the water-power company at Lawrence, Mass. At that time there were about seventy turbines in Lawrence for a total of about 15,000 hp., and it used to be said that the Merrimac River was the hardest-worked river in the world. Now a single one of the Chippawa turbines had a greater capacity than all those seventy turbines at Lawrence plus all the turbines then at Lowell and Manchester.

W. M. White,[3] thought the hydroelectric achievements in Ontario and Quebec as described by the speakers were a striking illustration of what the engineer could do in developing nature's resources. The reason why the American manufacturer could compete successfully in the markets of the world and yet pay higher wages than his foreign competitors was because each American workman had behind him more horsepower per man than his competitor's workman had. Since the cost varied directly as the amount of power expended in production, it naturally followed, by inevitable law of competition, that the workman who could direct the greatest amount of power would receive the greatest wage. He urged on the engineers that they recommend the development of power in any form.

Mr. Gregory[4] took up the question of interconnection of plants, interpreting Mr. Smith's statement that the electric steam generator was a necessary adjunct to all hydroelectric plants. This statement did not refer to a steam stand-by plant in connection with the hydro. It was not the custom, he said, to have steam stand-by plants, but as in all rivers in Canada the flow varied very greatly in different seasons, there were times in the year when water must be spilled over the dam, and it was in order to utilize this water that electric steam generators were being used and had been pushed to a high state of development. He mentioned as examples two electric steam generators in the plant of the Laurentide Company at Grand Mere which, united, had a capacity of 2500 kw., or 2500 steam b.hp., and also to a steam generator in the mill at Shawinigan having a capacity of about 3000 kw. or 3000 b.hp. The power that was used in these steam generator was surplus power which would otherwise spill over the dam. The interconnection which was made use of in Canada was interconnection of water-power plants on different rivers, on different watersheds where the periods of high water varied. For instance, if the plants which were now developed or would be developed on the Saguenay River could be connected with the plants developed on the St. Lawrence, there would result a far shorter period of low water because the high-water period on the Saguenay was from three weeks to a month or more behind the high-water period on the St. Lawrence. This would also apply to plants farther west which had their high-water period earlier than those on the St. Lawrence.

Mr. Gaby commented on Mr. Darlington's statement in regard to interconnection, mentioning illustrations of interconnection in the Ontario systems.

Mr. Freeman inquired as to the difference between steam-generated electricity and electricity generated by coal, that is, assuming coal to be worth an ordinary price of $8 or $10 a ton what did the companies get for their water power per year when they put it into steam boiler horsepower ?

Mr. Gregory, in reply, said that one kilowatt-hour of electrical energy would produce about 3 lb. of steam at ordinary pressure, say 125 lb. per sq. in. There were 3412 B.t.u. in a kilowatt-hour. Taking the average of evaporation of $7^1/_2$ lb. of steam per pound of coal, which was a reasonable average, one ton of coal would produce 15,000 lb. of steam; therefore 5000 kw-hr. was the equivalent of one ton of coal, and if a ton of coal cost $10, the 5000 kw-hr. would be worth two mills each. There were 6500 kw-hr. in one horsepower-year at 100 per cent load factor. At two mills each they would be worth $13 per horsepower-year, and so on in that regular ratio.

Effect of Feedwater Heating on Plant Economy

Studies of a Plant Equipped with 30,000-Kw. Units Which Clearly Indicate the Advantage of Bleeding the Main Turbine Both in Plants With and Without Economizers

By G. G. Bell,[1] Pittsburgh, Pa.

The effect of feedwater heating on plant economy is very interestingly discussed in a paper presented by Linn Helander[2] at the A.S.M.E. Annual Meeting, December, 1922. Mr. Helander has made a very complete study of the subject, and shows the theoretical relation between plants equipped with large and small house turbines, both with high boilers without economizers and medium-sized boilers with economizers.

In the spring of 1922 two more 30,000-kw. units were purchased for the Windsor station of the West Penn Power Co., Pittsburgh, Pa., the boiler-drum pressure was raised from 250 to 350 lb., and on account of this higher pressure steel-tube economizers were substituted for the cast-iron economizer which had been installed with the first 16 boilers in the plant.

The troubles which other plants had had with corrosion in steel-tube economizers necessitated the installation of deaërating apparatus. Manufacturers of deaërating apparatus claimed that air separation was easier at temperatures above 160 deg. fahr. Experience with a closed system of feedwater heating which prevented enrichment had maintained an average oxygen content in the feedwater above 0.25 cc. per liter, provided the feedwater temperature was maintained around 210 deg. fahr. Investigations of an existing plant equipped with economizers had indicated some advantages in increasing the feedwater temperature to 210 deg. fahr. by utilizing the exhaust steam from a house turbine of sufficient size

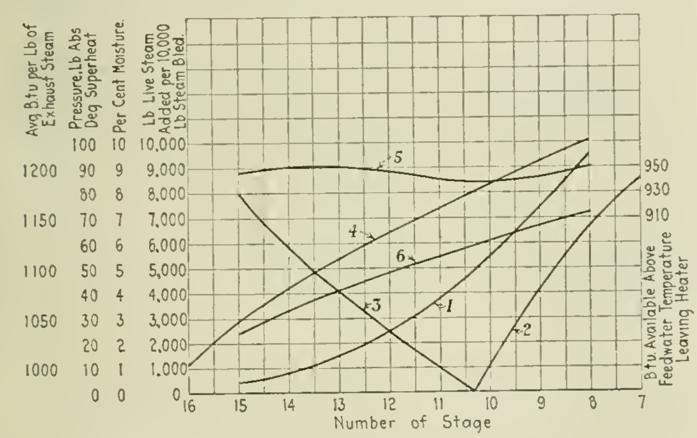

Fig. 1 Data on Steam Extracted from 30,000-kw. G. E. Curtis Turbine

(Steam condition, 300 lb., 200 deg., and 1 in. back pressure; load on turbine, 28,000 kw.
Curve 1—Absolute pressure at various stages
Curve 2—Deg. superheat in steam bled from the various stages
Curve 3—Percentage of moisture in bled steam
Curve 4—Average B.t.u. per lb. of bled steam

Curve 6—No. of lb. of live steam that must be added to permit extraction of 10,000 lb. of steam at various bleeding points.)

to supply the auxiliaries with power; although subsequent investigations have demonstrated that probably there would be a slightly higher saving if the study had been made for a temperature of 190 deg. instead of 210 deg.

In the new addition it was decided to heat the condensate by steam bled from the main unit instead of exhaust steam from the house turbine, and it was thought that the best temperature at which the feedwater should enter the economizers should not be less than 210 deg. on account of the more efficient use of the steam in the main unit. To check this a study was made, as a result of which it was decided to heat the feedwater to the highest temperature possible by extracting steam from the thirteenth stage.

Upon the preparation of Mr. Helander's paper, these studies were revised. Additional data on the turbine were obtained so as to give complete information for bleeding all stages from the eighth to the fifteenth, inclusive, and the effect on the economy of the station of single-, double-, and triple-stage bleeding within these limits was studied.

Data on steam extracted from the 30,000-kw. G. E. Curtis turbine at a load of 28,000-kw., steam conditions at throttle 300 lb., 200 deg., and 1 in. back pressure, are shown in Fig. 1.

In determining the temperature to which the feedwater could be heated by each of the various stages, it was assumed that there was

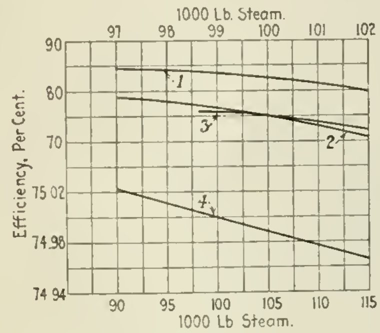

Fig. 2

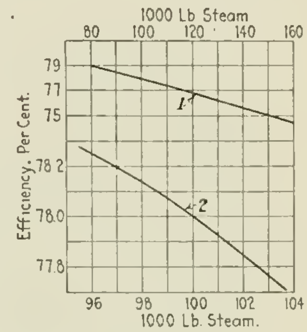

Fig. 3

Fig. 2 Efficiency of 14-High Cross-Drum B. & W. Boiler

(8341 sq. ft. of steel-tube economizer; steam pressure at drum, 325 lb.; temperature at superheater outlet, 225 deg. fahr.; feedwater temperature, 210 deg. fahr.)

Fig. 3 Efficiency of 20-High Cross-Drum B. & W. Boiler

(No economizer; steam pressure at drum, 325 lb.; temperature at superheater outlet, 225 deg.; feedwater temperature 210 deg.)

a loss between the turbine and the heater of 1 lb. when steam was extracted from the fifteenth stage, of $1^1/_2$ lb. when extracted from the fourteenth stage, and 2 lb. when extracted from the thirteenth or any higher stage; and that in all cases the maximum temperature to which the feedwater could be heated was 10 deg. lower than the temperature corresponding to the pressure of the steam at the heater.

The boilers purchased for Windsor are Babcock & Wilcox cross-drum boilers 14 tubes high and 42 tubes wide, and are equipped with a slag screen and Babcock & Wilcox inclined baffle. The front headers are set 21 ft. above the floor, the drum center being 35 ft. 3 in. Four boilers are provided per unit, although it was assumed that when the turbine was operating at its point of best efficiency, which is 28,000 kw., three boilers would supply steam for the unit, the output of each boiler being about 100,000 lb. when feedwater is supplied at a temperature of 210 deg.

The extra boiler capacity would be utilized in reducing the rating on the boilers in the older section of the plant, which are not as efficient or as liberally stokered as the newer boilers.

Fig. 2 shows the efficiency of the new boiler and steel-tube economizer at various ratings. Curve 1 shows the combined efficiency of boiler and economizer; curve 2 the efficiency of the boiler alone, and curve 3 the boiler efficiency corrected for the effect of change in capacity on the efficiency of the economizer. Curve 4 is that portion of curve 3 which is used, amplified so as to permit of reading any slight variation in the relative efficiency of the boiler when operating at slight differences in output.

These figures are based upon 12 per cent CO_2. It is necessary in order to compare the results of bleeding from various stages to work to a fraction of one per cent. All computations were checked by the comptometer.

Fig. 3 presents similar data for a 20-tube-high boiler without economizers. Curve 1 gives the efficiency of the boiler at various ratings, while curve 2 is that portion of curve 1 which is used, amplified so as to permit of reading any slight variation in the relative

[1] West Penn Power Co., Pittsburgh, Pa.

[2] Feed Heating for High Thermal Efficiency, by Linn Helander, Trans. A.S.M.E., vol. 44; also (abridged) Mechanical Engineering, February, 1923, p. 105.

efficiency of the boiler when operating at slight differences in output.

In connection with the 14-tube-high boiler, 8341-sq.-ft. steel economizers are installed. Table 1 gives the rise in the economizers when operating at a constant output of 100,000 lb. of steam per hour with feedwater temperatures of 135, 170, 210, and 250 deg.

TABLE 1 TEMPERATURE RISE IN ECONOMIZERS WHEN OPERATING AT A CONSTANT OUTPUT OF 100,000 LB. OF STEAM PER HOUR WITH VARIOUS FEEDWATER TEMPERATURES

	Feedwater temperatures, deg. fahr.			
	135	170	210	250
Gas temperature entering economizers, deg. fahr.	595	595	595	595
Gas temperature out of economizers, deg. fahr	297	319	345	370
Drop in economizers, deg. fahr.	298	276	250	225
Average gas temperature, deg. fahr.	446	457	470	482.5
Water inlet to economizers, deg. fahr.	135	170	210	250
Estimated rise in economizers, deg. fahr.	128	118	107	96
Temperature of water leaving economizers, deg. fahr.	263	288	317	346
Average water temperature, deg. fahr	199	229	263.5	298
Average thermal difference in economizers, deg. fahr.	247	228	206.5	184.5
Rise in economizers, deg. fahr.	128	118.4	107	95.8

The figures are derived from guarantees based on 210-deg. feedwater and are proportional to the arithmetical mean of the temperature differences.

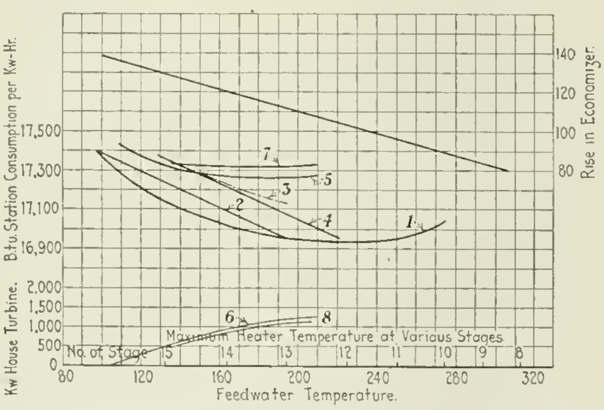

Fig. 4 Comparison of Effect on Station Economy of Heating Feedwater by Exhaust Steam from House Turbine, Efficient Duplex-Driven Auxiliaries and Single-Stage-Extraction Heating

(North extension of Windsor power station. 30,000-kw. G. E. turbines, 28,000-kw. load; 14-high cross-drum B. & W. boilers; induced draft; 60 per cent economizer; steam conditions at throttle, 300 lb., 200 deg., 1 in. back pressure.)

These results are plotted in Fig. 4, which also shows a comparison of single-extraction heating and heating the condensate by exhaust steam from a house turbine if the Windsor plant is equipped with a 14-tube-high boiler and 8341-sq.-ft. economizers.

Curve 1 shows the heat consumption of the plant if the turbine is arranged for single-stage bleeding. These results are arrived at by calculating the heat requirements with bleeding at various stages from the tenth to the fifteenth, and drawing a curve through the points thus obtained. The curve represents the results which might be obtained if the turbine were designed with an infinite number of stages and could be bled at any one of them. As a matter of practice these results can only be obtained when steam is bled from any one of the six stages coming within the limit of this curve and the feedwater is heated as hot as possible by the steam extracted from the turbine.

Curve 2 shows the effect of bleeding from the thirteenth stage and throttling the amount of steam bled so as to get a varying temperature. This is practically a straight line. For the purpose of this study the condensate was assumed to be heated first approximately 20 deg. by the heat contained in the steam escaping from the steam seal. Twenty degrees is also the amount the condensate would be heated if before passing into the first bleeder heater it first cooled the generator air and then absorbed the heat in the bearing and transformer oil for the unit.

On curves 1 and 2 it was assumed that the boiler-feed pump was motor-driven. If in place of a motor-driven boiler-feed pump a steam-driven pump is used, curve 3 will represent the heat requirements of the station. When sufficient steam is bled from the main unit to heat the feedwater to the maximum obtainable from the thirteenth stage, the heat consumption in the plant equipped with a motor-driven pump is approximately 1 per cent less than in one provided with a steam-turbine-driven pump. This is when the exhaust steam from the steam-driven boiler-feed pump is discharged into the same heater as the steam bled from the main unit. When using a steam-driven boiler-feed pump the minimum temperature increased from 97.5 to 127.5 deg. fahr.

Curve 4 shows the results if steam from the boiler-feed pump is discharged to a separate heater and used to heat the feedwater sufficiently above the temperature of the feedwater leaving the extraction heater to get the necessary reëvaporation to permit the deaërator to function satisfactorily. Where the pressure will permit, the exhaust steam from the turbine glands is discharged into the same condenser as the exhaust steam from the boiler-feed pump. The curve indicates that approximately the same results can be obtained by using the turbine-driven pump as with the motor-driven pump, provided that separate heaters are used and the feedwater is heated approximately 25 deg. above that used with a motor-driven-boiler-feed pump.

Curve 5 shows the results which would be obtained if the feedwater were heated by exhaust steam from a house turbine. Guarantees were obtained on house turbines designed for three different back pressures, and in figuring this curve the steam consumption used in each case would apply only if a special house turbine were designed for the operating conditions under consideration. This curve indicates that there is very little difference in the economy of using a house turbine in connection with the 14-tube-high boiler and 60 per cent economizer with feedwater temperatures between 170 and 190 deg. Assuming that this house turbine had been bought for a back pressure corresponding to 180 deg., if the feedwater temperature were then varied by increasing or decreasing the output from the house turbine, the heat requirements of the plant over the range would be higher than shown in curve 5, and would only coincide with that curve when using a feedwater temperature of 180 deg., the point for which this particular turbine was designed.

Curve 6 shows the amount of power which can be obtained from the house turbines when heating the feedwater to the temperatures shown in curve 5.

Curve 7 shows the results which would be obtained if the feedwater were heated by exhaust steam from efficient high-speed geared turbines driving the auxiliaries. In this case one design of turbine is used and operated with various back pressures, so that full advantage is not taken of the increase in vacuum which it is possible to get with the lower feedwater temperature. The water rate for various feedwater temperatures is given in Table 2.

TABLE 2 WATER RATE FOR VARIOUS FEEDWATER TEMPERATURES

Final feedwater temperature, deg. fahr.	Back pressure on turbine exhaust, lb. per sq. in.	Water rate, lb. per brake hp-hr.
135	4.53	16.5
170	7.99	17.0
210	16.13	21.0

The curve indicates that within the range of the temperatures under consideration there is practically no difference in the heat requirements of the plant, although if the small geared sets were so designed as to show an increase in economy with a decrease in back pressure, it would pay to lower the feedwater temperature to the lowest point that was practicable and still prevent the sweating of the economizer tubes.

Curve 8 shows the amount of power generated by the geared-turbine-driven sets. The reason that curves 5 and 7 approach each other at the lower temperatures is that the house turbine is of larger capacity and at low feedwater temperatures is operated at part loads, whereas in curve 7 it is assumed that only enough of the gear-driven units are run to give the required temperature when each turbine is carrying the maximum load.

Fig. 5 shows a comparison of results on the Windsor plant if the turbine were arranged for single-, double-, or triple-stage extraction heating and the plant equipped with 14-tube-high boilers and 8341-sq.-ft. economizers.

Curve 1 shows the heat consumption of a plant arranged for single-stage bleeding at any of the temperatures within the limits of the curve. This curve is the same as curve 1 of Fig. 4 and shows best results at a feedwater temperature of 225 deg. fahr., with a very slight increase in heat requirements by increasing or decreasing the feedwater temperature 25 or 30 deg.

Curve 2 shows the heat consumption of a plant arranged for bleeding from the fourteenth and a higher stage.

Curve 3 shows the heat consumption when bleeding from the thirteenth stage and a higher stage.

Curve 2 shows that minimum heat requirements are obtained by a combination of the fourteenth and twelfth or eleventh stages at a temperature of 225 or 251 deg. fahr.

Curve 4 shows that the best results with triple-stage heating are obtained with a combination of the fourteenth, twelfth, and tenth stages, the best results being obtained at a temperature of 275 deg. fahr.

Curve 5 shows the heat consumption with triple-stage heating using the fourteenth, eleventh, and a higher stage. This combination is not as efficient as that shown in curve 4.

These studies are all made for a plant operated with a motor-driven boiler-feed pump. They indicate that there is very little difference between bleeding the eleventh, twelfth, or the thirteenth stage with single-stage heating; and that for double-stage heating a combination of the fourteenth and twelfth or eleventh stages gives the best result, the heat requirements per net kw-hr. being about 16,750 as against 16,940 B.t.u. for single-stage heating. In triple-stage heating a combination of the fourteenth, twelfth, and tenth stages gives the best results, the heat requirements for triple-stage bleeding being about 16,600 B.t.u. as compared with 16,750 B.t.u. for the double-stage heating and 16,940 B.t.u. for single-stage heating.

While there are a number of points to consider in obtaining plant requirements, the work can be reduced to a comparatively simple form; and with a set of curves such as those in Fig. 1 which give information for various stages and temperatures, etc., a point can be determined every twenty minutes by using a slide rule. However, a slide rule is not accurate enough to give smooth curves.

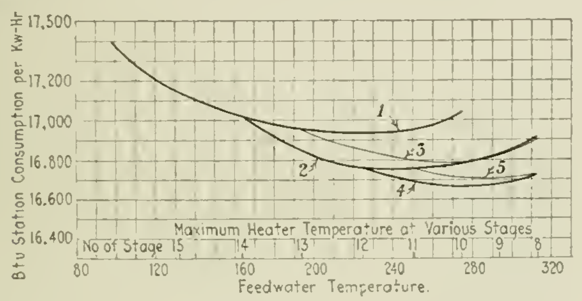

Fig. 5 Effect of Single-, Double-, and Triple-Stage Extraction Heating on Feedwater Temperature and Station Economy

(North extension of Windsor power station. 30,000-kw. G. E. turbines, 28,000-kw load; Steam conditions at throttle: 300 lb., 200 deg., and 1 in. back pressure. 14-high cross-drum B. & W. boiler; 60 per cent economizer; induced draft.)

In order to illustrate the method used in making these computations the formulas employed are given below, the following notation being adopted.

- A = pounds of steam required by main turbine to produce 28,000 kw. per hour when no steam is extracted from turbine
- X = thousands of pounds of steam bled from main unit to heat the feedwater in the first-stage heater
- Y = thousands of pounds of steam bled from main unit to heat the feedwater in the second-stage heater
- Z = thousands of pounds of steam bled from main unit to heat the feedwater in the third-stage heater
- r_x = pounds of steam which have to be added per thousand pounds extracted from the x-stage
- T_c = temperature in deg. fahr. of condensate leaving main condenser
- T_x = temperature of condensate leaving a heater supplied with steam from the x-stage
- B = pounds of steam entering condenser
- C = B.t.u. by test in the amount of steam required for sealing the high-pressure gland of main unit. This is a constant and is 5,500,000 B.t.u. above the liquid temperature of 78 deg. Where it is desired to use the number of B.t.u. in the gland steam above 32 deg., a figure of 5,700,000 is used
- D = total pounds of live steam to be supplied to turbine
- E = net kw-hr. put out by plant
- H_x = average total heat in steam bled from main unit at the x-stage
- F = equivalent pounds of steam that each boiler would evaporate if supplied with feedwater entering the 20-high boiler (or the economizer in case boiler is equipped with economizer) at 210 deg. fahr.
- H_s = total heat in steam leaving superheater
- h_x = heat in the condensate above 32 deg. after being heated by the steam bled from the main turbine at the x-stage
- R = rise in economizer after condensate has been heated by steam extracted from the one or more stages of the main unit
- R_{210} = rise in economizer when condensate enters economizer at a temperature of 210 deg.
- B_e = boiler efficiency
- P_e = ratio between results which we expect to get in ordinary operation as compared with the results which might be expected from manufacturer's guarantees. This ratio includes the plant losses from condensation, steam leaks, soot-blower loss, radiation from steam pipes, etc.
- G = total steam output of boilers in operation supplying each unit. In this study each boiler was assumed to have an efficiency of 75 per cent when the boiler and economizer together were supplying 100,000 lb. of steam per hour or 78 per cent when steam was supplied by a 20-high boiler operating at the same output.

Total live steam to turbine $= A + Xr_x + Yr_y + Zr_z$

Amount of steam to be bled by first-stage heater:

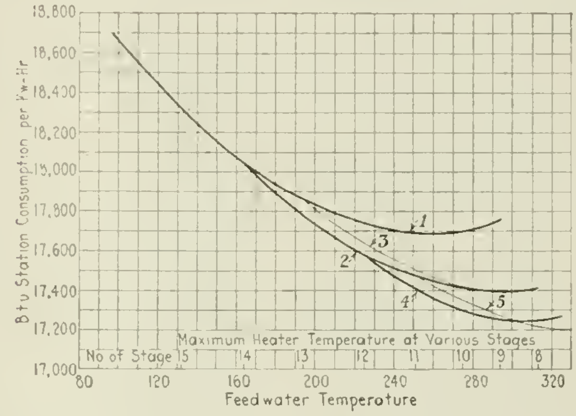

Fig. 6 Effect of Single-, Double-, and Triple-Stage Extraction Heating on Feedwater Temperature and Station Economy

(North extention of Windsor power station. 30,000-kw. G. E. turbines, 28,000-kw. load. Steam conditions at throttle: 300 lb., 200 deg., and 1 in. back pressure. 20-high cross-drum B. & W. boilers; no economizer; natural draft.)

$$X = \frac{(A - X - Y - Z + Xr_x + Yr_y + Zr_z)(T_x - T_c) - C}{H_x - h_x}$$

Amount of steam to be bled by second-stage heater:

$$Y = \frac{(A - Y - Z + Xr_x + Yr_y + Zr_z)(T_y - T_x)}{H_y - h_y}$$

Amount of steam to be bled by third-stage heater:

$$Z = \frac{(A - Z + Xr_x + Yr_y + Zr_z)(T_z - T_y)}{H_z - h_z}$$

To find the relation between X and Y, by changing the form of the equations we get

$$\frac{X(H_x - h_x) + C}{T_x - T_c} = A - X - Y - Z + Xr_x + Yr_y + Zr_z$$

$$\frac{Y(H_y - h_y)}{T_y - T_x} = A - Y - Z + Xr_x + Yr_p + Zr_z$$

Subtracting,

$$Y = \left[X + \frac{X(H_x - h_x) + C}{T_x - T_c}\right]\left(\frac{T_y - T_x}{H_y - h_y}\right)$$

All the quantities in the above equation are known except X and Y, so that a definite relation can be established between them.

Similarly, by combining the expressions for Y and Z the relation between them will be found to be

$$Z = Y\left[1 + \frac{H_y - h_y}{T_y - T_x}\right]\frac{T_z - T_y}{H_z - h_z}$$

Substituting the known values for a combination of the fourteenth, eleventh, and eighth stages we find that these equations when solved give simple answers.

$$Z = 0.771Y$$
$$Y = 1.110X + 5915$$
$$Z = 0.771Y = 855X + 4550$$

Substituting these values of Y and Z in the equation for X permits us to find X, and as the relations of X to Y and Z are known

we can then readily find the amount of steam bled at each stage; and multiplying this by the ratio of the amount of live steam that has to be added per 1000 lb. bled we can find readily the total steam supplied to the turbine, as follows:

$$D = A + Xr_x + Yr_y + Zr_z$$

The steam passing to the condenser is

$$B = (D - X - Y - Z)$$

There are two variables in considering the boiler rating; one is the number of pounds of steam to be evaporated, and the other is the number of B.t.u. to be added, which varies on account of varying feedwater temperature. When the economizer was supplied with 210-deg. feedwater each of the three 14-high boilers and economizers was assumed to be producing 100,000 lb. of steam or a total of 300,000 lb., the efficiency of the boilers alone was taken as 75 per cent (see Fig. 2), and the boiler efficiency under all other conditions was determined from this by correcting for changes in efficiency due to changed output and taking into account the effect of variation in feed temperature.

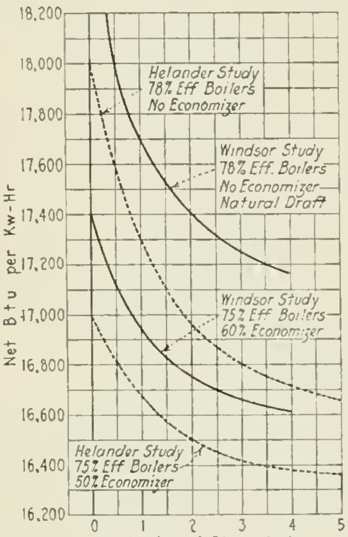

FIG. 7 COMPARISON OF WINDSOR AND HELANDER STUDIES OF EFFECT OF VARIOUS-STAGE BLEEDING ON POWER-STATION ECONOMY

If F = output of each boiler in pounds of steam per hour referred to 210-deg. feed temperature as a basis,

$$F = 100{,}000 \times \frac{H_z - h_z - R_z}{H_{210} - h_{210} - R_{210}} \times \frac{D}{300{,}000}$$

Fig. 2 gives the efficiency of the 14-tube-high boiler.

The net B.t.u. per kw-hr. output of the plant is obtained from the formula:

$$D \times \frac{H_z - h_z - R_z}{E} \times \frac{1}{B_e} \times \frac{1}{P_e}$$

where E is equal to the net kw-hr. put out by the plant.

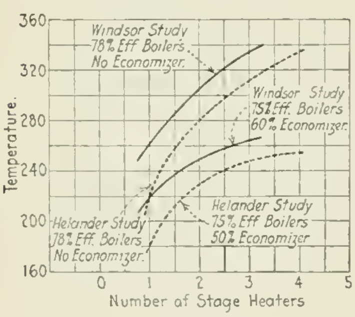

FIG. 8 COMPARISON OF WINDSOR AND HELANDER STUDIES SHOWING THE TEMPERATURE AT WHICH BEST RESULTS ARE OBTAINED FOR VARIOUS-STAGE BLEEDING

Where the plant was equipped with economizers and induced-draft fan, and a motor-driven boiler-feed pump was used, the plant-auxiliary power requirements were assumed to be 1600 kw. and E was equal to 28,000 — 1600 or 26,400 kw-hr. Where a turbine-driven boiler-feed pump was used, the plant-auxiliary power requirements were assumed to be 1400 kw. and E was equal to 28,000 − 1400 or 26,600 kw-hr.

In case the large boiler is used without the economizer, the rise in the economizer is neglected in the last two equations, and the boiler efficiency is taken from Fig. 3 instead of Fig. 2.

Where the high boiler is used with natural draft the boiler feed-pump requirements are reduced from 200 to 175 kw. and the auxiliary power is reduced 150 kw., on account of the omission of the induced-draft fan.

In case the steam-turbine-driven pumps are operated, Item C is increased by the amount of heat in the exhaust steam. In arriving at the B.t.u. in the exhaust steam, allowance was made for variations in back pressure by increasing the water rates of this unit $1/2$ per cent per pound increase of back pressure.

A great many of the above factors are constant, and only a few change so that when one is familiar with the method the points on the curves can be obtained at the rate of two or three per hour.

Fig. 6 is a study of single-, double-, and triple-stage heating for the Windsor turbines, in combination with a 20-tube-high boiler having an efficiency of about 78 per cent at the point at which it is operated.

Curve 1 shows the results obtained with single-stage bleeding.

Curves 2 and 3 show the results obtained with double-stage heating. There is apparently very little difference whether the thirteenth or fourteenth stage is used as the first stage.

Curve 5 shows the results obtained with triple-stage heating, the best being those obtained by a combination of the fourteenth, eleventh, and eighth stages. It is possible that a higher stage might be slightly more efficient, but the data therefore were not available.

Fig. 7 is a comparison of the results obtained by Mr. Helander for various-stage bleeding with the results of the Windsor study. Mr. Helander limited his study to four stages, but the curve is projected so as to show the approximate results for five stages. The Windsor study was made for three stages, but is extended so as to indicate the approximate results for four stages.

Fig. 8 shows the temperature at which the best results were obtained for single-, double-, and triple-stage bleeding in the Winsor study and single-, double, and quadruple-stage bleeding in the Helander study.

These studies clearly indicate the advantage of bleeding the main unit with or without economizers, there being a gain of 1.10 per cent for double-stage over single-stage heating and approximately one half that amount if triple-stage is used in place of double-stage heating, that is, for a 14-tube-high boiler equipped with economizer; whereas for a 20-tube-high boiler there is a gain of 1.64 per cent in double-stage heating over single-stage, and about 1.00 per cent if triple-stage heating is used in place of double-stage.

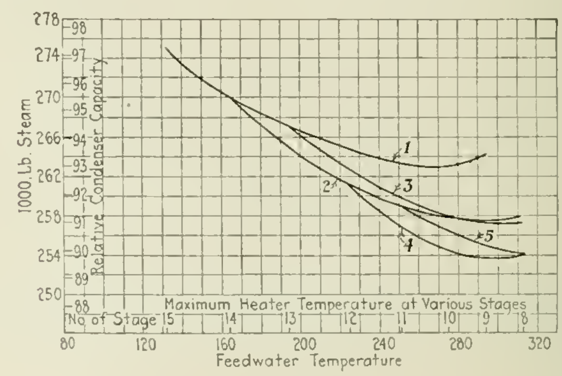

FIG. 9 AMOUNT OF STEAM PASSING TO MAIN CONDENSER AND RELATIVE SIZE OF MAIN CONDENSER REQUIRED

Regarding reliability, while the heater condensers will complicate the condensate piping and increase the pumping head, with the possible exception of the effect of breakage of extraction heater tubes, it is difficult to see how they will affect the reliability of the plant or complicate the operating problems. The breakage of a condenser tube can be taken care of either by installing check valves between the heater and the main unit, or in the lower-stage heaters by putting in drip lines of large enough capacity to take care of possible leakage. Condensate that leaks through a broken tube in this way is returned to the condenser or condensate system, and is not lost. Gate valves should be installed between the heater and the main unit so that the heater can be disconnected from the unit if desired.

Regarding the capacity of condensing equipment, as the bleeding of the main unit reduces the amount of heat passing to the main condenser, some reduction in its size is permissible. Fig. 9 shows the pounds of vapor and condensed steam entering the main condenser per hour for various bleeding combinations. This study indicates that for single-stage bleeding the condenser capacity need only be 93 per cent of that required if steam is bled from the main unit. For double-stage heating this ratio becomes 91 per cent and for triple-stage heating 90 per cent.

Fig. 4 indicates that heating the feedwater by exhaust steam

(Continued on page 429)

Diesel-Engine Progress on the Pacific Coast

By H. W. Crozier, John Stigen, and C. E. Nagel, San Francisco, Cal.

Diesel designers and builders on the Pacific Coast have been making important strides in the development of the full Diesel engine, particularly since they have resolutely turned from the so-called semi-Diesel engine, dependent for ignition of the fuel on a hot surface, and have concentrated their efforts on the true Diesel type, which uses only the heat of compression for that purpose. The bravery of these men in departing from European precedents in simplifying and strengthening the designs of their engines and their daring in using thousands of pounds pressure in attaining a solution of the mechanical solid-injection problem have resulted in the construction of splendidly satisfactory engines, a feat of which the profession may well be proud.

As an indication of the quality of the engines produced, practically all manufacturers fit forced-feed lubrication through drilled holes in crankshafts and drilled holes through connecting rods, insuring ample lubrication of the bearings, with resulting long life. Cylinder lubrication has careful attention and individual feed lines running to each cylinder from McCord-type force-feed lubricators are practically universal. No dependence is placed on splash, as forced feed is fitted to camshafts, timing gears, and other similar parts. Circulating pumps are nearly always direct-connected and in duplicate, and the prevalence of the marine demand necessitates use of brass and other high-grade metals suitable for salt-water service.

Favorable to the extended use of Diesel engines is the ample supply of suitable fuel, assured for many years to come, and an informed public accustomed to the extensive use of carburetor-type internal-combustion engines. True Diesel engines are being manufactured in increasing quantities and are being introduced for practically every mechanical purpose. Marine service has taken by far the largest proportion of the production, but stationary service is not neglected by any means. The whole range, from the smallest to the largest, and of good quality, is obtainable from one or more of the six or eight prominent manufacturers. In adaptability to new uses the Pacific Coast is leading along certain lines, particularly in the use of small and moderate-sized engines in heavy-duty marine service.

A Large Stationary Diesel-Electric Generating Set[1]

The recent shipment from Oakland, Cal., of a large stationary Diesel engine marks a forward step in California Diesel practice as it is the largest engine so far supplied for electric service.

This Diesel-electric unit consists of a six-cylinder, four-stroke-cycle, $20^1/_2$-in. by $35^1/_2$-in., 150-r.p.m., Pacific Werkspoor Diesel engine, direct-connected to a 925-kva., three-phase, 60-cycle, 2400-volt, Westinghouse alternating-current generator, with direct-connected exciter, and goes to the electric central station of the Tucson (Ariz.) Gas, Electric Light, and Power Company for installation as the fifth Diesel-electric unit.

It will run in parallel with four 500-b.hp. Diesel-electric units, each having direct-connected alternating-current generators and with 870 kw. of Corliss non-condensing steam-driven equipment used for standby and to assist over the peaks.

Of the crosshead type, so called, which has been so successful in the large sizes at sea, the new engine is materially different and much simpler than the four operating units at present in operation, which are all of the conventional trunk-piston type. Complete separation of the cylinder and engine lubricating systems and elimination of the oil contamination by discharges from the cylinders; simple and efficient piston cooling piping; ease of inspection of all operating parts while running, and ease with which pistons and piston rings may be inspected or removed, are some of the advantages of the crosshead type.

One of the important features of the design is the accessibility of the piston and piston rings. The cylinder is in two parts. The upper part includes practically all of the cylinder exposed to the hot gases; the lower part or skirt, mates with the upper in a stepped ground joint. With the piston on the lower dead center, removal of eight bolts permits lowering of the skirt, thereby exposing the piston and rings, for inspection or removal of rings. If the bolts holding the piston have been previously taken out, the piston may be removed from the engine in its entirety; all this of course without dismantling any other part of the engine.

Tucson has a high-grade circulating-water cooling system in service, which has been extended to supply the new engine. Its particular feature is the use of clean or distilled water in a closed circuit consisting of the engine jackets, heat-exchanger coils placed in the cooling towers, and a motor-driven circulating pump (in duplicate). The object attained is the prevention of scale on the cylinder cooling surfaces.

This engine was given a 24-hour full-load continuous test by the builders and the following performance data were obtained, the power being measured by a hydraulic brake:

Average output		562 kw. or 847 b.hp.
Indicated power of all 6 cylinders		1185 i.hp.
Average mean effective pressure		96 lb. persq. in.
Compressor:		
Low-pressure cylinder (15 lb. m.e.p.)	17 i.hp.	
Int.-pressure cylinder (57 lb. m.e.p.)	16 i.hp.	
High-pressure cylinder (386 lb. m.e.p.)	16 i.hp.	49 i.hp.
(Compressor i.hp. = 4.2 per cent of main engine i.hp.)		
Average fuel consumption		0.43 lb. per b.hp-hr.

For the moderate-sized units a station duty of 0.72 lb. per kw-hr. generated may be expected, corresponding to 0.47 lb. per b.hp-hr. Larger sizes comparable to the new engine may be expected to have a station duty of 0.67 lb. per kw-hr. or 0.415 lb. per b.hp-hr.

Lubricating oil will be required at the rate of about 1375 kw-hr. per gal. for trunk-type engines, but the larger engines, particularly of the crosshead type, have a higher lubricating oil economy and may reach 2000 kw-hr. per gal. if intelligently operated.

Pacific Coast Experience with Large Diesel-Engined Motorships[1]

It is but natural that the many advantages claimed for the Diesel engine should attract the attention of both the engineers and business men who have the present as well as the future welfare of the shipping industry in their charge. For marine work this type of motive power seems particularly adapted, especially in cases where the total horsepower required is not excessive. The simplest and most reliable arrangement for a marine steam power plant appears to be the Scotch marine boiler with marine superheaters and the triple- or quadruple-expansion engine, with which a total fuel-oil consumption of 1.25 to 1.40 lb. per shaft hp. is a fair average for up-to-date plants. When, then, the Diesel-engine advocate comes along claiming a fuel-oil consumption of from 0.38 to 0.45 lb. per shaft hp., it is no wonder that the man who holds the destiny of so vital an industry as our merchant marine should take notice. Besides this great fuel economy, the advantage of which increases with the increase in length of voyage, there are other features of the Diesel engine which prove a decided advantage when applied to a marine power plant. Among these are the instantaneous availability of full power at a moment's notice, without any special preparation; quick reversal from full speed ahead to full speed astern; immediate shutdown of engine in cases of emergency; a greater number of operating days per year, due to avoided delay in boiler cleaning and annual inspection; an increase in cargo capacity, due to reduced bunker oil required; and a reduction in the number of the crew, as no firemen are required. Against these advantages must be charged the disadvantages of a higher first cost, with the attendant increase in depreciation and insurance, a higher lubricating-oil consumption, and a smaller

Presented at the Pacific Coast Regional Meeting of The American Society of Mechanical Engineers, Los Angeles, Cal., April 16 to 18, 1923. Abridged.

[1] By H. W. Crozier, who also prepared the preceding introduction and the remaining portions of the paper not otherwise credited. Mr. Crozier is engineer with Sanderson & Porter, San Francisco, and a member of the A.S.M.E.

[1] By John Stigen, naval architect, Standard Oil Co. of California.

field from which to select the men to care for the plant. In view of these facts it is rather surprising that there are not more Diesel-engined motorships in the American merchant marine.

On the Pacific Coast the Standard Oil Company (Cal.), with which the writer has the privilege of being connected, has taken a leading part in introducing this type of motive power in the marine service.

In November, 1920, this company put in commission its first motorship, the *Charlie Watson*, a tanker of about 2135 dead-weight tons, propelled by two 550-b.hp. Pacific Werkspoor Diesel engines. A year later, a second motorship, the *H. T. Harper*, a tanker of 4700 deadweight tons equipped with two 850-b.hp. engines of the same make, was added. This vessel, as far as principal dimensions and lines of hull are concerned, is an exact duplicate of the Company's *El Segundo*, which has two Scotch marine boilers and a triple-expansion engine developing 1850 i.hp.

The fact that after two years' continuous operation of its Diesel-engined ships this company in July, 1922, placed an order for a third vessel with Diesel power should be sufficient proof that they regard their motorship enterprise as a success. This last vessel, which is now being completed, is a Diesel-electric tanker of about 1875 d.w. tons, equipped with two 400-b.hp. Pacific Werkspoor Diesel engines connected to direct-current generators which in turn supply power for a 600-b.hp. motor coupled direct to the propeller shaft. The vessel is designed for bay and harbor service as well as coastwise, and the Diesel-electric type of propulsion with direct pilot-house control was selected as particularly well adapted for this kind of work where a great deal of maneuvering has to be done.

The question of machinery weights is often quoted as being against the Diesel engine. This may or may not be correct, depending on the engines themselves, and also upon how much and what kind of auxiliaries are selected. With all capacity requirements equal the machinery weights of a motorship will approximate very closely those of a steamer, and should never exceed them by more than 10 per cent. This increase in machinery weights, however, is more than offset by the reduction in fuel oil required for any given length of voyage.

Basing our figures on the total fuel oil consumed for all purposes aud the shaft horsepower developed, the fuel consumption per shaft horsepower per hour will be 1.35 lb. for the steamer *El Segundo* and 0.475 lb. for the motorship *H. T. Harper*. A correction must be made here to take care of the increase in the horsepower required due to reduced propulsive efficiency of the twin-screw installation of the motorship, which will bring the fuel consumption to 0.51 lb. per hp-hr.

This shows a decided advantage for the Diesel engine for propulsion, but in comparing the port consumption which takes in power used for discharging the oil cargo as well as for all other purposes, we find that the motorship, with its electric auxiliaries, performs this work with a fuel consumption of from 15 to 20 per cent of that required by the steamer.

Diesel-Electric Ferry, San Francisco Bay

San Francisco Bay has been noted for the high-class ferry service given with the fast, clean, and commodious ferry boats plying its waters. These are of the double-ended, two-deck type and are, with the exception of the new Diesel-electric ferry, *Golden Gate*, propelled by steam, several types of steam propelling machinery being used.

Diesel engineers attacking the problem of the San Francisco Bay ferries were astonished to find that the old walking-beam, low-pressure, jet condensing engines, noted as they are for their reliability and maneuvering qualities, are at the same time the most economical on the bay.

On the $4\frac{1}{2}$-mile route between Hyde street, San Francisco, and Sausalito, service is given with the Diesel-electric ferry running 16 hours and the steam ferry running 12 hours daily, the fuel consumptions being 5 gallons and 14 gallons per mile, respectively. Under construction at Los Angeles are two new steam turbine-electric ferries with double-end propellers which are expected to have the good economy for steam of about 30 gallons per mile. A Diesel-electric installation in this size ferry would use around 14 gallons per mile.

The Diesel-electric ferry *Golden Gate* has been running long enough for her merits to be recognized. She is particularly good in manoeuvering ability, accelerates rapidly, and on the whole is an exceedingly economical and profitable investment.

Her machinery consists of two Pacific Werkspoor Diesel engines, each direct-connected to 360-kw. 250-volt direct-current generators with direct-connected exciters which furnish current to drive the 500-volt propeller motors each of 750 b.hp. Kingsbury thrust bearings are fitted. The after propeller does most of the work of propelling the boat, and the leading one is controlled to operate at reduced speed and practically idles, consuming from 10 to 15 per cent of the power. This arrangement results in good economy because it is possible to design the propellers for the best operating conditions.

The ferry is usually operated directly from the pilot house. It may be thrown over from full speed ahead to full speed astern while under way, and the machinery responds immediately.

The combination of the electric drive with the advantages of speed control to get high propeller efficiency and the Diesel engine with its high fuel economy and reliability makes an excellent arrangement, and it is expected that many more Diesel-electric boats will be built. A second ferry, the *Golden West*, is nearly ready for its trial trip.

The 18,000 B.Hp. of Diesel Engines Built in Oakland, Cal.[1]

An important impulse was given to the Diesel industry on the Pacific Coast by the United States Shipping Board Emergency Fleet Corporation in awarding a contract for twenty 850-b.hp. Diesel marine engines to be built on San Francisco Bay, later reduced to 10 engines after the armistice was signed. Engines were constructed in accordance with this contract under the Dutch Werkspoor patents, but differed from the Dutch designs in having strong cast-iron pedestals in place of the characteristic steel diagonal rods of the Werkspoor design, resulting in a much stiffer engine.

The first engine was given a 32-day continuous test run under full load, and to show the good condition in which the engine was at the end of this run, a 20 per cent overload was put on for several hours before stopping. This engine and a second one, to make a pair of engines, were, with the permission of the Emergency Fleet Corporation, sold during construction to the Standard Oil Company of California, and were installed in the M.S. *H. T. Harper*.

Substantially the same design, now designated as the Pacific Werkspoor design, was followed for two 600-b.hp. engines for the motorship *Charlie Watson* and two 400-b.hp. engines for the Diesel-electric tanker *Standard Service*, all for the Standard Oil Company of California.

The ten engines built for the Emergency Fleet Corporation were sold by the Corporation several months ago, the first one being the engine described by Mr. Crozier for the installation at Tucson, Ariz. Two were secured by the Standard Oil Company of California, and the remainder by various Pacific Coast marine interests.

One of the three purchased by the Lynch and Grey interests has already been installed in the *Frank Lynch*, a Great Lakes type vessel from which the steam plant was taken out. In this installation while under way at sea the exhaust gases from the Diesel engine are passed through a steam boiler, which generates steam for the steering engine and electric-lighting equipment.

The 850-b.hp. and 600-b.hp. engines are of the large, slow-turning crosshead type, but many of the smaller trunk-piston type, the smallest so far being a 70-b.hp. two-cylinder engine, have been built, two of the latter size going to a gold dredge operated in Alaska.

Of the large-size trunk-type engines which have been built and installed on the Pacific Coast, the following are of interest:

A set of three 525-b.hp. engines in a Diesel-electric power station in Nome, Alaska, where the electric power is carried to floating gold dredges through an overhead cable. Two of this same power are in operation on the Diesel-electric ferry *Golden Gate* running between San Francisco and Sausalito. Another pair of these engines is being installed in a sister ship the *Golden West* now being built for the same company and which will soon be in operation. One of these 525-b.hp. engines is being operated in the Columbia River territory.

[1] By C. E. Nagel, chief engineer, Pacific Diesel Engine Co., Oakland, Cal.

The 250-b.hp. engine in four cylinders is another popular size of which many have been installed.

On the whole, there has so far been built 18,000 b.hp. of full Diesel engines in one shop in Oakland, Cal., not a bad record by any means.

Small Marine Motors

The Pacific Coast uses literally thousands of small motorboats fitted with gas engines ranging from the 6-hp. outfit of the crab fisherman through the 80- to 150-hp. launches to tugs of 300 hp. and upward. Designed to operate on the California distillate, a semi-volatile liquid fuel one step downward on the scale from common gasoline, the marine gas engine, usually designated as the Pacific Coast type, is a rugged, heavy-duty, reliable and substantially built machine.

These machines are built in quantities by a dozen or so manufacturers and the gas-engine industry is of considerable importance. Imagine the consternation two years ago when the oil companies, forced by scarcity of suitable refining crudes coincident with increasing demands for gasoline, had to withdraw distillate from the market and were only able to supply gasoline at two and a half times the price.

With twenty years or so of experience back of them in building marine motors to meet the severe Pacific Ocean conditions, what was more logical for the builders than to turn to the Diesel engine for the solution of the problem and to develop from the various types something which would fit the demand.

Increasing quantities of Diesel engines are now being manufactured which are operated on the four-stroke cycle with mechanical airless injection, using an oil pressure of around 4000 lb. per sq. in., and which also have all the excellent features of the marine gas engine, which they are rapidly superseding, being in essentials but little different. The oil-injection pressure is obtained by a two- or three-plunger pump driven off the camshaft and fitted with a relief valve for limiting the pressure. Some engines are fitted with an accumulator also. For idling at reduced speeds means are provided to reduce the injection pressure to 2000 lb. per sq. in. or even to 1500 lb.

The high-pressure oil is injected into the cylinder through an injection valve of the needle type which has a removable tip drilled with a number of small holes ranging from 0.006 in. to 0.01 in. in diameter in the various designs. Regulation is obtained by varying the lift of the injection-valve needle. To facilitate maneuvering all engines are fitted with governors.

A compression of approximately 420 lb. per sq. in. is usual and 390 lb. is the operative minimum below which ignition is uncertain. Pressure during burning of the fuel varies from 450 to 500 lb. per sq. in. and the conditions are in general like those which obtain in the air-injection engine, save that the horizontal admission line of the indicator card of the air-injection engine is usually not realized.

Like the larger Diesel engines, starting is by compressed air, and a small single-acting compressor cylinder is fitted to furnish a supply sufficient for several starts, a small tank being supplied.

As a general rule the marine fraternity has taken well to the new engines and generally the opinion appears to be that they are thoroughly reliable and dependable and easier, if anything, to take care of than the gas engines which it has used for so many years. The great economy in both fuel and lubricating oil is of course an exceedingly important factor.

The fuel supplied by the oil companies as Diesel oil is designated as 24 deg. B., but is sometimes much lighter. The engines will operate on heavier oils, and in fact on practically any clean suitable oil if it is heated to increase the limpidity, although this is not done to any extent as yet.

As Diesel fuel costs around $3^1/_2$ cents per gallon, the fuel consumption of a 100-b.hp. launch working ten hours a day will be about $11 per week as compared to $50 per week with distillate and $100 per week with gasoline. Parenthetically it may be said that distillate is again available since the bringing in of the phenomenal oil fields in Southern California.

Lubricating-oil consumption at the rate of 1 gal. per 1000 b.hp. is claimed, or about half that of the gas engines, which were heavy consumers of lubricants.

Effect of Altitude on Engine Capacity

Whenever inland Diesel installations are contemplated the question of the effect of altitude on the capacity of the engine arises, and in Pacific Coast practice this is of considerable importance because of the high altitudes of our inland states in the Sierra and Rocky Mountain regions. This effect is easily calculated as it is due to the reduction in the weight of air which enters the cylinder at each stroke because of the lower pressure of the atmosphere at higher altitudes. The reduction in capacity of the engine is about $3^1/_2$ per cent for each 1000 feet elevation above sea level, and is not usually taken to account for altitudes up to 1000 feet.

At Tucson, Ariz., for example, altitude 2440 ft., the normal barometer is 27.34 in. as compared to 30 in. at San Francisco, and the atmospheric pressure is 13.4 lb. per sq. in. as compared to 14.7 lb. at San Francisco. In a Diesel engine having a normal compression of 460 to 480 lb. per sq. in. at San Francisco there would be a reduction of this pressure of about 50 lb. In the installation being made at Tucson this is compensated for by making the piston rods slightly longer.

Compensation for the loss in capacity can be made in various ways and for the first few thousand feet is effected in part by making use of the excess capacity of the engine over full rated load, and by making up in part by increasing the amount of injection air used. This is regularly done at Tucson, and is one of the advantages of the air-injection system.

When altitudes of 5000 ft. or more are encountered, an engine may be run up to its full sea-level rating by adding an air compressor and supplying air at a few pounds pressure to the air inlet valves or by using an electrically driven rotary pressure blower, which will raise the pressure about three pounds per square inch.

Diesel Engines for Agricultural Purposes

Waiting for solution by Pacific Coast engineers is the problem of applying of Diesel engines to agricultural purposes, particularly to tractors. Working on an average of 250 days per year as against 20 days per year in eastern usage, California-manufactured tractors have reached a high stage of development.

The farmer needs the benefit to be obtained from use of the cheaper Diesel fuel and also relief from the ever-present crankcase contamination which plays such havoc with his lubricating oil and bearings; and for tractor purposes a high-speed light-weight engine must be developed having all the excellencies of the present new tractor designs and about the same weight.

In Arizona, Nevada, and the inland mountain country where hydroelectric transmitted power is only available in certain territories, large numbers of Diesels are being bought for pumping, a service requiring reliability and durability, and in particular an efficient oiling system covering every bearing so that no attention is required for days or weeks.

Summary

The Diesel industry in California is now manufacturing and supplying engines from 50 b.hp. up to 1000 b.hp. and can handle even larger types, of which satisfactory service records are available. It has built about 40,000 b.hp. to date. Doubtless the limits given above as already attained will be extended both upward and downward. Its great need at present is the confidence of the public in what it is in a position to deliver, and the assurance of the owners that the engines they purchase will be given fair treatment and necessary attention. The general education of the public as to the internal-combustion engine of the automobile and the steadily growing example of Diesel engines of the smaller sizes on the Pacific waters in the hands of fishermen and others of but limited mechanical knowledge will soon create a spirit of confidence which will wipe out the uncertainty which still persists.

While but little has been done in building large Diesel-engine electric central stations of a magnitude similar to the steam plants of the large power companies, there is nothing to prevent its being done, with profit both to the buyer and the builder. It may be pointed out that a Diesel-electric power plant of 10,000 kw. capacity need have no more than forty cylinders in operation to carry full load. Such a station could give instantaneous stand-by service, or, if sufficient reserve units were installed, would be an economical source of primary power.

Canadian and American Engineers Coöperate to Make A.S.M.E. Meeting a Success

Wholehearted Canadian Hospitality, Excellent Technical Sessions and Unusual Entertainment and Excursion Events Make 1923 Montreal Spring Meeting Memorable

THE Spring Meeting of The American Society of Mechanical Engineers, held in Montreal May 28–31, was featured by an interesting program of technical sessions, industrial visits, and entertainments. The registration for the meeting was 631, which included 149 members of the Engineering Institute of Canada and 120 ladies. Although this number was not large compared to the Chicago meeting of 1921 or the Detroit meeting of 1919, it must be remembered that numbers have very little to do with the success of a Spring Meeting; every one who was at Montreal enjoyed it thoroughly and will testify to its successful attributes.

The entertainment and excursion events were conducted in an excellent manner and everywhere there was praise for the Local Executive Committee, made up of H. H. Vaughan, Chairman, Major J. A. Duchastel, Vice-Chairman, Fraser S. Keith, Secretary, and Fred. B. Brown, John T. Farmer, George R. MacLeod, and Major C. M. McKergow. The unusually large number of ladies at this meeting made the entertainment features very enjoyable. The ladies were received by a committee made up of the wives of the Local Executive Committee, with Mrs. Fred. B. Brown as chairman. The *A.S.M.E. News* of June 7 contained an account of the entertainment and excursion features.

The feature of the technical sessions at Montreal was the wholehearted manner in which the engineers of Canada coöperated in the meeting. Of the seventeen papers presented at the meeting, seven were written by Canadians, and their contribution to the program will have a notable effect in increasing the understanding by Americans of the problems and progress of the Canadian engineer. The American Society of Mechanical Engineers was fortunate to have on its program such exponents of hydroelectric power development as Julian C. Smith of the Shawinigan Water and Power Company, and Frederick A. Gaby of the Hydro-Electric Power Commission of Ontario. H. G. Acres, of the Ontario Hydro-Electric Power Commission, presented an exceedingly interesting paper on large hydraulic turbines. Fred W. Cowie, Chief Engineer of the Montreal Harbor told of the remarkable accomplishments in the harbor of Montreal. J. A. Wilson, General Secretary of the Canadian Air Board, explained the progress made by the Canadian Government in encouraging and regulating aviation. The two papers on the program for the Railroad Session were presented by Canadians, H. R. Naylor of the Canadian Pacific Railroad and C. E. Brooks of the Canadian National. In this manner, therefore, the Canadian engineers coöperated most wholeheartedly and substantiated the sentiment expressed by the President of the Engineering Institute of Canada in his opening remarks that the engineering profession, as such, recognized no international boundary.

The Council of The American Society of Mechanical Engineers was very well represented at the meeting, there being only four absentees. However, there were nine past-presidents on hand for the deliberations and for the enjoyable dinner which was tendered by the Council of the Engineering Institute of Canada to the A.S.M.E. Council.

Business Meeting

THE first session was the Business Meeting of the Society, held Monday afternoon, May 28. Walter J. Francis, President of the Engineering Institute of Canada, spoke a few words of warm greeting on behalf of the engineers of Canada and emphasized the community of interest among engineers. President Harrington responded in kind.

The only matter of business was the announcement of Cleveland, Ohio, as the place for the 1924 Spring Meeting of the Society. John Price Jackson, Mem. A.S.M.E., and Executive Director of the Sesqui-Centennial Exposition to be held in Philadelphia in 1926, was then introduced. Mr. Jackson explained the importance of the coming exposition not only as a record of the remarkable advances in science and industry in the immediate past but as an inspiration for tremendous new advances.

The business meeting was then turned over to Calvin W. Rice, Secretary of The American Society of Mechanical Engineers, who delivered his travelogue on his trip to South America, when he bore credentials from the Engineering Institute of Canada to the South American Engineering Congress. This was the first opportunity given to members of the Engineering Institute of Canada to hear the report from the Congress and the account of Mr. Rice's trip through South America.

First Power Session

PROF. A. G. Christie of Johns Hopkins University, Past Chairman of the Power Division and Member of the Council, A.S.M.E., called the first Power Session to order on Tuesday morning, May 29, and introduced Philip S. Gregory,[1] who presented the paper by Julian C. Smith, Chief Engineer of the Shawinigan Water and Power Co., on Power Development in the Province of Quebec. Mr. Gregory was followed by Fred A. Gaby, Chief Engineer of the Hydroelectric Power Commission of Ontario, who presented the paper on the development of Hydroelectric Power Plants in Ontario. These two papers and the discussion contributed by F. Darlington of New York,[2] John R. Freeman[3] of Providence, and William M. White[4] of Milwaukee, appear in generous abstract on preceding pages of this issue of MECHANICAL ENGINEERING. The program for this session was arranged for the Power Division by the Montreal Committee.

Management Session

DEAN Dexter S. Kimball, Past-President of the A.S.M.E., wielded the gavel at the Session on Management, Tuesday morning, May 29, the program for which had been provided by the Management Division.

The paper by R. B. Wolf[5] on Management Engineering in the Paper Industry was read first. This paper appeared in the May issue of MECHANICAL ENGINEERING. The discussion on Mr. Wolf's paper was opened by L. W. Wallace,[6] who agreed with Mr. Wolf that the most difficult problem in installing improved management methods was in overcoming the non-response of superintendents and foremen. Mr. Wallace also agreed that a correct approach to the solution to this problem was the stimulation of interest in production achievements and costs. He emphasized the need for measuring the performance of the individual operators and the provision of an adequate avenue of self-expression for the individuals in industry.

Wallace Clark[7] agreed in the main with the statements made by Mr. Wolf but he pointed out that while departmental cost sheets are practical in continuous industry, they are difficult to secure in a non-continuous industry, where the cost of idleness is not maintained separately from the cost of work done. Mr. Clark also emphasized the need of translating costs to time, which is an element which the operator understands. He knows that he should accomplish a certain amount of work in a certain time;

[4] Mgr. Ch. Engr., Hyd. Dept., Allis Chalmers Mfg. Co Mem. A.S.M.E.
[5] R. B. Wolf Co., New York, N. Y. Past Vice-Pres., A S M.E.
[6] Exec. Sec., Federated American Engineering Societies, Washington, D. C. Mem. A.S.M.E.
[7] Indus. Engr., New York, N. Y. Mem A.S.M.E.

and if the time he consumes is compared by the Gantt chart with some sort of standard of time necessary, great improvements in operation will result. Mr. Clark stated that the important factors to be evaluated are whether the machines are running and whether operators are doing their work within an estimated time.

In answer to a question as to the cost of clerical work for a cost system, Mr. Wolf stated that in one particular plant by adding $13,000 a year to the engineering and clerical force, the first year's actual saving was approximately $40,000.

In closing the discussion Mr. Wolf admitted the difficulty of developing departmental cost sheets in a non-continuous process factory. Mr. Wolf did believe, however, that in a department organized for a specific purpose, a measurement of accomplishment was necessary to develop the individuality of the department.

The question of industrial engineering education has always been a prolific source of discussion. The paper by Professor Myron A. Lee[8] on a Practical Laboratory and Drawing-Room Course in Industrial Engineering, was no exception and discussion was contributed by a large number of educators and industrial engineers. Professor Lee's paper, with the discussion, will appear in the August issue of Mechanical Engineering.

The Railroad Session

The Railroad Session with the program prepared by the Railroad Division was presided over by H. H. Vaughan, Member of the A.S.M.E. Council. The first paper presented was by H. R. Naylor,[9] on Steel Car Construction at the Angus Shops of the Canadian Pacific Railroad. This paper appeared in the June issue of Mechanical Engineering. In the discussion Ernest R. Viberg[10] stated that the box car is one of the most important element of stock equipment used by the railroads. He ventured to guess that the railroads of Canada and the U. S. used about 250,000 box cars of the steel-frame, single-sheathed type.

F. O. Whitcomb,[11] discussed the subject of car construction from the point of view of the contract shop. The diversity of types and sizes of cars and the small orders executed at one time at such a shop precluded the spending of money on large special tools. The railway men could work with the car designer and build the cars around existing tools. Mr. Whitcomb believed that the jig method of assembling freight cars was more expensive than the skid method, in which in six positions the underframe was sheathed and assembled, then placed on its own trucks and in ten moves was ready for the woodwork. Under such an arrangement an average of forty-two cars per day for over a month had been made, with 52 in one day of eleven hours as the maximum. Mr. Whitcomb mentioned the use of electric rivet heaters as a desirable economy and endorsed the continuous painting machine described by Mr. Naylor. Max Toltz[12] expressed the opinion that the dead weight of the car could be considerably reduced, for reducing dead weight was necessary if greater economy of operation was to be attained. Mr. Toltz recommended the consideration of alloy steel in cars under construction. Augustus Smith[13] pointed out the need for designing bodies of cars that would lend themselves more readily to handling contents mechanically.

In closing the discussion, Mr. Naylor expressed the opinion that by use of the jig method a tighter box car is secured, and in enumerating the various moves under the system of jig assembling, he found only six. Mr. Naylor reported that electric rivet heaters were not found satisfactory. He also stated that the proportion of dead weight to limit loads in steel box cars had not increased as the size increased.

The paper by C. E. Brooks[14] on More Recent Developments of the Motor Coach treated of a subject which is only in the earliest stages of development but covers a large field and variety of equipment. Mr. Brooks' paper precipitated a discussion as to the relative merits of the gasoline motor car and the electric storage-battery car. The paper with the discussion will appear in the August issue of Mechanical Engineering.

Second Power Session

A. G. Christie, Member of Council, A.S.M.E., presided Wednesday, May 30, at the second session under the auspices of the Power Division. Two papers were presented: the first, by H. G. Acres,[15] was entitled Modern Hydraulic Turbines of Large Capacity, and the second, by Peter Payne Dean,[16] Sectionalization and Remote Control of High-Pressure Steam Lines. Mr. Acres' paper brought out considerable interesting discussion on the various mechanisms in use in modern large-capacity hydraulic power plants. The paper will appear in the August issue of Mechanical Engineering with the discussion, as will also the paper by Mr. Dean and its discussion.

Port Development

The program on Port Development was arranged by the Materials Handling Division, and its chairman, H. V. Coes, presided at the session on Wednesday morning, May 30. The first speaker was Fred W. Cowie,[17] who gave a broad outline of the port development of Montreal. Mr. Cowie has served as chief engineer for the Montreal Harbor Board for sixteen years and is recognized as an authority on transportation and harbor development. A second paper was presented by Carroll R. Thompson, Assistant Director of Wharves, Docks and Ferries of the City of Philadelphia. Mr. Thompson's paper was a résumé of the papers presented under the auspices of the Materials Handling Division at various Atlantic seaports during the past year. The papers by Messrs. Cowie and Thompson with the discussion will appear in the September issue of Mechanical Engineering.

At the close the chairman presented a report of a committee appointed by the Materials Handling Division to devise a formula which might be used in determining the justifiable investment for labor-saving machinery. The report of the Formula Committee will be presented in the August issue of Mechanical Engineering.

Textile Session

The textile program, arranged by the Textiles Division, consisted of one paper which was presented on Wednesday morning, May 30 with C. R. Main, member of the Executive Committee of the Textiles Division, in the chair. Under the title Bleachery Engineering and Operation, the authors, Frank P. Bascom[18] and J. C. McDowell,[19] explained the extreme complication of the process of converting gray cotton cloth into bleached, dyed, or printed fabric. They emphasized the artistry required by the bleacher, the finisher, and the dyer in working the raw material and producing the final result that would be pleasing and useful to the discriminating housewife. They showed the difficulty of determining the exact amount of starch required merely by the feel of the goods and the exact quantities of dyes to be used. as examples pointing to the need of great experience and familiarity of the bleachery foremen with processing methods. Great care must be exercised. The authors visualized an ideal plant and briefly traced the goods through the various processes. They pointed out that the grouping of operations formerly conducted independently is the most important recent development in the bleaching industry. By the use of variable-speed motors driving the various units, the cloth may be led from one machine to the next and with automatic speed controls the tension of the cloth from machine to machine and process to process may be properly maintained. In this grouping of units for continuity of processing lies the key to rapid production

and minimum operating costs. Economical handling of materials is a point of great interest to the plant designer. The provision of proper water is also an item of great importance; for high-class work, many plants require elaborate water-filtering and purifying apparatus. In all problems of bleachery design it is necessary to study local conditions, goods to be treated, the results desired, and apply a thorough knowledge of proper equipment and methods.

Fuels Session

TWO interesting papers presented at the Fuels Session on Thursday morning, May 31, brought forth considerable discussion. The program was arranged by the Fuels Division and the session was presided over by Fred R. Low, chairman of the Division. Chimney Sizes was the title of a paper by Alfred Cotton[20] which was presented at the meeting by E. R. Fish.[21] This paper will be abstracted in a later issue of Mechanical Engineering.

The second paper, on Lignite Char, appeared in the May issue of Mechanical Engineering. In presenting it, O. P. Hood,[22] the author, submitted considerable additional information. He called attention to the apparently abnormal fact that people in some of the western states were living on a bed of fuel and yet burning coal brought from a distance of 1000 to 2000 miles. While comparatively unimportant in ordinary times, this threw an apparently unnecessary burden on the transportation system of the country in time of war, and was one of the circumstances that led to undertaking the investigation described in his paper.

The main difficulty in developing the lignite-char industry at present, he said, was economic. Nobody knew whether the product would find a steady market, and until this had been determined the industry could not be developed. Present stoves and furnaces would not burn it, and there would be no stoves to burn it until there was a lignite char that could be bought freely on the market, and it was difficult to produce the material in quantity until there was a market for it. Furthermore, production of lignite char was supposed to require fairly expensive equipment and this constituted a serious obstacle in two ways. In the first place, no one cared to make the heavy investment necessary for the experimental period in view of the general uncertainty of both the technical and commercial elements of the proposition; and, secondly, lignite mines were comparatively small and it did not appear commercially attractive to put up expensive furnaces in connection with mines of limited output.

This affected the by-product phase of lignite coal manufacture. The business of making lignite char with the saving of by-products was essentially a large-scale business. As such, it required very considerable investments which financial people were not ready to make, particularly as lignite mines were in districts only thinly populated (e.g., North Dakota and Texas) where both the economic and labor conditions were unsuitable for big industrial developments.

Of late, however, the Bureau of Mines had developed an experimental furnace and several hundred tons of char had been produced. The char, in general, was the result of the concentration of about $2^1/_2$ tons of lignite into one ton of char. Whatever ash there was in the original lignite would be found in the char multiplied by $2^1/_2$. The volatile matter in the char was controlled within certain limits but in general ranged from 8 to 12 per cent. The fixed carbon was 65 to 70 per cent, the moisture practically nil. This coincided closely with the analysis of anthracite coal. The grains of char were not as hard as anthracite, were clean, and did not break with weathering. One of the favorable characteristics of char was that there was practically no carbon in the ash, in addition to which the char had the ability to hold the fire and burned out very much as a piece of charcoal did. Lignite char ignited much easier than anthracite—in fact, the fire could be started with paper. .

All that was necessary to make char was to heat the lignite. The moisture came off first; then if heating was continued to a higher temperature, volatile matter began to come off.

The lignite char when burned in a base burner gave service comparable with anthracite coal, but required an adapter on the ordinary grate of the base burner. Efforts to obtain a similar simple solution to the cook-stove problem and the house-heating furnace had not succeeded, and apparently an entire remodeling of the two furnaces would be required to fit them for burning char.

It was possible to produce lignite char at the mine at about \$5 per ton, allowing \$1.50 to the mine operator for his slack, and obtaining at this price a fuel of 12,000 B.t.u. per lb. This made the proposition worth serious consideration.

Max Toltz,[23] among other things, called attention to the developments in lignite and brown-coal utilization in Germany resulting from the pressure of economic conditions. Their central power plants were built adjoining lignite deposits so that the mined fuel could be supplied to the grate of the boiler without being stored, for storage disintegrated or slacked this fuel. In one of these central stations which delivers electrical power to cities within a radius of 120 miles, the majority of the boilers were equipped with step grates upon which the lignite was burned successfully. Chain-grate stokers were also used, but care was required as part of the finer lignite would sift through the grates into the ashpit. This station consumed 900 tons of brown coal every 24 hours.

Another successful appliance for using lignite under boilers was a combination of a semi-gas producer and step grates. The furnace was of the Dutch-oven type projecting in front of the boiler which had a gas-producer chamber partitioned off from the lower step grates by a wall and arch with an opening in the top through which the gases escaped into the combustion chamber over the step grates. The lignite was not fully consumed in the producer, but fell through the bottom of the producer upon the step grates where final consumption of the fuel took place.

The gases of combustion from this fuel upon the step grates combined with the gases leaving the producer and were ignited by an arch back of the grates. The process that took place in the producer was nothing less than that of low-temperature carbonizing of the fuel, so that the lignite falling to the grates was practically half coke. The air for combustion was partly supplied by fans under the step grates and partly (after being heated in ducts of the setting) at a point under the back arch. The latter air would mix with the gases of combustion from the grates and from the producer. The following results had been obtained in this kind of longitudinal boiler installation with lignite of 5400 B.t.u. containing 43 per cent moisture and 6 per cent ash:

Evaporation from and at 212 deg. fahr.	6.9 lb.
Efficiency of furnace and boiler	66 per cent
Chimney losses	21 per cent
Losses due to ashes, radiation	12.5 per cent
CO_2	13.5 per cent

It was claimed that when using part of the chimney gases for predrying the lignite a furnace and boiler efficiency of from 75 to 80 per cent had been obtained. The rate at which lignite was burned per square foot of grate per hour was from 60 to 100 lb., and when peat was burned, up to 130 lb. In addition to these processes, other ways had been developed for the recovery of by-products.

The speaker stated further that some months previous a chemist in St. Paul had demonstrated by a laboratory test that North Dakota lignite could be briquetted without a binder after the sulphur had been extracted. No further details could be given regarding this, but it might lead to some briquetting process, which, if successful, would at least take care of the fuel supply of the Northwest for domestic purposes. During last winter about 5000 tons of North Dakota lignite had been shipped to St. Paul and Minneapolis and used for domestic purposes under special instructions given the consumers by the mine owners. Those who had used this fuel had been satisfied with it, although there had been a general complaint regarding the odor arising from its combustion.

In conclusion Mr. Toltz said it was gratifying to report that besides the U. S. Bureau of Mines, the Mining Department of the University of North Dakota as well as the Government of the Province of Saskatchewan were working for better methods of

[20] Chief, Research Dept., Heine Boiler Co., St. Louis, Mo. Mem. A.S.M.E.

utilizing lignite, and it was hoped that in the near future the value of this fuel as a source of power, domestic or industrial, would be determined so that at least the northwestern part of the United States, as well as the central provinces of the Dominion of Canada, would derive the benefit of their lignite resources which were now practically lying idle.

Leslie R. Thomson of Montreal, Secretary of the Lignite Utilization Board of Canada, told about the Board and its work. It was a body representing the Dominion Government and the governments of the provinces of Manitoba and Saskatchewan, created in 1918 to demonstrate the commercial possibilities of providing a high-grade domestic fuel to compete with American imported anthracite in the Canadian Central West. The problem was limited to the Central West because as one moved westward from Mid-Saskatchewan the decrease in price of fairly good Alberta coal made it impossible for an expensive briquet to compete. The Board was mainly concerned with the production of a high-grade domestic fuel and did not touch the power question.

The problem of handling Canadian lignites was made increasingly difficult by the fact that they were hygroscopic and if exposed to the air after drying reabsorbed moisture to the extent of from 15 to 17 per cent.

Operation based on the recovery of by-products was out of the question in Canada as far as by-products of the fertilizer type were concerned, because, owing to local agricultural conditions, there was no demand for fertilizers. The only by-product likely to have an immediate market was a motor fuel.

The experimental work done by the Board was described in some detail. Several sizes of retorts were built one after another. All gave trouble at first, but were made to produce ultimately. Even now the operation was too expensive and could not be termed commercial, the main troubles being due to poor floor material and lack of a satisfactory refractory. A carbonizer was being erected now.

Certain technical and commercial points had been discovered in the course of this work. It was found that the B.t.u. content of char varied with the temperature of carbonizing, the curve reaching its peak at 1050 B.t.u. The next point was that char could be sold in the Canadian Northwest only if briquetted.

As regarded sizes, the char would pass through a $^1/_8$ mesh and be retained on about 170 or 180.

The only criticisms offered for the future of the retort were the two points mentioned by the author, one of which was that it was necessary to feed it certain screened sizes. In a country where there was a large amount of lignite slack and small sizes it would seem expedient when attempting to make a high-grade fuel to buy the original fuel of the cheapest material. If the retort would not use that, one very large portion of the possible supply would thus be limited. The second criticism was on the fact that although there was provision for a small amount of by-product recovery, the final solution of lignite retorting must be found, especially as the population increased, in a retort that would give the by-products if and when necessary.

E. N. Trump[24] told of what he had seen in Germany in 1913, in particular the type of furnace for carbonizing lignite. This was a cylinder about 12 ft. in length, lined with refractory brick. At the end away from the furnace was a hole through which the air for combustion entered. That furnace gave a long flame of a very high temperature and the lignite going into it was first dried by the heat from the brick and then as it became char it burned by the direct entrance of the air at the other end, which was regulated. The air was not supplied in sufficient quantities to entirely consume the fuel. The arrangement appeared to be superior to the step-grate furnace and used lignite without any previous preparation.

Col. H. D. Savage[25] stated that the simplest and most efficient way of burning lignite was in powdered form. In tests made some years ago, about seven carloads of lignite had been burned in pulverized form without any change in the plant and with an efficiency of about 78 per cent. More recently in another plant five carloads of lignite of good grade from Colorado were burned likewise in pulverized form without any difficulty. According to the speaker, drying of lignite did not seem to be necessary and moisture up to 22 per cent did not create any difficulty in burning lignite in pulverized form. A plant was now being built at Boulder, Col., to utilize that coal with the necessary rating.

In his closure Mr. Hood stated that there did not appear to be any need of processing lignite when it was to be used for steam-making purposes, and mentioned some tests of burning lignite on a chain-grate stoker.

Answering a question as to whether the experimental device used the heat in the gases, Mr. Hood said that the gases left the device at a low temperature. In fact that was one of the troubles encountered; the gases went off at such a low temperature that they did not burn. The smell was too much for the college campus and it was found necessary to raise the temperature of the gases in order to burn it. One speaker had remarked about reducing the sulphur content of lignite—which was, by the way, already low—and thereby obtaining a product which would briquet. It was interesting to put this in juxtaposition with a statement that came from Oregon, where, with their lignite, by the addition of sulphur they were now producing a briquet.

Mr. Hood called particular attention to the fact that what was known in Germany as "Braunkohle," or brown coal, was not the same thing as the lignite found in this country. The distillation of brown coal was very interesting. If one looked at the bed of brown coal as it lay in the ground in Central Germany, one would notice the bonded formation. Some of it was very light, some would be dark cream color, varying all the way from that to a barely distinguishable lighter shade than the black-brown of the main body. It was these special veins or beds that were used for distillation purposes. Instead of mining the whole mass these beds were mined by hand and kept separate from the rest. Some of it would run as high as 13 per cent in paraffin. When it was considered that the moisture content of that was about 50 per cent, it meant a very high percentage of paraffin on a dry basis. That paraffin was the base of a considerable string of products, one of which was the lubricating oils. They were not taking the whole lignite but taking particular pieces. We in America had our own material and problem and must solve it in our own way and not merely import a way from abroad.

Machine Shop Session

On Thursday morning, May 31, the session on Machine-Shop Practice was held with F. O. Hoagland, Chairman of the Machine Shop Practice Division, presiding. The first paper presented was that of C. R. Söderberg[26] on Recent Developments in Balancing Machines. Mr. Söderberg's paper appeared in the June issue of Mechanical Engineering.

In opening the discussion, G. M. Eaton[27] pointed out that the use of balancing machines for electric rotating apparatus has largely been confined to the works of electrical manufacturers. The shop for maintaining electric machinery finds it extremely difficult to balance rotors of machines being repaired. In view of this, Mr. Eaton stated that the aim of the manufacturers should be to reduce the necessary balancing operation to the simplest procedure in keeping with the fundamental requirements. Mr. Eaton also stated the importance of rendering balancing machines available either by installing such mechanisms in centrally located service stations or by the introduction of portable balancing machines. At present it was generally believed that if service conditions were rough, running balance was an expensive luxury and attention was focused exclusively on making the apparatus rugged and the resulting maintenance expense accepted as a necessary evil. This old belief, however, was being shaken by researches into vibration disturbance and resulting fatigue phenomena. Mr. Söderberg's paper was therefore regarded as very timely.

Carl A. Johnson[28] presented a description of the Newkirk balancing machine. C. C. Brinton[29] pointed out that the development

[29] Asst., Supt. Westinghouse Elec. and Mfg. Co., East Pittsburgh, Pa.

of the future should be a line of portable balancing machines where accuracy was essential and production not a requirement. He stated that one type of shaft which had given trouble in obtaining good balancing was the three-bearing type with two rotors on the same shaft.

In closing the discussion, Mr. Söderberg answered a question as to the practicality of balancing a centrifugal pump rotor that the problem could be solved by mathematical analysis. He pointed out that the difficulties of balancing were multiplied many times when working with small rotors.

After Mr. Söderberg's paper was presented, there was a symposium on the Machine Tool and the Pulp and Paper Industry. Six written discussions were presented with a foreword by George E. Williamson[30] who pointed out the probability that the interrelation of the machine-tool industry and the paper and pulp industry had not been given the detailed study which the subject warranted.

In the first three of this group of discussions, shop problems in paper-machinery manufacturing and the general requirements of the machine tools employed therefore were dealt with by E. T. Spidy,[31] Geo. S. Barton,[32] and H. L. Kutter.[33]

Mr. Spidy spoke of the shop problems involved in the building of the modern newsprint machine, approximately 300 ft. long 14 to 20 ft. wide, and containing 800 tons of metal, as well as the methods of scheduling to insure delivery in the six to seven months allowed for that purpose. He described, among other operations, the methods used in casting and machining driers 20 ft. long by 5 ft. in diameter; straightening, grinding, and balancing the various types of rolls; the securing of interchangeability; methods of erection, etc.

Mr. Barton pointed out that the paper-making machine was not a precision tool, and while many of its parts were often finely and accurately made, nevertheless the tolerances as to bearing sizes and other machined surfaces were far more liberal than was customary or even permissible in machine-tool construction. Every shop building paper machinery should be provided first of all with heavy-duty lathes capable of swinging parts 72 in. in diameter by 20 ft. long and weighing 15 to 20 tons. One of these lathes should be fitted with a boring bar.

Mr. Kutter stated that the general tool requirements of shops making paper-mill machinery were substantially those of establishments doing general heavy work in which no extensive standardization was possible. In addition to the heavy-duty lathes mentioned by Mr. Barton and the more common tools used in machine shops, he enumerated lathes for machining press rolls (32 in. swing by 25 ft. between centers); special machinery for grinding press rolls; a 300-ton hydraulic press for forcing bronze jackets over press rolls; lathes for machining felt and paper-carrying rolls made of pipe or steel tubes (24 in. swing by 23 ft. between centers); a hydraulic machine for straightening these tubes or pipes; planers up to 84 in. wide, and boring mills taking work up to 10 ft. in diameter.

Jas. A. Cameron[34] discussed the plant equipment necessary for producing paper-working machinery. In this class were included paper-coating machines, slitting and roll-winding machines, printing machinery, machines and appliances for making boxes, envelopes, bags, etc. Such machines were built in so great a range of types and sizes for specific requirements that there was no such thing as standardized shop facilities in connection with their manufacture. A web press might accommodate a web 12 in. or less wide for tickets, or more than 6 ft. wide for magazines. Boxes, bags, envelopes, tubes, etc., varied so much in size, kind, and style that shops building the machinery to make any of these products must be equipped for all-round work.

Edward Hutchins[35] and E. B. Wardle[36] dealt with the requirements of pulp- and paper-mill repair shops. Mr. Hutchins called attention to the fact that practically all repair work not caused by actual breakdown of machinery must be done on Sundays and holidays. The paper-mill repair man had to be an all-round mechanic who had great pride in his ability to do a good, rugged piece of repair work with makeshift tools and materials when such work was necessary to keep the plant in operation. The equipment of the repair shop must be suited for work on large and heavy machine parts and must be reliable, simple, and easy to run. On account of Sunday and holiday operation of the tools motor drives were to be preferred.

Mr. Wardle stated that as pulp and paper mills ran continuously on a schedule of six days per week, it was essential to minimize loss of production by making repair parts in advance when the need for them could be foreseen, and by installing necessary equipment to make quick repairs in emergencies. Mills making paper and pulp were naturally located where the supply of wood and power was most plentiful and suitable. This generally meant that the location was more or less remote from centers where facilities were available for repair work, and such mills must therefore be equipped with tools to handle anything up to rolls weighing 25 tons and 25 ft. in length. Both Mr. Wardle and Mr. Hutchins gave lists of the various machines that should be included in the equipment of such repair shops.

An understanding of the far-reaching importance of the work of the Machine-Shop Practice Division in American industry was convincingly demonstrated in the report of the Special Committee on Plan and Scope, which presented its report at this session.

The Committee recommended that the activities of the A.S.M.E. in the field of machine-shop practice be as follows: (*a*) To promote the art of machine-shop practice; (*b*) To encourage original research in the machine-shop field; (*c*) To foster education in machine-shop practice, and to persuade educational institutions to increase their attention to this subject; (*d*) To advance the standards of machine-shop practice, and its exact knowledge; (*e*) To promote the intercourse of those engaged in machine-shop practice among themselves and with the other members of the Society, and with other societies. To carry out these activities the Committee recommended an organization of sub-committees and outlined their relation with the present Executive Committee. To understand the broad scope of the plan, attention is called to the fact that the Division intends to search out for papers, information of a fundamental and research nature applicable to all machine shops. As such papers cannot be obtained on the spur of the moment or even on several months' notice, the new Snb-Committee on Planning is charged with the responsibility of laying down a ten-year plan under which the various shop processes can be taken up. By laying plans thus far ahead, it will be possible to keep in touch with the experimental work of various kinds, and when its development is sufficiently advanced, arrange to have it presented before the Society. The Committee also analyzed the various products that might well be considered in the field of the Machine-Shop Practice Division and the various processes employed in their manufacture.

The Committee on Plan and Scope consists of K. H. Condit, Chairman, A. L. De Leeuw, Erik Oberg, Earle Buckingham, J. J. Reynolds, Frederick Franz, and W. J. Peets.

General Session

THE ONLY General Session of the Meeting was held on Thursday morning, May 31, with Earl F. Scott, member of the Council, acting as presiding officer. A paper on the Control of Civil Aviation in Canada was presented through the Aeronautic Division by J. A. Wilson[37] Secretary of the Canadian Air Board. Mr. Wilson's paper, which will appear in a later issue of Mechanical Engineering, treats of international flying regulations and the rules in force in Canada for the development of safe flying. The subject of Endurance Data and Its Interpretation was treated by K. Heindlhofer[38] and H. Sjövall.[39] Their paper will appear in a later issue of Mechanical Engineering, as will the paper on the Bending Stresses in Curved Tubes of Rectangular Cross-

Public Hearings and Committee Meetings

FRED R. LOW, Chairman of the Main Committee on Power Test Codes, presided at the Public Hearing on Tuesday, May 28, at which the Codes on Internal-Combustion Engines and two chapters of the Code on Instruments and Apparatus were presented. A number of suggestions were received and referred to the Sub-Committees interested for their guidance in completing the codes.

In connection with the recent revision work on the Boiler Code, sufficient progress has been made by the Sub-Committee on Rules for the Care of Power Boilers and on Rules for Inspection of Materials and Boilers, so that their preliminary reports were submitted to Public Hearing at the Spring Meeting. The hearing on the Proposed Rules for the Care of Power Boilers was on Tuesday, May 29, while the hearing on the Proposed Rules for Inspection of Materials for Boilers was held on Wednesday, May 30. Both hearings were well attended and developed valuable suggestions in regard to the proposed new sections of the code.

The results of years of effort on the part of the Research Sub-Committee on Fluid Meters, were presented in a report at an open meeting on Thursday, May 31, for discussion and comment. The report is in the form of a reference book on flow meters of all kinds and is in two parts. Part I treats the general types of meters as well as the principles and methods involved and gives information which may in many cases be applicable to various commercial meters. Part II gives more detailed information concerning the practical use of all the flow meters now in common use. The discussion at the open meeting brought out a great many valuable suggestions that will be followed by the committee in the completion of its report. The work will be brought up for further public consideration at the Annual Meeting of the Society in December.

On Thursday, May 31, the regular May meeting of the A.S.M.E. Boiler Code Committee was held, at which there were present, in addition to a splendid representation of the Committee members, inspectors from the Canadian provinces and boiler manufacturers and engineers from distant points who are interested in the Committee's activities. The program of this meeting involved the usual interpretation work and a number of official communications in regard to boiler-construction matter.

Hydroelectric Possibilities of Quebec

(*Continued from page 409*)

b Troubles occurring in the water channels above or below the power house affecting the head acting on the turbine.

To a large extent the troubles in classification (*a*) have been overcome by better design of the power house and better knowledge of the cause of these troubles. By enclosing the rack structure and by getting the turbine chambers warm and in general by the use of larger units, much of the trouble which was experienced formerly has vanished. The other trouble is more difficult to remedy, and inasmuch as the change of levels may be due to blockades of considerable area, the remedy in most cases is peculiar to the power development.

Most plants on the St. Lawrence River experience variations in height of headwater or tailwater due to ice blockades at long distances from the power house. On smaller streams, and particularly on very small streams, these blockades may be extremely serious, as they may and do affect a large portion of the flow of the river.

In large power developments, ways and means have been developed which minimize to a considerable extent these difficulties, and the expense of carrying out such efforts is justified in case of large plants where it would not be in small ones. By keeping the channels open to permit the frazil ice to come up to the surface, and by the use of various skimming devices for keeping rid of this ice, a very considerable degree of success has been obtained at the Cedars Rapids plant on the St. Lawrence River. It may fairly be stated that while this ice difficulty was a serious menace some years ago, now such is not the case, provided the plant is a large one and has been located and built with the knowledge acquired from the operation of existing installations.

The growth of hydraulic and hydroelectric development has been rapid and continuous over the past twenty years. The yearly rate of increase has been about seven per cent of the installed capacity per year over the last fifteen years, and the present total development is 1,070,000 hp. of hydraulic and electrical capacity combined.

At the present rate of increase the total available amount of hydraulic power, which is estimated at 5.25 million kilowatts or about seven million horsepower, will be developed and utilized in the next twenty-nine years. However, as the increase in development will in general follow the increase in population, it will take considerably less than twenty-nine years to develop all the power now in sight, and a careful study indicates that in twenty to twenty-five years the 7,000,000 hp. will be used up. Further, this time might be materially shortened if any large amount of power were exported from Canada.

Feedwater Heating and Plant Economy

(*Continued from page 420*)

from the house turbine is much less efficient than by bleeding the main unit, there being an advantage of approximately 1.85 per cent in favor of bleeding the main unit. This has led to a change in the type of house turbine installed. The tendency seems to be to carry only as much load on the house turbine as is necessary for the sake of reliability, paralleling the house turbine with the main unit and carrying all the load on the main unit, the switch being so arranged that in case of a heavy overload on the system, the house turbine with certain auxiliaries will pull away from the main unit and the house turbine will carry these auxiliaries at a slightly lower frequency until such time as the load can be again picked up by the main unit. The latest proposition is to carry no load on the house turbine but have it running so as to be able to pick up the necessary auxiliaries in case of trouble to the main unit. With this latter arrangement it is proposed to run a small pipe from the exhaust end of the house turbine to the condenser of the main unit, a check valve being placed in the main exhaust pipe from the main unit, maintaining in this way a rarefied medium for the rotor to spin in, so that it will not overheat when running idle. The vacuum required in the exhaust end of the house turbine to prevent overheating varies with the design of the house turbine. It is only with the most efficient types of turbine that there is any danger that the vacuum which it is possible to maintain in the exhaust end of the house turbine will not be high enough during the warm summer months. The losses of such a stand-by house turbine when running in a high vacuum are very small.

It is possible to heat the condensate about 13 deg. by using the condensate to cool the air in a closed generator-cooling system; and a rise of 7 deg. more may be obtained by absorbing the heat in the transformer and turbine oil. The use of condensate in these cooling coils will keep them clean; but there is some slight complication in regard to the operation of such a system during the warm summer months, or in case of dropping of load by the main unit. This latter is probably only important in case the transformers and turbine are not paralleled as a unit on the high side of the transformers but paralleled with the other units on the low side. These transformers will stand an interruption in the cooling-water supply for several minutes without injurious effect. In studying such a system and comparing the reduction in heat requirements, consideration must be given to the fact that by absorbing this waste heat the amount of steam which can be bled from the main unit is reduced; and while there is a possible reduction in the heat requirements of the plant of $1^3/_4$ per cent by absorbing the waste heat, if additional steam is bled from the thirteenth stage of the main unit the heat requirements will be about 136 B.t.u. per net kw-hr. higher than if the condensate temperature is raised by the waste heat in the generator air and transformer and turbine oil or the net gain in station economy of absorbing this waste heat is about eight-tenths of one per cent.

SURVEY OF ENGINEERING PROGRESS

A Review of Attainment in Mechanical Engineering and Related Fields

Recent Developments in Steam-Turbine Design

Largest Single-Cylinder Single-Flow Reaction Turbine Yet Built

DESCRIPTION of a turbine built by the Westinghouse Company in which large capacity at moderate peripheral speeds and conservative stresses have been made possible by the use of the Baumann system of blading, while a symmetrically expanding steam path eliminates eddies. Certain constructional features are also described.

The great problem in a large turbine is to provide enough large blades at the exhaust end to pass steam efficiently, while centrifugal

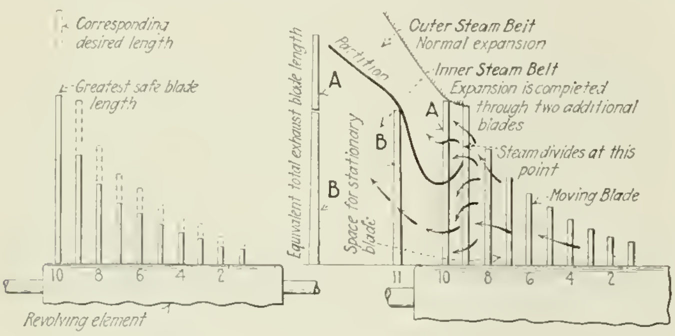

Fig. 1 Fig. 2

Figs. 1 and 2 Baumann Principle Increases Capacity of Single-Flow Turbine

force limits the blade length and diameters to those which will not exceed safe stresses in the materials available.

Designers have hit upon two ways for providing vane area for the complete expansion of the increased volume of the steam and its discharge to the condenser at a moderate velocity. One school has adhered to the single-cylinder direct-flow type, meeting the necessarily high peripheral velocities by refinements in material, design, and workmanship combined with a reduced factor of safety. Another school has attacked the problem by dividing the exhaust and providing two sets of exhaust blading, one at each end of the cylinder, making what is called the double-flow type; or by dividing the turbine into several turbine-generator units, with a high-speed, high-pressure unit exhausting into one or two lower-speed, low-pressure units. In the latter "cross-compound" type, high speed in the high-pressure unit is made possible by the relatively small high-pressure blades. This means that more work can be obtained efficiently per row of blades, since the work done per blade is approximately proportional to the square of the blade speed, and therefore less blade area is required. The slower low-pressure units are better for the employment of long vanes at the exhaust on account of lower centrifugal force at the required blade speed, and the double-flow principle is easily applied. The cross-compound unit possesses additional advantages of flexibility and reliability, but involves considerably greater first cost. Both of these expedients involve some disadvantages.

For the turbine described here, which is a 35,000-kw. unit under construction by the Westinghouse Co. for the Springdale Station of the West Penn Power Co., a method devised by Karl Baumann, of England, has been adopted.

Suppose that the largest single-flow reaction turbine, as limited by the safe length of the last row of blades, under ordinary design conditions carried 10,000 kw. at the most economical load and it is desired to increase this to 15,000 kw. at practically the same economy.

The high-pressure blades can easily be made longer so as to pass the greater volume of steam at about the same velocity, but the last row of low-pressure vanes is already of greatest safe length and cannot be extended.

Fig. 1 shows schematically such a reaction turbine, the blades in solid lines representing those for the largest single-flow machine of the usual design and dotted extensions suggesting added length for increased capacity, the proportions being only approximate. The last blade, row 10, is already of the greatest safe length and cannot be extended to A when the capacity is increased.

To pass the additional steam volume through the existing blade area in row 10 would mean increased steam velocity. Steam would then be discharged into the condenser at a high rate of speed, representing insufficient expansion and therefore lost energy that should have been used in driving the rotor.

The Baumann method of obtaining sufficient exhaust-blade area is illustrated in Fig. 2, where steam is divided into two belts at the last blade rows by means of partitions in the blades. The outer path allows expansion through ample blade area so as to do work efficiently.

Steam of the inner path is bypassed through rows 10, expanding only a small amount and doing little work. The expansion of this steam, however, is completed by adding a row of stationary and moving blades, rows 11, which contain sufficient area to use the remaining available energy efficiently and discharge into the condenser with the least practical amount of velocity remaining.

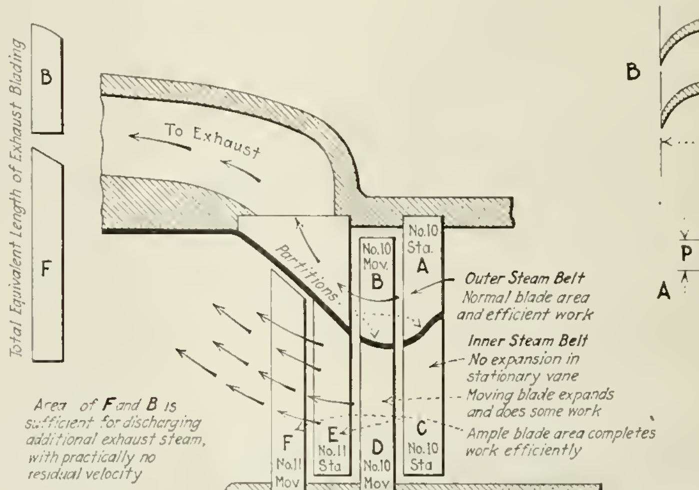

Fig. 3

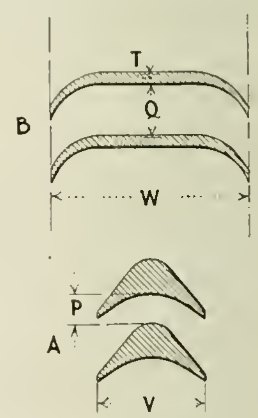

Fig. 4

Figs. 3 and 4 Inner Belt Does Less Work per Blade

The combined length of exhaust blades A and B is sufficient to give the desired total exhaust-blade area without an increase in blade length.

Fig. 3 shows in more detail the construction of rows 10 of blades, as well as added rows 11. The outer belt expands normally and efficiently through sections A and B.

The inner belt separated by partitions from the outer, is bypassed

through C stationary row 10 with practically no expansion; this section acts merely as a port. Moving section D expands steam to some extent, which helps drive the reaction vanes of the rotor.

There is still a comparatively great amount of energy remaining in the steam, and this is efficiently used by adding two rows of blades, E stationary and F revolving, which are proportioned for expansion to condenser pressure with ample exhaust area. By adding one row each of revolving and stationary blades, the capacity will be increased 60 per cent above the original. In adding two rows of each type of vanes and arranging an additional steam belt the increase is 120 per cent, and with three additional rows, 170 per cent.

Another means of increasing blade area due to Baumann is by greatly enlarging the blade width at the rotor, as shown in Fig. 4. Long blades must have a comparatively heavy cross-section at the rotor, as shown at A, which limits the width of the steam passage P between blades. The same cross-sectional area used in the blades at B with greater width W, permits thinner structure and consequently a wider steam passage Q between blades. Three steam passages to exhaust are provided in the 35,000-kw. units for Springdale.

In the original article the whole blading of the turbine is shown, the Baumann construction beginning only at a certain point toward the low-pressure side. The actual conditions are such that expansion takes place in the last moving vane so that it operates on the reaction principle.

Steam enters the first blade ring at 120 lb. abs., assuming that the most economical load, 26,000 kw., is being carried. The blade rings, instead of being supported loosely in rectangular grooves in the casing, are keyed into position, so that any tendency to close in on the rotor due to abnormal conditions is restrained by the resistance of the outer cylinder.

The rotor is of forged steel and a pressed fit reinforced by bolts unites the high-pressure with the low-pressure end. To make the rotor adaptable to high temperature the joint is located where there is very little difference of temperature, and the higher temperature if any is effective on the interior member of this pressed fit which would tend to hold it tight in case it became warmer than the recessed member of the fit.

The form of rotating and stationary packing employed is described and illustrated in the original article. In this the rotating element is finished in a number of conical surfaces, while the stationary member contains thin brass annular rings or fins which project very close to the rotating body. Clearances are adjusted by moving the rotating body in an axial direction. If rubbing should occur the conical elements will radiate heat much more rapidly than the old type of ring of cylindrical shape, and there is less liability of stripping than would occur in case thin fins were used in both the moving and stationary elements.

Numerous other features are described in the original article. Of these may be mentioned the emergency governor, which, in accordance with the recent tendencies in design, is of a type that will reset itself automatically while the turbine is running, thus avoiding the excessive slowing down for resetting that was necessary with the older type. In this case the governor includes means for checking approximately whether it operates at the correct speed.

The guaranteed steam consumption of this unit at 300 lb. 650 deg. fahr. steam at the throttle, with a vacuum of 29 in. of mercury, is as follows:

Load, kw.	1,750	26,250	35,000
Lb. per kw-hr.	10.30	9.75	10.15

At the most economical load of 26,000 kw. the following amounts of steam are to be extracted:

High-temperature heater, 12.9 lb. sq. in. abs.: 16,380 lb. per hour.

Low-temperature heater, 3.20 lb. sq. in. abs.: 12,910 lb. per hour. (*Power*, vol. 57, no. 20, May 15, 1923, pp. 746–752, 14 figs., *dA*)

5000-Kw. Brush-Ljungström Steam Turbine

THE first public description of the Ljungström steam turbine appeared in *Engineering* of April 12, 1912. Since then it has been successfully introduced in many places. As is well known, the particular feature of this turbine is that the fixed casing and single rotor of an ordinary turbine are replaced by two rotors turning in opposite directions.

The original 1000-kw. unit was soon followed by larger units until the size of 5000 to 7000-kw. was reached in 1916. These turbines were designed, however, to work with a vacuum not exceeding 28 in., and when with the development of condensing apparatus a vacuum of 29.1 in. was commercially reached, the Ljungström turbine had to encounter the same difficulty as all other turbines, namely, producing a steam path sufficiently ample to reduce "leaving losses" to a reasonable percentage. In the Ljungström turbine this problem was solved by fitting radial blades to the periphery of the Ljungström rotors.

The essential features of the construction of the turbine may be seen from Fig. 5 showing the upper half. The two steam rotors are denoted by h and h^1, respectively. The steam enters between the rotors near the center and flows radially to their circumference passing through the blading shown. This blading was described in detail in a previous article, as also the methods used in its manufacture, so it is not necessary to refer to it more particularly here.

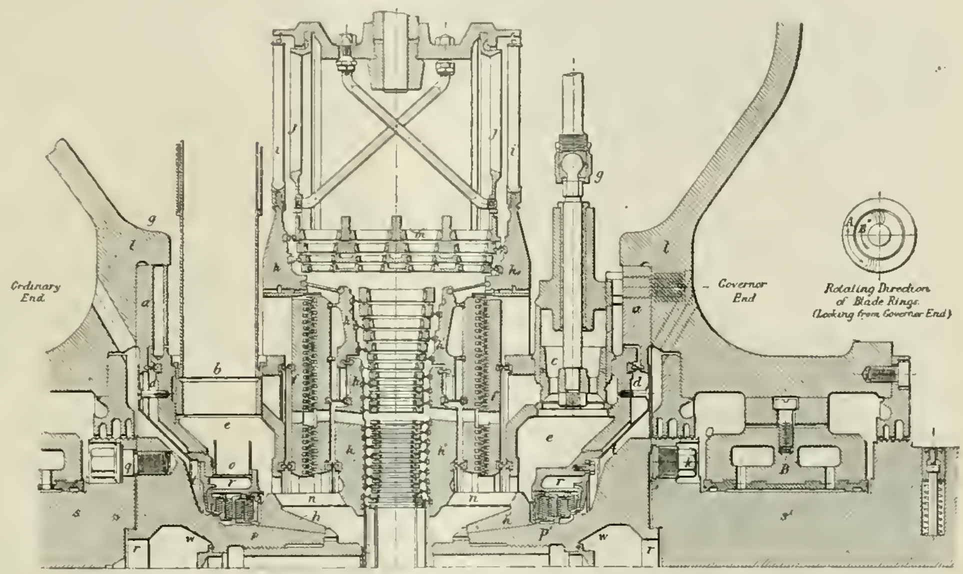

Fig. 5 Section through the Upper Half of the Brush-Ljungstrom Steam Turbine Showing the Direction of Rotation and Blade Rings

The original Ljungström turbine terminated in the row of blades lettered m, but with the high vacuums now specified it was impracticable to make such blading long enough to provide the requisite steam way. Hence, in the new model, after leaving m, the steam is passed through the fixed guide blades j, which direct it on to impulse blading i, which is, it will be seen, mounted radially on the periphery of the rotors. This last stage of the turbine provides, it will be seen, a "double flow," giving an ample steam way and moderate "leaving losses," the axial velocity of the steam on leaving the last row of blades being from 500 to 550 ft. per sec. The steam chest e is machined out of a solid steel forging and is carried from the flanges a, a by means of the dumb-bell expansion rings shown at d,d. These enable the components to adjust themselves, without heavy strain to changes of temperature. Similar dumb-bell rings connect to the steam chests e,e, the stationery labyrinth disks f,f, which form one-half of the dummies which prevent serious leakage from the steam chest to the exhaust space g. These dummies were fully described in previous articles, to which reference has already been made.

Each of the rotors h and h^1 is built up of three main components exclusive of the labyrinth disks. These three sections are also connected to each other by dumb-bell expansion rings. The innermost section of each rotor fits on to a conical seat p or p^1,

which can be bolted to the corresponding generator shaft s or s^1 by a ring of bolts one of which is shown to the left at q.

At the corresponding position on the opposite side of Fig. 5 is shown a starting bolt k which, when the turbine is to be dismantled, is used to bring out of their recesses the registers at r or r^1. In effecting this operation, the rotor of one of the generators is displaced for a short distance axially. The flanges a,a are, of course, free once the top cover has been removed, and once the registers are clear, the whole of the turbine can be lifted out of place as the steam-pipe joints are merely telescopic. Special tackle is provided for this operation which will be discussed later.

Steam from the steam chest c gets access to the blading through a series of openings n,n machined in the innermost sections of the rotors. In passing between the rotors, the steam produces a heavy axial thrust on each, and this thrust is balanced by the counter pressure of the steam which is simultaneously leaking through the dummies f. Any residual thrust is carried by Michell thrust bearings. As originally constructed, oil-filled dashpots were provided for this purpose, but while quite effective, they required careful attention to prevent leakage of oil or the entrance of air.

The glands w,w, where the rotor shafts pass through the fixed steam chest, have to be packed against high pressures. The escaping steam, as it leaves the last constriction of the gland, is caused to draw in air, by an ejector action, from the spaces t,t; and to discharge it into the spaces r,r, which are connected by pipes, one of which is indicated at o. This pipe leads away the mixture of steam and air to a separate condenser. The object of this arrangement is to prevent the possibility of steam leaking into the space t, where it might condense and fall into the oil, while further steam might pass beyond the bearings to the generator windings.

Owing to the gland steam being thus diluted with a large admixture of air, it cannot be turned into the main condenser, and a small auxiliary condenser has to be provided accordingly. The main condensate from the turbine passes through the tubes of this condenser, thus recovering the heat from the gland steam. Repeated measurements have shown that this gland leakage amounts to from $^3/_4$ per cent to 1 per cent of the total steam passing through the blades.

The turbine is governed by throttling the supply to a small servo-motor arranged above the steam stop valve. The piston of this motor is spring-loaded, and the stop and governor valves are opened by forcing oil below this piston so as to raise it against the pressure of the spring. The valve opening depends upon the height to which the piston is raised, and this depends, in its turn, on the pressure of the oil admitted below it.

A noticeable point in this governor is that no dashpot is provided to stop hunting, as it has been found unnecessary if friction be adequately eliminated. To this end ball bearings have been freely employed and very ample and complete lubrication provided for. The builders state that this is so effective that in certain cases the rise in speed between full load and no load has been under 1 per cent. In addition to this, emergency governors described in the original article are fitted into the generator shafts.

The original article also describes the many interesting details of the installation, such as the construction of the main bearings, details of the Michell thrust bearings, overload valve, steam glands, oil cooler, the special tackle used for lifting the turbine in and out of place, and the air pump—which is really a Brush-Delas ejector, as well as the generator driven by the turbine. No data of tests are presented. (*Engineering*, vol. 115, no. 2992 and 2993, May 4 and 11, 1923, pp. 542–545 and 577–578 and 2 plates of drawings, illustrated, dA)

Hardness and Hardness Testing

The Quality of Hardness

To FIND OUT exactly what hardness is and to state its measure in the fundamental units is a work of pure science which no one seems yet to have attempted. The first step in the process is for some physicist with insight, a type of man which this country fortunately produces fairly frequently, to frame a hypothesis based on what is known of molecular physics, and consistent with the various phenomena of hardness. The confirmation of the theory, by experimental verification of the conclusions which logically follow it, is a matter for the commonplace type of careful research worker, and can be carried out in any physical laboratory provided with the necessary equipment. The absence of any theory of what constitutes hardness is significant of the complexity of the characteristic of materials which is denoted by the term. The hardness of ivory is different from the hardness of lead, and this again is different from that of india rubber, yet any definition of hardness which is to be as scientifically precise as that of temperature, density, or elasticity, for example, must be applicable equally to all substances.

Several ways of testing hardness depending on different variables have been devised. If all these tests are true measures of hardness, it follows logically that there must be some consistent relationship between them so that their indications are convertible into the same scale of hardness. A vast amount of labor has been expended in the endeavor to establish mutual relationships between many of them, but with little real success.

Special attention is called to the scratch test described in a paper presented to the Institution of Mechanical Engineers recently. This test, like others, will no doubt have its uses in a particular field, but the field is likely to be a very limited one. Even if diamonds ground to standard angles could be commercially obtained, and a reliable scratching instrument could be devised, the measurement of the width of the scratches to the accuracy required by means of a high-power microscope is not for the ordinary workshop.

Exactly what property of the material the scratch test measures is by no means clear, but this is a defect common to all the other hardness tests. It has nothing in common with the old mineralogical hardness test which graded a material according to whether it would scratch or be scratched by any member of a series of standard materials. The point of a diamond will, of course, scratch anything, so that there is nothing comparative about the diamond scratch test except the size of the scratches a standard diamond will make under standard conditions. The first diamond point used in the experiments at the National Physical Laboratory was something like a blunt inverted pyramid, and, as might have been expected, the scratches were too ragged for accurate measurement to be made. They were, indeed, real scratches in the ordinary sense of the word. The next diamond tried was shaped something like a screw-cutting tool for cutting brass, but, again, as might have been foreseen, its action was to cut rather than to scratch the metal, and it "dug in" and cut wider and wider, exactly as a lathe tool would do under similar conditions. Finally, the diamond was reversed and the metal was dragged under it in the reverse direction, and under these conditions V-shaped grooves were pressed in the test piece. It is the widths of these grooves, which are of microscopic dimensions, which it was the object of the research to correlate with the hardness of the material.

Until our physicists have come to some agreement as to what property of the molecules of a substance, or what configuration of these molecules gives the quality to a material which we connote by hardness, the subject will never be put on a really scientific basis. There are enough and to spare of so-called "hardness tests," and nothing is to be gained by devising any more. If a certain Brinell number, scleroscope number, or scratch width is found to be associated with the quality of material which is satisfactory for a certain purpose, then the particular number or width can be used as an acceptance test for the material. This, in fact, is what is done in practice, and further than this the engineer cannot go at present. In spite of all the efforts which have been made to justify the several tests by scientific considerations they still remain empirical determinations of an unknown quantity. If hardness is wanted in a material for the resistance of abrasion, the amount of abrasion produced under given conditions is the only true measure of the kind of hardness required. If penetration is to be resisted, as in the case of armor plate, some kind of penetra-

tion or indentation test is obviously suggested. If, on the other hand, hardness is taken as an indication of tensile strength, or of chemical composition, it is surely better, whenever possible, to determine these characteristics directly. The ease by which certain so-called tests of hardness can be applied to finished material without injuring it, and the pseudo-quantitative nature of the numerical results obtained, tend, by reason of their attractiveness, to disguise the fact that it is an unknown quantity which is being measured, and one which may, or may not, be correlated with the characteristics desired.

The conclusion to which the author arrives is that the accumulation of the results of hardness tests of numerous kinds is now so vast that it seems that the time has come for the physicist to step in, and that the invention of further hardness tests and the collection of additional uncorrelated data are to be deprecated until some agreement can be arrived at as to the exact property of the tested material which is in question. (Editorial in *Engineering*, vol. 115, no. 2991, Apr. 27, 1923, pp. 527–528, *gA*)

Relation Between Width of Scratch and Load on Diamond in the Scratch Hardness Tests

By G. A. Hankins

Experiments described in the present paper have been carried out by the National Physical Laboratory for the Hardness Tests Research Committee of the Institution. The work was suggested originally by Dr. Unwin, who considered that the relation between the width of the scratch and the hardness number required further investigation.

The apparatus used for the tests is described. Of particular interest is the description of the various types of diamonds used for the test, as the type employed appears to affect the results to quite a material extent.

The results obtained show that with the materials used a straight-line law exists between the square of the width of the scratch and the load on the diamond, and that with each diamond under constant conditions the straight lines appear to meet at the same point for all materials. Taking p and q as the coördinates of this point, it appears that a law exists of the form:

$$(P-p) = k(w^2-q)$$

where P = load on diamond, w = width of scratch, and k = a constant for each material. Hence

$$k = \frac{P-p}{w^2-q}$$

k will thus be a stress, and it is suggested that the values of k for different materials may be taken as a measure for the hardness of the materials as determined by the scratch method.

Scratch hardness as thus defined has been plotted against the apparent Brinell hardness. The actual values of k appear to be dependent on the shape of the diamond and the angle with the test surface, but the type of curve is the same in all cases. The ratios of the scratch hardness to the Brinell hardness numbers have been calculated and are given in a table in the original article, from which it appears that a minimum value occurs at a Brinell hardness of about 450. With the exception of the value for copper, a progressive increase in the ratio occurs for both higher and lower values of the Brinell numbers. The manner in which the diamond has been used in the present tests appears to give a scratch which is of the nature of an indentation test on the materials, and therefore agreement with the Brinell numbers might be expected. The variations in the ratios seem too uniform to be due to experimental errors, and it appears that the test does measure a property of the material slightly different from that measured by the Brinell test. The value of the ratio found for copper is interesting when considered in connection with Professor Turner's statement, that "a piece of hard-rolled copper may give a greater hardness number than one of mild steel, yet a tool made of mild steel will always cut copper and no amount of cold rolling will make copper cut steel."

The results show that the method can be utilized to obtain a measure of the hardness of metals on the same scale over a very wide range, but at present the most useful applications would appear to be in the case of the harder materials or where only small or valuable specimens are available. For general use it seems that a standard shape of diamond would have to be adopted, since the results obtained depend on the shape of the diamond, but comparison of the results obtained with two of the diamonds used appears to show that small variations in the angles of different diamonds do not have a large effect on the results obtained. (Paper read before The Institution of Mechanical Engineers, Apr. 20, 1923, abstracted through *Engineering*, vol. 115, no. 2991, Apr. 27, 1923, pp. 537–540, 17 figs., *el*)

Static Indentation Tests

By R. G. C. Batson

This paper contains the results of various investigations which have been carried out for, and reported to, the Hardness Tests Research Committee for the Institution of Mechanical Engineers during the years 1919–1922, with a view to elucidating various points in connection with the application of indentation test as a measure of the hardness of materials. The points considered are as follows: (1) Investigation of law of comparison for ball indentation tests; (2) a comparison of the ball and cone methods of test; and (3) the determination of the relative hardness of very hard steels by means of ball hardness tests, in which the permanent deformation of the ball is taken as a measure of the hardness of the material producing it.

Among other things, the author compares results obtained by the employment of the cone pressure test such as is used on the Continent with those obtained with the standard ball method. For this purpose a series of tests has been carried out on four materials to compare the hardness numbers obtained by using a 10-mm. diameter ball and a 90-deg. cone, when these numbers are in each case calculated from (1) the diameter of the impressions as obtained by a measuring microscope after the test, and (2) the depth of the impressions when the pressure has been removed, measured from the original surface of the materials.

From these tests it would appear that

1 The hardness numbers obtained with a 10-mm. ball and calculated from the diameters of the impressions are not independent of the load. This fact is well known and has been pointed out by many experimenters.

2 When the depth of the ball indentation (from the original surface) is used for calculating the hardness numbers, the numbers obtained are independent of the load within the range of these experiments. This fact was pointed out by R. P. Devries in 1911 (U. S. Bureau of Standards Technologic Paper No. 11).

3 With the cone test the experiments made for the purpose of the present paper appear to show an effect of the opposite kind from that described under conclusions (1) and (2) for the ball test. The hardness numbers calculated from the diameters of the impression (using the conical area of the impression as recommended by Ludwik) are approximately constant, and those obtained from the depth of the identation vary with the load.

4 It follows from conclusions (1), (2), and (3) that with varying loads the complete impressions with the ball test are dissimilar, and with the cone test are similar. It also follows that, when the part of the impression caused by the "ridge" is neglected, the impression under varying loads given by the ball test are similar and by the cone test are dissimilar.

5 The hardness numbers with a load of 3000 kg. show that, whereas for three of the materials the ratio is approximately the same, for manganese steel the cone test gives a much higher relative result than the ball test. For this reason it is not possible to give a definite ratio under these conditions between ball-test results and cone-test results for all materials.

It will be noticed that for the three materials and with the methods of calculation adopted, the ball test gives numbers which are from 8 per cent to 13 per cent higher than the cone-test numbers when using the diameter of the indentation, and 3 per cent to 9 per cent lower when using the depth of indentation from the original surface of the test piece. It was suggested that in order to obtain the same hardness number for both ball and cone tests, the hardness number should be taken as equal to

$$\frac{\text{Load}}{\text{projected area of indentation}} = \frac{L}{\pi d^2}$$

where L = load and d = diameter of the indentation. By adopting this method of calculation the cone hardness numbers would be 41.4 per cent higher and the ball hardness numbers less than 12 per cent higher (this depending on the diameter of the indentation) than those obtained by the method previously described. There would thus be a still greater difference between the cone- and ball-hardness test numbers if this method of calculation was used. (Paper read before the Institution of Mechanical Engineers, Apr. 20, 1923, abstracted through *Engineering*, vol. 115, no. 2991, Apr. 27, 1923, pp. 534–537, 10 figs., *et*)

Short Abstracts of the Month

AERONAUTICS

Cycle Engines for Light Planes. Description of the Bradshaw 500-cc. oil-cooled engine. The main feature of this engine is that with the exception of the cylinder heads it is cooled by the lubricating oil, which is in turn cooled by radiation from the walls of the crankcase, which is therefore made of particularly large proportions.

Owing to the fact that the oil is used for cooling as well as for lubrication, the lubrication arrangement is naturally somewhat unusual. Driven from the camshaft is a gear pump, which draws oil from the sump in the crankcase through a large gauze filter, and delivers it under pressure to the internally drilled crankshaft. By a special system of oil-release grooves the flow of oil through the crankshaft and from the big ends has been increased by 100 per cent, so as to give cooling as well as lubrication. From the big ends the oil is splashed on to the cylinder walls, the inside of the pistons, to the valve gear, etc., and it is claimed that the whole oiling system requires no attention.

The engine, which is a flat-twin, is rated to develop in the neighborhood of 11 b.hp. at 2500 to 3000 r.p.m. and for this power weighs approximately 70 lb. in full running order, or about 46 lb. without flywheel, magneto and carburetor. (*Flight*, vol. 15, no. 18/749, May 3, 1923, pp. 240–241, 3 figs., *d*)

Jet Propulsion for Aeroplanes

Jet Propulsion for Airplanes, Edgar Buckingham. Data of work undertaken at the Bureau of Standards on the request of the Engineering Division, Air Service, U. S. Army, and later submitted with their approval to the National Advisory Committee for Aeronautics.

The term "jet propulsion" as commonly understood implies the use of a small intense jet maintained by some other means than an airscrew. Thus, if air is compressed and mixed with fuel in a combustion chamber where the mixture burns at constant pressure, and the combustion products issue through a nozzle, the reaction of the jet constitutes the thrust.

Only the simple nozzle such as is used in steam turbines is considered in the present investigation, which did not cover in detail the possibility of improving the propulsive efficiency of the jet by any of the aspirator or ejector devices that have been proposed for increasing the momentum and thrust.

Data are now available for an approximate comparison of the performance of a jet propulsion device with that of the motor-driven airscrew.

The conclusions at which the author arrives are not in favor of propulsion by the reaction of a simple jet, which he claims cannot compete in any respect with airscrew propulsion at such flying speeds as are now in prospect.

While the relative fuel consumption and weight of machinery for the jet increases as the flying speed increases, still even at 250 m.p.h. the jet would take about four times as much fuel per thrust horsepower-hour as the airscrew, and the power plant would be heavier, much more complicated, and also more delicate.

To say nothing of the fuel-injection system, the combined compressor and engine would have about twice as many pistons, valves, and other moving parts as a simple engine, and the chances of breakdown and the difficulties of upkeep would be correspondingly increased.

There are, to be sure, a few obvious advantages in the jet scheme. The large, awkward, and fragile propeller would be eliminated, and only the nozzle and not the engine would have to be located with regard to the axis of thrust. Thus the design would be more flexible. The machine might also, if strong enough, be given brilliant maneuvering powers by utilizing the powerful steering effect of swinging the nozzle. On the other hand, a machine which had to start, if it could get off the ground at all, by emitting a jet of flame at 2500 deg. fahr. and a speed of one mile a second would hardly be a welcome visitor at flying fields.

The only hope of success lies in the use of thrust augmenters which are devices or arrangements that will increase the momentum of a jet already formed without increasing the fuel consumption needed for maintaining the jet or adding seriously to the weight. Devices of this sort have been proposed and the author discusses them qualitatively. These devices consist mainly in surrounding the jet after it has left the nozzle by a series of ring-shaped guides, of curved profile, after the manner of an ejector or aspirator. If these guides are properly designed, the pressure in the internal free space about the jet falls below atmospheric, air is drawn in, and before it comes into actual contact with the jet, it has already, in its passage through the curved ports between the guides, acquired a considerable component of velocity in the same direction as the jet. The idea seems to be that the shock loss will be reduced and kinetic energy saved; that the backward momentum of the entering air will be added to that already present in the jet so as to increase the thrust; and that the thrust horsepower of the whole combination will be augmented, without any modification of the part of the apparatus originally provided for maintaining the jet or any increase of fuel consumption.

It is hard to see just how this sort of process can be analyzed and referred to the elementary principles of mechanics and thermodynamics so as to permit of forming any definite quantitative opinion of its feasibility. There is no doubt that ejectors and aspirators built on this plant have been very useful and effective for certain purposes; but whether, in the application now in question, they would have the effect hoped for seems very problematical, and the present writer remains skeptical. (*National Advisory Committee for Aeronautics*, Report no. 159, 1923, 18 pp., 7 figs., *et*)

Gyroscopes in Aircraft Instruments—Gray Stabilizer

On the Application of the Gyroscope to the Solution of the "Vertical" Problem on Aircraft, Prof. James Gordon Gray and Capt. J. Gray. Description of various devices, chiefly those developed from research work carried out in the Natural Philosophy Institute of the University of Glasgow, where the first of the authors is Cargill Professor of Applied Physics. These devices relate to apparatus for finding, maintaining, and thus defining the true vertical and horizontal on aeroplanes and airships. The so-called "vertical" problem and with it the application of the gyroscope is of importance. Navigation must be made precise by the provision of gyroscopic sextants; photography from airplanes to be accurate must be carried out by means of special cameras stabilized so that the photographs are true vertical productions; bombing from airplanes must be rendered accurate by designing the bombsight as part of an accurate stabilizer, etc.

The article is very extensive and can be abstracted only very briefly. Among the interesting portions which cannot be abstracted is a discussion of the behavior of a gyroscopic pendulum when it is mounted on an airplane which moves in a curved path. The authors derive the equations determining such behavior. From this it would appear that if the spin of the gyroscope is clockwise as seen from above, and the airplane moves round in the counter-clockwise direction as also seen from above, there will be a growing deflection of the pivoted system with respect to the vertical. In general, they come to the conclusion that if the gyroscopic pendulum is to meet with success it must have a real periodic time of precessional motion or virtual periodic time in the presence of curvilinear motion on the part of the airplane which is upward

of one hour. This would make pendulums which have a periodic time in excess of only 4 min. useless, notwithstanding the fact that such pendulums have been highly endorsed.

Furthermore, under the conditions which prevail on aircraft, gyroscopic pendulums which depend for their action on gravity control and dashpots are of little or no use; under such conditions these devices leave the vertical quickly and return very slowly.

The gyroscopic pendulum of the type in which the erecting action depends on the existence of precessional motion, is subject to an error due to the rotation of the earth when supported on a steady platform at rest. But if it is carried on a moving vehicle, such as an airplane, the errors due to the motion of the vehicle are so large that it is unnecessary to consider those due to the earth's rotation.

From this the paper proceeds to the description of the Gray stabilizer. It consists of a gyroscopic system pivoted in the conventional manner and having the following properties. Should the pivoted system be inclined to the vertical during normal flight of the airplane or airship, a stabilizing couple is applied to the gyroscope and the device is restored to the vertical. The stabilizing couple is obtained by means of a special erecting device, and depends in no way on precession of the gyroscope in the ordinary sense of the term. During curved flight of the airplane the erecting device goes automatically out of action. Thus the pivoted system leaves the true vertical very slowly, if at all, in the presence of curved flight, and approaches it relatively quickly during normal flight.

The various designs of this stabilizer are described in great detail. Experiments carried out by means of the sun-shadow methods (described in the original article) are claimed to have shown that these stabilizers remain absolutely undisturbed by the pitching and rolling motions of an airplane.

The authors recommend using powerful gyroscopes for airplanes with their stabilizers, such as, for example, those having an angular momentum of 2000 in ft-lb-sec. units. This is the angular momentum possessed by a whirl of mass 20 lb., radius of gyration 3 in., when performing 250 r.p.s. Complete with its casing and bearings such a gyroscope would have a mass of about 25 lb. and the diameter of its casing would lie between 7 and 8 in. For use on board ships of war in connection with anti-aircraft devices, much larger gyroscopes are recommended such as those having an angular momentum upward of 5000 in. ft-lb-sec. units.

An interesting feature claimed for the Gray stabilizer is that it is free of error due to rotation of earth. (*Proceedings of the Royal Society of Edinburgh*, vol. 42, no. 3, pp. 257–317, 38 figs., *tdA*)

AIR MACHINERY (See also Aeronautics)

Surface Air Coolers

Physical Consideration and Design of Surface Air Coolers. A. R. Smith. This article forms a part of a series under the general title of Cooling of Turbine Generators and deals with the details of design of surface air coolers.

The size of tube now used is $^5/_8$ in. outside diameter, 18 B.W.G. wall, and made of either muntz metal or Admiralty brass. While larger tubes may be used, it would appear that they do not present any important advantages.

In order to give the maximum amount of cooling surface at the minimum expense, the tubes are wound with copper fins spaced seven to the inch and having an effective depth of $^1/_4$ in. The addition of fins increases the external radiating surface of the tube, which is the high-resistance side, over six times. The fins are shouldered and soldered to the tube so that the joint presents no resistance to the flow of heat. They are flat and smooth.

The tube sheets are made of rolled muntz metal, which gives a non-porous tube sheet, and this prevents water from seeping through into the air space.

Over each of the tube sheets are bolted by means of studs and nuts cast-iron water boxes, provided with a large inlet and outlet to reduce turbulence, which would tend to affect the distribution of water through the tubes. The coolers are arranged so that the tube sheets form a part of the air duct, which leaves the water boxes accessible so that the tubes can be inspected or cleaned with the least possible inconvenience.

The plan so far has been to maintain a minimum water velocity through the tubes which would be in excess of the critical velocity. The maximum water velocity naturally depends on the pumping head permissible. The number of water passes depends on the number of tubes in the cooler and on whether condensate or circulating water is used. Eventually, the number of water passes will probably become more or less standard because the conditions under which turbine generators operate are not very different. For the present, however, any number of water passes can be obtained to meet conditions.

The flow of water with respect to the flow of air is counter-current.

The resistance to the flow of air through the cooler is dependent on the air velocity and the depth of the cooler, the temperature of the air having only a slight effect on the drop in air pressure through the cooler. If a fixed amount of surface is so distributed that the air velocity is low, the depth of the cooler will naturally be reduced; but the same amount of surface can be so distributed that the depth is considerably greater, which will result in a higher air velocity. When an approximation of the amount of surface is made, it is obvious that it can be so arranged, provided there is sufficient space, to obtain almost any resistance that may be desired.

Resistance to the flow of air in large air ducts of moderate lengths is almost a negligible factor. Excessive pressure drops are the result of eddying and loss of velocity heads. In laying out any duct system, and especially those in connection with surface coolers, where all of the available pressure loss should be applied to the cooler, the ducts should be carefully designed and in many cases can be so designed that the duct loss can almost be neglected.

The loss of head or resistance to the flow of water is also a variable quantity, and there is considerable latitude in regulating the total pressure drop. A velocity in the tubes of not less than 2 ft. per sec. is desired so as to keep the flow above the critical velocity. If a velocity of 5 or 6 ft. per sec. is attempted, the number of water passes are increased and the friction head increases very rapidly.

Where the coolers utilize the condensate as a circulating medium, then a relatively high velocity, say, of 4 or $4^1/_2$ ft., is desirable when the turbine is operating at full load, so that at partial loads the velocity is more nearly normal. The total pressure drop in the cooler from the inlet to the outlet nozzle usually runs in the neighborhood of 20 ft.

In most cases the surface cooler presents a number of economical and operating advantages. To what extent these advantages may be capitalized depends of course upon local conditions. The common advantages are as follows:

1 If the air-duct system contains but a small volume of air, no fire extinguisher should be necessary because the oxygen will be rapidly consumed and the fire smothered without requiring the attention of an operator, or the operation of any dampers.

2 If the proper precautions are taken to prevent any material infiltration of air, the deposits in the machine or on the cooler should be insignificant. If a clean generator is maintained, the temperature rise of the winding above the incoming air temperature should not increase with age.

3 The volume of water required for cooling the air can be regulated because the flow of water is counter-current with respect to the flow of air. Where water is expensive it is therefore possible to economize on the quantity.

4 The pumping head or the amount of auxiliary power required is extremely low.

5 Where condensate can be employed either wholly or in part, for the cooling of a generator, some or all of the generator losses are returned to the system in the form of heat.

There may be arrangements adopted where the puncture of a tube might release water into the generator. Such a condition can be guarded against by the installation of water eliminators which have been developed especially for such a purpose. The employment of eliminators, however, will introduce additional friction in the air circuit and it is recommended that the coolers be so located as to avoid the necessity of using eliminators. With the cooler sections located below the generator the spouting velocities of the water may prevent it from entering the generator winding even though it is assumed that such a leak develop at just the right point on the upper row of tubes. (*General Electric Review*, vol. 26, no. 5, May, 1923, pp. 298–303, 5 figs., *d*)

ENGINEERING MATERIALS

New Bearing Metal—Thermit. Data of a new metal developed by Professor von Hanffstengel together with the Th. Goldschmidt Co. in Essen. The exact composition of the new metal is not given. It is stated, however, that it belongs to the class of materials containing lead, in addition to which it has other ingredients. Its properties depend essentially on correct alloying and mixing practice, and it is stated that it gives better results than certain other bearing metals used in machinery when it so happens that the bearings fail to receive proper lubrication. (*Technische Blaetter*, published weekly by the Deutsche Bergwerks-Zeitung, vol. 13, no. 16, Apr. 21, 1923, pp. 113-114, 4 figs., *d*)

Coronium Bronze Alloy. The precise composition and process of manufacture of the alloy is not given, but it is stated that it contains copper, 16 parts; zinc, 3 parts; and tin, 1 part, which figures include the usual impurities.

With regard to physical properties, in ordinary sand castings of handy size, tensile tests have given 16 to 18 tons per sq. in., according to conditions connected with each case. In some cases where very special castings have been made and unusual precautions taken in the pouring and cooling, an ultimate tensile test of 22 tons per sq. in. has been officially reported. In one of the cases last referred to, the elongation was officially given as 38 per cent on 2 in., this having reference to the same test piece, and at the same time there was a reduction of area observed of 37 per cent. The elastic ratio observed at the same time was 0.6, a figure of great importance. Referring again to the figure of from 16 to 18 tons per sq. in., engineers using the material for commercial purposes can safely rely upon an elongation taken on the same test piece having a figure in excess of 25 per cent in 2 in., with a reduction of area in excess of 25 per cent at the same time. The Brinell hardness as cast may be taken under any circumstances at a figure of 85 to 90 on the Brinell scale, and the machinability—assuming good brass to be 80—at 100.

The metal can be rolled cold into sheet of the finest gages, and drawn into rods or tubes and generally wrought with ease. The effect on the physical properties of rolling into rod is a good general example of the result of mechanical treatment, and the tests that have been made gave very interesting results. Test pieces were taken from a bar rolled from the ingot to $^5/_8$ in. in diameter, and the maximum tensile stress was proved to be over 35 tons per sq. in., with a corresponding elongation in 2 in. of 58 per cent and a reduction of area of just over 60 per cent. The specific gravity in the cast state is 8.9, as compared with 8.8 as the maximum figure obtained in the heaviest phosphor bronze as cast. The melting point is 1100 deg. cent. (2030 deg. fahr.). The strength and elastic limit are not seriously affected by annealing. Compared with phosphor bronze, the latent heat is greater, and the heat conductivity correspondingly rather less. The alloy has an electric resistance as great as that of nickel (whose resistance is materially higher than that of any copper alloy). The power of resistance to corrosion, so far as it has been possible to test the matter, seems to be very high. The coefficient of expansion has not been finally determined, but observations up to date show that it corresponds very closely to that of cast iron. (*Foundry Trade Journal*, vol. 27, no. 350, May 3, 1923, pp. 359, *d*)

Centrifugally Made Concrete Poles

Concrete Poles Made by Centrifugal Process. Reinforced-concrete poles made by centrifugal process are receiving considerable attention these days, particularly in Europe.

One of the largest power-transmission lines in Sweden is carried by means of such poles. These carry two cables between the poles, which are about 36 ft. apart, and two at the ends of the cross-beam, which is about 54 ft. in length. According to the changing local conditions along the line and the variations in the load from 1200 to 1400 lb., four different sizes of poles were made which were from 56 to 59 ft. in height, from 9 to 10 in. in diameter at the top, and from 18.5 to 23 in. at the bottom. The average wall thickness is 2 in. Nearly 6 per cent of them were tested, and some—about 1 per cent of the whole number—were subjected to bending stresses till fracture occurred.

It was stipulated that the latter had to withstand at least four times the highest ultimate load at the top. The others had to be subjected to double that load without showing any cracks or alterations of form. The tests proved, however, that the poles were exceedingly elastic and could carry six to eight times the highest ultimate top load. During the tests the load was taken off several times, and the top went almost completely back into its original position, showing that the bending was of an entirely elastic nature. Even after fracture had occurred the steel reinforcement was still able to stand considerable stress as it had only slightly been damaged. In some cases when the breaking stress had been reached, cracks from the tensile stress outside the bend and signs of excessive pressure inside the bend appeared at the same time, which shows that the tensile stress which centrifugal concrete will stand is considerably above the usual normal for concrete. Some of the poles, 64 ft. long, being subjected to a bending stress of 7300 lb. bent $7^1/_2$ ft. at the top without any signs of damage. The poles were tested at an age of six to seven weeks. It had also been proved that their earth connection, which was brought about by attaching contact pieces to the steel reinforcement, was good, and that the electric resistance was less than 0.2 ohm.

These poles are manufactured in a wooden mold which is revolved in a special machine. This mold consists of two half-round forms, and is lined with sheet iron inside. The reinforcement is formed by rolled rods, of open-hearth material, going lengthwise, which are interwoven with three spirals of wire one within the other. It is wound upon a special automatic machine, so that the uniformity in their measurements and the strength of the poles is insured. The spirals influence the fracture stress comparatively little but they determine to a certain extent the rigidity of the pole, and by using three spirals it has been possible to reduce the bending to 0.5 per cent of the length at the normal load, and to 1.5 per cent at the double load. In order to give the maximum strength to the pole, care is taken that the reinforcement comes as close as possible to the circumference and is at an equal distance away from it. The cement mortar is mixed in proportion of one to three, and some asbestos fiber is added to assist in holding the sand and cement together.

After the wire structure and the cement have been put into the mold, it is closed and put into the machine. According to the diameter of the pole, the mold is then revolved at a speed of 500 to 1000 r.p.m. This high velocity, which is attained immediately after starting, and continued revolution at the same speed are necessary to prevent a decomposition of the mortar, which would take place on account of the different specific gravities of sand and cement. The excessive water in the mortar accumulates in the hole in the center, and in striking the wall of the pole during the rotation, increases the compactness of the grain. The fears that the cement would be thrown to the outside and that the mixture would become less rich toward the center have been proved unfounded.

The centrifugal arrangement consists of several machines which are lined up one behind the other. Each machine has two strong side frames with a large center bore. Inserted in the bore is a tube which rolls freely between six wheels carried by three shafts which may be adjusted radially in relation to the bore. The tube is fitted with a self-centering chuck for holding the wooden mold. All machines are driven from a main shaft, the center tube serving as a pulley. After revolving the mold in the machines for about 10 to 15 min. it is taken out, the lid at the end is removed, and the water is poured out of the center. The pole is left in the mold for 1 or 2 days. It has then set sufficiently to be taken out, and is kept in moist sand for about 3 to 4 weeks. (*Power Plant Engineering*, vol. 27, no. 10, May 15, 1923, pp. 531–532, 2 figs., *d*)

HYDRAULICS

The 40,000-Kva. Shawinigan Falls Water-Wheel Generator, J. Ralph Johnson. Description of a generator installed in a Canadian plant and notable not only on account of its size but also for certain features of design of the most modern character. It has been in operation since October, 1922, and is a unit of the vertical type with direct-connected exciter designed to deliver normally 40,000 kva. of three-phase current at 0.75 power factor,

60 cycles, and 11,000 volts while running at a speed of 138.5 r.p.m. It is, however, capable of working at considerable overloads and overvoltages for limited periods of time.

Only the mechanical features of design will be primarily reported in this abstract, although the article contains also the description of several interesting electrical features.

In this installation the operating floor is level with the top of the stator frame. This construction gives ample space round the generator on the main floor and provides a convenient means for dealing with the exhaust air from the generator in the annular space beneath this floor. The air may either be utilized to heat the generator room in winter by opening up steel trap doors in the floor, or in the summer it may be ejected outdoors through the windows in the outer wall beneath the main floor.

The rotor spider is made of cast steel and consists of three wheels, each made up of two semicircular sections bolted together at the hub and linked together to the rim by shrink keys. The rim, arms, and hub of each section are cast solid. Some manufacturers have raised objection to this type of rotor construction in large units owing to the difficulty of obtaining reliable castings. If, however, proper care is taken in annealing, testing of samples, and keeping stresses at overspeed within half the elastic limit, entirely reliable castings can be and have been made. The shaft is made of forged steel and has a solid forged flange which is bolted to the water-wheel shaft flange for coupling. The coupling bolt holes were reamed on site, thus insuring proper alignment of the two shafts.

The total weight of the complete rotor is 201 tons and the flywheel effect is 35,034,000 lb-ft.[2] In view of the enormous kinetic energy stored in the rotating parts a mechanical braking system was installed to bring the machine from normal speed quickly to rest. This braking system also helps to hold the rotor at rest against possible leakage past the water-wheel gates when the Johnson valve is not closed. The braking system is described in some detail in the original article. An interesting feature of it is that the brakes may be used when necessary as jacks to raise the rotor from the thrust bearing for inspection or repair purposes.

The generator guide bearing is of the standard babbitted type and the water-wheel guide bearing is of the water-lubricated lignum vitae type. On the machine itself is used a spring thrust bearing consisting essentially of a spring-supported stationary babbitted plate and a highly polished hard, gray-cast-iron rotating plate. The stationary plate is supported on a large number of helical springs loosely pinned to a baseplate which is doweled to the machined face of the upper bearing bracket. The flexibility of this support allows the plate to conform to the natural alignment of the shaft, thus preventing excessive local pressures in the bearing and allowing the maintenance of an oil film between the bearing surfaces.

The bearing operates in an oil bath and the heat generated is taken up by the oil as it passes by centrifugal action between the bearing surfaces. Heat is also transmitted to the oil through the metal of the bearing plates. The heat is removed from the oil by the circulating water in a stack of cooling coils immersed in the oil bath. Clean oil is pumped from a filter tank on the ground floor to an upper tank above the level of the machine. From the latter tank the oil is piped to the guide and thrust bearings, thence to a common drain which returns to the filter tank. If by any chance the oil pumps (one of which is in reserve) have to be shut down, the generator may still run if the thrust-bearing oil-supply line is shut off, as the storage tank can supply the guide bearing for several hours and the cooling coils will maintain the oil in the thrust bearing at normal temperature. (*General Electric Review*, vol. 26, no. 5, May, 1923, pp. 263–268, 7 figs., *d*)

Flow of Water Through Pipe

The Flow of Water Through Vitrified-Clay and Corrugated-Metal Culvert Pipe. Results of an extensive investigation conducted by the U. S. Bureau of Public Roads at the State University of Iowa Hydraulic Laboratory. Among other things capacities of the two kinds of pipe are compared and values of coefficient of roughness in the Kutter formula have been determined.

The sizes tested of each kind of pipe were 12, 18, 24, and 30 in. in diameter, and to determine the effect of the length of the culvert on its capacity the 24-in. pipe of both materials was tested in three lengths, namely, 24, 30, and 36 ft. Many different types of entrances were tried, such as various conical entrances, straight end-wall entrances, wing walls set at 45 deg. to the pipe line, and the new-type wings. The effect of varying the height of the wing wall was also tested.

The testing equipment and procedure of testing are described and the experimental results given in the form of characteristic curves for the various types of pipe and a short table.

Piezometer readings were found to be quite inconsistent and more erratic in general with the vitrified-clay pipe than with the corrugated-metal pipe. The piezometer closest to the entrance end of every pipe invariably showed a reading below the average hydraulic gradient when the velocity was high.

Perhaps the most surprising thing about these diagrams is the striking way in which they reveal the fact that for such short pipe the element of friction in the pipe itself is much dwarfed in comparison with the head consumed at entrance in getting the water into the pipe. As shown in Fig. 1, the friction head for the 12-in.

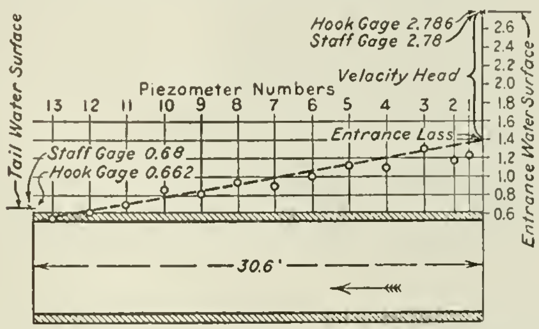

Fig. 1 12-in. Vitrified-Clay Pipe, 30 ft. Length, Straight End-Wall Entrance, Flat Slope

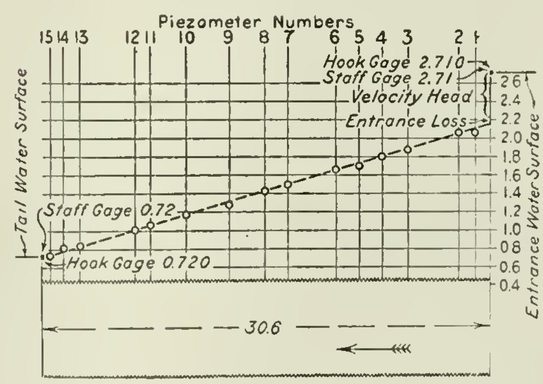

Fig. 2 12-in. Corrugated-Metal Pipe, 30 ft. Length, Straight End-Wall Entrance

clay pipe was much less than the velocity head consumed at entrance. This relation is independent of the velocity of flow, for as the velocity increases both the friction loss and the velocity head increase in substantially the same proportion. For pipe of larger diameters the frictiou loss has less importance.

With corrugated-metal pipe the friction factor is much greater than with clay pipe and is therefore of greater importance. Fig. 2 shows a 12-in. corrugated metal pipe carrying nearly the same quantity of water as is carried by the 12-in. clay pipe represented in Fig. 1. Although the velocity head is about the same in the two figures, the friction head in Fig. 2 is several times as great as in Fig. 1. The friction loss in vitrified-clay pipe and corrugated-metal pipe may be compared by calculating for each the coefficient of roughness by Kutter's formula. When this was done it was found that the results varied slightly with different sizes of pipe and different velocities of flow. For clay pipe the values obtained for Kutter's exponent n varied between 0.011 and 0.014; for corrugated-metal pipe between 0.019 and 0.024. The greater resistance to flow in the metal pipe is undoubtedly caused by the corrugations. (*Good Roads*, vol. 64, no. 14, Apr. 4, 1923, pp. 131–133, 2 figs., *e*)

MACHINE TOOLS (See Special Machinery)

MARINE ENGINEERING

Water-Tube Boilers in Marine Service

Operation of Water-Tube Boilers in Passenger and Cargo Ships, R. Clark. A paper of largely practical character discussing the operation of three types of boilers, namely, Babcock & Wilcox, Yarrow, and Stirling, along with various automatic controls required in their operation. The author has mainly in view the Class H standard ships. These ships have a carrying capacity of 3800 to 4000 tons and are driven by triple-expansion engines.

Among other things, the author mentions that a considerable time ago, owing to certain troubles developing in cylindrical boilers, the Admiralty Boiler Committee made investigations, and it was shown that the limit to which cylindrical boilers could be worked represented a transmission of 12,000 to 14,000 B.t.u. per sq. ft. per hour; as a matter of fact the author is of the opinion that half of this rate would be a reasonable margin of safety. The inefficient circulation which sometimes results in overheating is responsible for this low transmission.

The war period has shown the mercantile service what can be done with water-tube boilers, and the author is of the opinion that the majority of new ships which will be built in the future will be fitted with water-tube boilers of some type or other because of the efficient and satisfactory performance of the same in the past, and after all it is a type of boiler which can always be depended upon to give 40 to 50 per cent of the rated capacity without injury to the tubes or the shell.

Mechanical stoking in conjunction with mechanical draft is also having serious consideration, and a large number of Babcock & Wilcox marine boilers are being fitted with several types of forced-draft stokers. However, there are certain disadvantages which must be referred to. Particularly where ships are already in service it is somewhat difficult to install the stokers, but where new ships are being built arrangements can easily be made whereby the designs can be so altered as to include the handling of the coal and ashes on an economical basis. Other disadvantages are the extra weight and complication involved, and also the difficulty of finding mechanical stokers suitable for the various classes of fuels which have to be dealt with on board ship. This difficulty, however, is gradually being overcome and the results as far as the author has been informed are very promising indeed. It is also difficult to show that mechanical stoking is an improvement over good hand firing, but the fact remains that it is difficult to find a really good fireman who will fire a boiler as efficiently and skilfully as a mechanical stoker. With a mechanical stoker one will always obtain a steady pressure. It is not necessary to clean out fires because the stokers are self-cleaning, and, taking a general view, the author is of the opinion that sooner or later a big percentage of the ships now sailing will have mechanical stokers fitted where it is absolutely necessary that vessels have to be kept to coal fuel. There can be no doubt that the water-tube boiler with its large combustion chamber can be made to suit and is far better adapted to the mechanical stokers than the cylindrical boiler, and it is on these lines that improvements are likely to materialize.

The author strongly advocates the use of oil fuel and discusses briefly the various types of oil burners. From his own tests on ships of the H-type using the forced draft he suggests that where this is done it is desirable, in order to control fully the operation of the boiler, to have the speed of the fan engines regulated by some automatic device so that when the boiler pressure rises to the working pressure the fan engine is slowed down, and when the boiler pressure falls, say, 2 or 3 lb., below the blow-off pressure the engine is speeded up again.

During the trials at which the author of this paper was present he noticed that the regulation of the fan-engine speed had to be undertaken very frequently, taking up the attention of the leading fireman when he might have been otherwise engaged. To get over a difficulty of this description an automatic fan-engine control fitted to a steam supply pipe and thence to a fan engine was designed. Fig. 3 illustrates this as working in conjunction with the Babcock & Wilcox boiler, stoker-fired.

This consists of a double-seated balanced valve, diaphragm-operated. The diaphragm chamber is connected by a copper pipe to either the boiler or the main steam pipe so that when the steam rises to blowing-off pressure the diaphragm is depressed and automatically closes the valve, shutting off steam to the engine. The reverse process takes place when the pressure is relieved due to the steam pressure falling back, say, 2 or 3 lb. This is a very useful control and has been used in a number of ships, the result being that the fireman does not require to trouble himself about regulating the speed of the fan and can devote his time to other matters.

The author further describes and advocates the use of water-level regulators such as the Babcock & Wilcox and the Crosby.

Usually when new steamers are taken over by the superintendent, and the chief engineer is installed, he is not furnished with all the records which the author considers he is entitled to.

In running trial trips it is the custom of the engineering staff responsible to the builders to take draft readings and flue temperatures at various positions in the boiler, and it is the author's contention that a set of these figures should be furnished to the chief engineer so that he can with similar instruments take records, and by these means be able to keep the water-tube boilers working in an efficient manner. The author quotes a case in point where the rate of burning per square foot of grate area was in the vicinity of 20 lb. The temperature of the escaping gases at a point in the uptake was 510 deg. fahr. The evaporation per square foot of heating surface was 4 lb. CO_2 readings ranged from 10 to 12 per cent, making an overall efficiency of 73 per cent. The engineer complained when his ship arrived back in port that he was burning too much coal, and that, therefore, the particular water-tube boiler was not efficient. It was, however, pointed out that he had never cleaned the exterior surface of the tubes and it was probable that the gases were passing into the chimney at a very high temperature. After investigation this was proved to be correct, and that particular chief engineer demanded a flue pyrometer, draft gages, and a portable CO_2 tester, and was able on his next trip to report that the escaping gases kept in the vicinity of 510 deg. fahr.; and, generally speaking, this investigation sharpened up the wits of the engineers in that particular ship and made them very keen to obtain low running costs. (Paper read Apr. 17, 1923 before the *Institute of Marine Engineers*, abstracted from advance proof, illustrated, pc)

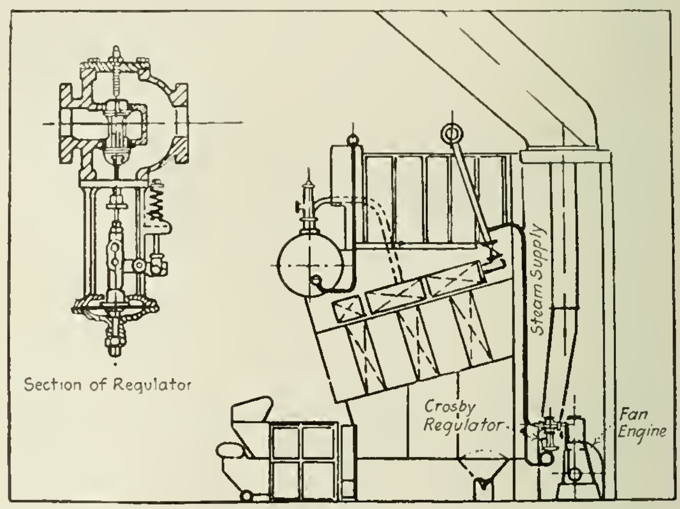

Fig. 3 Fan-Engine Control for Stoker-Fired Babcock & Wilcox Marine Water-Tube Boiler

MOTOR-CAR ENGINEERING

Andrade Differential for Motor Cars

New Differential for Motor Cars. Description of a design of differential developed by C. Andrade, Jr. It is a gearless, self-locking type and is so arranged that it delivers most, or if necessary,

all of the power transmitted to the wheel that has the most resistance on the roadbed, and therefore prevents the vehicles in which it is installed from stalling when one wheel only has traction and the other wheel is on slippery footing.

In this differential the outer or driving member is made in three parts, two of which are identical flanged hubs and the third a drum, the inner surface of which is broached to form a number of cylindrical surfaces, the axes of which lie in a cylindrical surface whose axis is the axis of rotation of the differential. The two inner driven members are splined to the axle ends and have external surfaces which are true cylinders of equal diameter. Between the driving and the driven members lie two sets of rollers, of such diameter that they clear the arcs or cylindrical surfaces of the driven member when the latter is in neutral position, as shown in Fig. 4. When the driving member starts to move ahead, the rollers all lock after they have moved about $^1/_{16}$ in. behind the center of the eccentric arcs, due to the wedging action which results.

When one of the rear wheels start to run ahead of the master gear, as the outer wheel does when the car rounds a curve, the rollers engaging that driven member roll out of locking contact and go back to the centers of the eccentric arcs. They cannot go beyond this point for the reason that the control members

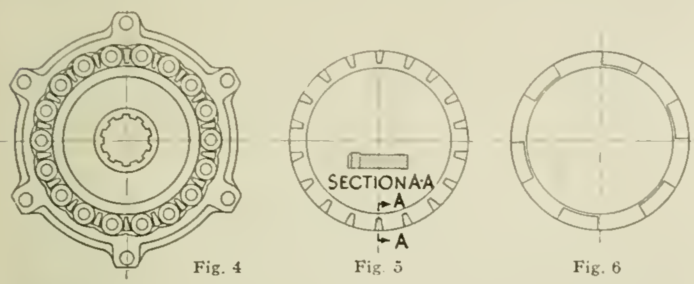

Fig. 4 Fig. 5 Fig. 6

Figs. 4, 5 and 6 Assembly and Parts for the Andrade Differential

shown in Figs. 5 and 6 prevent them from so doing. The control members are provided, on their back faces, with lugs similar to the jaws of a positive clutch, which permit them to turn only $^1/_{16}$ in. in relation to each other.

In backing the action of the differential is precisely the same as in forward motion and it also permits the normal operation of the car when the latter is going down hill and the engine is used as a brake driven from the car wheel.

Because of the large number of rollers, their considerable length, and their distance from the axle center, there is said to be only a small fraction of compressive stress on each inch of length of the rollers as there is on the gear teeth of the ordinary gear-type differential. (*Automotive Industries*, vol. 48, no. 18, May 3, 1923, pp. 979–980, 6 figs., *d*)

POWER-PLANT ENGINEERING (See Marine Engineering; Testing and Measurements)

RAILROAD ENGINEERING (See also Special Machinery)

Kunze-Knorr Air Brake. Description of a new type of air brake recently introduced on the State Railways of Sweden. It works on the principle of a single-cylinder automatic compressed-air brake.

The graduation up and down is obtained by placing a pressure transformer between the auxiliary reservoir and the valve chamber of the triple valve, by means of which the pressure in these two chambers rises and falls together in such a way that the pressure in the valve chamber of the triple valve is always higher by a certain ratio than it is in the auxiliary reservoir.

In an editorial in the same issue a careful analysis of the probable performance of the new brake is made and the conclusion to which the writer comes is that it does not appear that the new brake possesses any real advantage over the brakes that are used in the United States. (*Railway and Locomotive Engineering*, vol. 36, no. 5, May 25, 1923, pp. 143–147, illustrated, and editorial, pp. 149–150, *d*)

Newest German Type of 3-Cylinder Mikado. Description of a standard fast-freight Mikado locomotive, which is the most recent type developed in Germany. It is of the single-expansion type using superheated steam and is said to present many advantages.

It employs a crank axle, a feature which might be objected to, although with two cylinders placed outside and one inside of the frames so that the cranks form exactly or nearly an angle of 120 deg. with one another, the design of the crank axle is very simple and its manufacture is cheap compared to that of the four-cylinder locomotive which many railways were forced to abandon owing to the difficulty of manufacturing the crank axle.

The Mikado locomotive described here weighs 216,000 lb. It is intended for operation in heavy passenger as well as fast freight service and is designed for operation up to the maximum speed limit on the German railways, which is 120 km. (74.5 miles) per hour. In this locomotive the usual arrangement is found in that the main rod is connected to the second pair of driving wheels, while the return crank actuating the Walschaerts valve motion is connected to the third pair of driving wheels. This enables the use of a long eccentric rod, which serves to minimize any effect that vertical spring play of the axle in the frames may have upon the action of the valve. The piston valve controlling steam admission and exhaust from the inside cylinder is actuated by a separate valve gear connected to an eccentric crank on the left side of the locomotive. Extended piston and valve rods are used throughout.

The special equipment for this locomotive includes a pyrometer and speed indicator, also steam heat regulator. (*Railway Review*, vol. 72, no. 18, May 5, 1923, pp. 757–760, 7 figs., *d*)

SPECIAL MACHINERY

Diesel-Engine Dredge. The dredge *Elizabeth Pfeil*, the first of its type to be constructed, is equipped with Diesel-electric drive. The reason for this innovation is a practical one as the dredge is intended for service in the impure-water regions encountered in the Ohio and other rivers in the Pittsburgh district, this impure water being highly detrimental to boiler tubes.

The dredge is equipped with a 300-hp. Diesel-type, four-cylinder two-cycle, self-injection, oil-burning engine and is direct-connected to a 270-kva., 60-cycle, three-phase, 440-volt generator which drives the machinery of the entire boat.

The excavating equipment of the ladder type is made up of an endless chain of 87 manganese-steel-lipped steel buckets of 8 cu. ft. capacity weighing 1500 lb. each. This chain is mounted on a structural-steel ladder 95 ft. long, the total weight of the ladder and chain of buckets being 125 tons.

The entire operation of the dredge is controlled by one man in an elevated pilot house where there are twelve levers. From this pilot house the operator has a perfect view of the ladder and bucket line. The action of the bucket line is controlled directly by five levers connected to a 5-drum winch on the port side of the dredge forward of the tumbler center line. This winch is direct-connected by gear to a 125-hp. motor. Irrespective of the position or speed of the bucket line, complete control of the ladder and bucket line is effected at all times through brakes on the winch which hold the ladder in any position. (*Oil Engine Power*, vol. 1, no. 4, Apr., 1923, pp. 182–183, 2 figs., *d*)

Vertical Plate-Milling Machine. Description of two new tools built by Alfred Herbert, Ltd., Coventry, England, for reducing the thickness of copper plates as used in the construction of locomotive fireboxes.

Hitherto this job was done by swaging the metal down by hammering. With the new machine the preparation of the plates is reduced to a simple milling operation capable of being performed at high cutting speeds and feeds. Actual production times for this machine are not available at this moment. The machine is intended for a specific object, milling at any point on the surface of plates that may be anything up to 6 ft. sq. by $1^1/_2$ in. in thickness. It is provided with a work table of large area having longitudinal, transverse, and rotary motions and a vertical column with a long overhang to carry the spindle slide. Therefore it is possible to traverse

the plates in any direction and for the spindle to reach to the center of the maximum-size plates likely to be dealt with. The machine is not provided with low spindle speeds, but there is a range of eight of the spindle speeds varying from 100 to 350 r.p.m. which are suited for machining copper. In other respects the machine is designed and operated on the same lines as a standard vertical milling machine. The original article illustrates and describes it in considerable detail.

In conclusion it may be mentioned that the leading dimensions of the machine allow for a longitudinal feed of 78 in. and a transverse feed of 39 in. The maximum distance from the surface of the table to the end of the spindle is 13 in., while the distance from the center of the spindle to the vertical face of the column is 42 in. The working surface of the table is 78 sq. in., and the total floor space occupied by the machine is 17 ft. 6 in. sq., and its approximate net weight 40,000 lb. (*Machinery*, London, vol. 22, no. 552, Apr. 26, 1923, pp. 117–120, 4 figs., *d*)

SPECIAL PROCESSES (See Engineering Materials)

STEAM ENGINEERING (See Thermodynamics)

TESTING AND MEASUREMENTS

A Method of Determining Loss of Heat in Flue Gases Due to Incomplete Combustion, O. I. Hanson and K. E. Nielsen. An investigation conducted by the Danish Society of Fuel Economy into the composition of waste gases from steam generating plants and central heating furnaces has shown that their content of unburned gases is higher than is generally appreciated. The method of analysis by which unburned gases can be determined within a small limit of error and the calculation of heat loss from the results obtained are described in the paper. The apparatus works with a view to obtaining all the data by a single combustion analysis after the removal of carbon dioxide, and is therefore essentially different from the Orsat apparatus; it is described in detail in the original article and the errors of calculation are carefully considered. From this it would appear that the maximum percentage error of calculation of the calorific value of the fuel will only occur when either methane alone or hydrogen alone are present mixed with the carbon monoxide, and even then apparently the error will not be large enough to affect practical results. (*Fuel in Science and Practice*, vol. 2, no. 4, May, 1923, pp. 115–120, 4 figs., *d*)

THERMODYNAMICS

An Imaginary Thermodynamic Process, Jos. S. Ames. An article is not suitable for abstracting. The author assumes the existence of a being who has no knowledge of space or of space measurements but has sense organs for temperature, entropy, and force, and instruments for giving numbers to them. He makes certain other assumptions and then shows how such a being would have no trouble in comprehending the true nature of entropy. This is supposed to facilitate the understanding of entropy by ordinary students of thermodynamics. (*Journal of the Franklin Institute*, vol. 195, no. 5, May, 1923, pp. 655–663, 1 fig., *tA*)

The Supersaturation Limit—Steam at Wilson Line

The Supersaturation Limit, H. M. Martin. The author has compiled new tables of the properties of steam at the Wilson line to replace those given in his New Theory of the Steam Engine. In compiling these tables a new formula has been derived for the ratio between the actual pressure of the supersaturated steam and the pressure corresponding to the temperature. This formula is

$$\log_{10}\frac{p}{p_s} = \frac{2.96\sigma}{T}$$

where p is the actual pressure of steam when condensation commences, p_s the pressure corresponding to the absolute temperature T, and σ is the surface tension of water at that temperature. The complete derivation of this formula will be found in the original article.

The last column of Table 1 shows what the volume of the steam would have been, had it expanded in thermal equilibrium, while the column headed t_s shows the corresponding temperature. It will be seen that at the Wilson point the defect of temperature is about 28.7 deg. cent. when the condensation occurs at —10 deg. cent. The specific volume of steam at the Wilson line is very approximately 90 per cent of the specific volume at the same pressure, but at the saturation line.

The experiments of Professor Stodola confirm the view that at all temperatures the limit of supersaturation is fixed by the presence of co-aggregated molecules, the dimensions of which are independent of the temperature.

The data now most urgently required are the relationships between the pressure and volume of the steam when the expansion extends beyond the Wilson line. Mr. Wilson found in his own experiments that in this case the further condensation came down on new nuclei instead of on the droplets already formed. This shows that the temperature of the steam in this further expansion must have been that corresponding to the Wilson line and not to the saturation line. This conclusion is confirmed by the measurement of the temperature of the exhaust from steam turbines, which is commonly found to be perceptibly below the saturation temperature corresponding to the pressure. Since any thermometer placed in supersaturated steam records, not the temperature of this steam, but merely the temperature of the film of moisture which condenses on its surface, the slight defect of temperature observed is no doubt an indication of a very much larger true defect. As matters stand, however, we have no information as to the relationship between pressure and volume during most of the expansion through a low-pressure turbine, but are obliged to rely on purely empirical rules.

TABLE 1 PROPERTIES OF STEAM AT THE SUPERSATURATION LIMIT OR WILSON LINE

Temperature at Wilson point, deg. cent.	Pressure at Wilson point, lb. per sq. in.	Ratio $\frac{p}{p_s}$	Volume at Wilson point, cu. ft. per lb.	Total heat at Wilson point, lb. cent. units	Entropy at Wilson point	Equilibrium temperature, deg. cent.	Equilibrium volume, cu. ft. per lb.

100	43.46	2.959	8.775	633.97	1.63850	133.47	9.378

The determination of the true relationship between the pressure and the volume of the steam during an expansion beyond the Wilson line, should not present any insuperable difficulties. All that would seem necessary is the taking of an accurate indicator diagram by optical means under conditions in which the volume occupied by the steam was accurately known at each point of the stroke. No expensive special apparatus would seem to be necessary. The cylinder need not be more than, say, 1 in. in diameter, and its base might well form the elastic diaphragm of the indicator, while the movement of the piston might be effected by a falling weight. In order to insure a complete absence of moisture it would no doubt be advisable to work with steam which was slightly superheated at the outset. By jacketing the cylinder and piston with steam at the initial temperature no moisture would be deposited on these, while the amount of heat which could pass from these surfaces into the expanding steam during the small fraction of a second occupied by the stroke would be negligible. (*Engineering*, vol. 115, no. 2994, May 18, 1923, p. 607, *tA*)

CLASSIFICATION OF ARTICLES

Articles appearing in the Survey are classified as *c* comparative; *d* descriptive; *e* experimental; *g* general; *h* historical; *m* mathematical; *p* practical; *s* statistical; *t* theoretical. Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

Résumé of the Month

A—Research Results

The purpose of this section of Engineering Research is to give the origin of research information which has been completed, to give a résumé of research results with formulas or curves where such may be readily given, and to report results of non-extensive researches which in the opinion of the investigators do not warrant a paper.

Framed Structures A2–23. Compression Tests of Structural Steel Angles. This article, known as Technologic Paper No. 218, presents the results of compression tests of 170 structural angles, made at the Pittsburgh branch, Bureau of Standards, by A. H. Stand and L. R. Strickenberg. The object of the tests was to determine the ultimate compressive strength of angles fastened at the ends in such ways as would closely correspond to their connections in the construction of transmission towers. There was also tested a series of angles with square ends. An end fixation factor was found to represent satisfactorily the effect of different types of end connections. Using this fixation factor, the average values for large slenderness ratios were well represented by Euler's formula. The results obtained from shorter columns agreed with the experimental and theoretical results of Karman. The effect of eccentric loading was most marked at the slenderness ratios indicated by Karman's theory. Price per copy, 10 cents. Address Superintendent of Documents, Government Printing Office, Washington, D. C.

Properties of Engineering Materials A2–23. Some Tests of Steel-Wire Rope on Sheaves. This Technologic Paper No. 229 has been just published by the Bureau of Standards. It was prepared by Edward Skillman from data obtained as a result of tests made at the request of the erection department of the American Bridge Company.

Tests of wire rope $^5/_8$, $^3/_4$, $^7/_8$, 1, and $1^1/_4$ in. in diameter were made on sheaves of 10, 14, and 18 in. diameter to determine their strength under static load. The ropes were all of 6-strand, 19-wire construction made from "plow" steel. It was found that the strength on sheaves was less than that of the straight ropes, the ratio of the strengths being 0.87 for $^5/_8$-in. rope on 10-in. sheaves and 0.95 on 18-in. sheaves; for $1^1/_4$-in. rope the corresponding values were 0.76 and 0.85.

The tensile strength of individual wires was about 230,000 lb. per sq. in., elongation in 8 in. about 2 per cent, and reduction of area about 46 per cent. These were practically the same for all sizes of wire. The strength of the straight ropes followed closely the equation S = 83,000 d^2, in which S is the strength in pounds and d the diameter of the rope in inches. One worn rope which was tested showed a surprisingly high strength when its condition is considered.

A point of inflection in the load diagrams was found at from 56 to 65 per cent of the ultimate load, above which the elongation increased rapidly. The elongation of straight rope over a gage length of about 40 in. was about 2.5 per cent and the reduction of diameter about 4 per cent. The modulus of elasticity of a new rope was about 8,500,000 lb. per sq. in. and of worn rope about 13,500,000 lb. per sq. in.

Price per copy, 10 cents. Address the Superintendent of Documents, Government Printing Office, Washington, D. C.

Iron and Steel A5–23. Some Tests of Steel-Wire Rope on Sheaves. See *Properties of Engineering Materials A2–23.*

Properties of Engineering Materials A3–23. Investigation of the Fatigue of Metals Results of 1922. In the February, 1922, issue of Mechanical Engineering the first report of this investigation (Bulletin No. 124) was listed under "Mechanics A1–22." This second printed report was prepared by Messrs. H. F. Moore and T. M. Jasper and is known as Bulletin No. 136 of University of Illinois Engineering Experiment Station.

The tests recorded in this bulletin have all been made on specimens of wrought ferrous metal, free from flaws and large inclusions, as shown by micrographs, and tested under continuous series of cycles of stress. All specimens were turned with the longitudinal axis in the direction of rolling of the steel. The information gained from these specimens may not be true for steel with serious flaws or large inclusions, nor should such conclusions be extended to cast steel, cast iron, or non-ferrous metals. Subject to the above limitations, the conclusions drawn from the tests herein recorded may be summarized as follows:

1 A study of the test data obtained as well as of those secured from other laboratories tends to confirm the existence of an endurance limit for wrought ferrous metals, the endurance limit being defined as the unit stress below which a metal is capable of withstanding an indefinitely large number of reversals of stress.

2 The test results obtained and those from other laboratories confirm the conclusion drawn in Bulletin No. 124 that the endurance limit of a wrought ferrous metal may be determined with a fair degree of accuracy by a short-time test in which the rise of temperature under reversed stress is measured.

3 The tests recorded in this bulletin confirm the conclusion drawn in Bulletin No. 124 that for wrought ferrous metals the endurance limit seems to be correlated with the ultimate tensile strength, with the Brinell hardness number, and in a much smaller degree with the yield point and the proportional elastic limit. No correlation was found between the endurance limit and the ductility, the results of Charpy impact tests of notched bars, or repeated-impact tests.

4 The effect of speed of reversal of stress on the determination of the endurance limit seems to be slightly below a speed of 5000 r.p.m. for tests made on a Farmer rotating-beam testing machine. A slight increase of endurance limit was noted for increased speed of reversal of stress.

5 The results of the tests of specimens with various temperatures of "draw" after oil quenching indicate that for the carbon-steel specimens tested neither the ultimate tensile strength, the endurance limit for flexure, nor the ductility was appreciably affected by draws at a temperature lower than 600 deg. fahr. For the nickel-steel specimens for draws up to 400 deg. fahr. the ultimate tensile strength and the endurance limit for flexure diminished slightly while the ductility increased a little. For draws at higher temperatures the changes in values of strength and ductility were more marked, the ultimate tensile strength and endurance limit decreasing, and the ductility increasing. Whatever advantages may be gained by draws below about 600 deg. fahr. such as relief from internal stress and increased machinability, may be attained with but little, if any, sacrifice of tensile strength or of endurance strength under flexure.

6 The results of tests of the specimens subjected to severe tensile overstress before being tested in reversed bending indicate that a few applications of stress, well above the proportional elastic limit of the metal, lowered the endurance limit under subsequent reversed stress, the endurance being diminished by 22.9 per cent of its original value for one set of specimens. The effect of polishing the specimens after overstressing has not yet been investigated. Placing the specimens in boiling water did not seem to have any appreciable beneficial effect on the endurance limit.

7 From the test data recorded in this bulletin the following tentative formula is given for wrought ferrous metals as expressing with a fair degree of accuracy the relation between the endurance limit for cycles of completely reversed stress and the endurance limit for cycles of stress not involving complete reversal:

$$S_r = S_{-1} \left(\frac{r+3}{2}\right)$$

in which r is the algebraic ratio of minimum stress to maximum stress during a cycle of stress (for completely reversed stress, $r = -1.0$), S_r is the endurance limit for ratio r, and S_{-1} the endurance limit for completely reversed stress.

8 If a specimen or machine part is subjected to cycles of repeated-bending stress higher than the proportional elastic limit of the metal, the tests indicate that there may result a failure by excessive distortion of the specimen or the machine part. The endurance limit under repeated-bending stress should, then, never be considered as higher than the proportional elastic limit of the metal.

Iron and Steel A6–23. Investigation of the Fatigue of Metals Results of 1922. See *Properties of Engineering Materials A3–23.*

Mechanics A1–23. Investigation of the Fatigue of Metals Results of 1922. See *Properties of Engineering Materials A3–23.*

Fuel Utilization A5–23. Preparation, Transportation, and Combustion of Powdered Coal. This pamphlet, known as Bureau of Mines Bulletin 217, by John Blizard, sets forth the many methods, advantages and disadvantages of preparing and burning powdered coal, and states that manufacturers and operators of coal-fired furnaces cannot afford to disregard the advantages of pulverizing their coal before burning it.

The chapter headings, which are as follows, give a good idea of the scope of this publication: I, Powdered Coal, Definitions and General Discussion; II, Preparation of Powdered Coal; III, Distribution of the Powdered Coal; IV, Feeders, Mixers, and Burners—Bin-at-Furnace System; V, Uses of Powdered Coal; VI, Powdered Coal for Steam Raising; VII, Costs of Preparing and Delivering Powdered Coal to the Furnace; VIII, Danger from Use of Powdered Coal; and IX, Conclusions. Price per copy, 50 cents. Address the Superintendent of Documents, Government Printing Office, Washington, D. C.

Refrigeration A2–23. Tables of Thermodynamic Properties of Ammonia. These tables are the result of measurements made by the Bureau of Standards to determine fundamental physical data of refrigerating engineering. The Bureau's researches in this field were undertaken in response to the wishes of the refrigerating industry as expressed through its national associations and were specifically authorized by act of Congress. In carrying out the experimental program the bureau has had the benefit of the advice of The American Society

of Refrigerating Engineers, one of the organizations which originally requested that the work be done.

The tables, which are published in foot-pound-fahrenheit units only, embody the results of an elaborate series of measurements of the thermodynamic properties of ammonia. The fundamental units and constants used in the tables are defined. The empirical equations used in computing the tables, and also the references to the publications dealing with the experimental data, are given. The tables have been prepared in the forms convenient for use in refrigerating engineering. The same data are also presented graphically in the form of a Mollier chart.

Price per copy, 15 cents. Address Superintendent of Documents, Government Printing Office, Washington, D. C., asking for Bureau of Standards Circular No. 142.

F—Bibliographies

The purpose of this section of Engineering Research is to inform the profession of bibliographies which have been prepared. In general this work is done at the expense of the Society. Extensive bibliographies require the approval of the Research Committee. All bibliographies are loaned for a period of one month only. Additional copies are available, however, for periods of two weeks to members of the A.S.M.E. These bibliographies are on file at the headquarters of the Society.

Petroleum and Allied Substances F2-23. This Bulletin No. 216, covering the years 1919 and 1920, is the fifth in the series of petroleum bibliographies published by the Bureau of Mines, Bulletins 149, 165, 180, and 189 being compilations for the years 1915, 1916, 1917, and 1918, respectively. The publications examined number 169 and include both domestic and foreign. The references are arranged under the following headings: (000) General treatises; (100) Countries and regions; (200) Geology and origin; (300) Development and production; (400) Transportation, storage, and distribution; (500) Properties and their determination; (600) Refining and refineries; (700) Utilization; (800) Legislation and legal regulations; and (900) Miscellaneous.

Price per copy, 40 cents. Address the Superintendent of Documents, Government Printing Office, Washington, D. C.

CORRESPONDENCE

Contributions to the Correspondence Department of Mechanical Engineering are solicited. Contributions particularly welcomed are discussions of papers published in this journal, brief articles of current interest to mechanical engineers, or comments from members of The American Society of Mechanical Engineers on activities and policies of the Society in Research and Standardization.

The Efficiency of the Scotch Marine Boiler

To the Editor:

Mr. C. J. Jefferson's article in the April Mechanical Engineering on the Efficiency of the Scotch Marine Boiler shows very good results for the recent tests on two Scotch marine boilers by the U. S. Shipping Board and the Bureau of Mines, but there are several points regarding the tests which differ from marine practice and which should be added to his article.

One of the most noticeable things in the test is the variation in the average feedwater temperatures, which ranged from 288 to 212 deg. fahr., with one temperature of 232 deg. It is interesting to note that the highest boiler efficiency was obtained with the lowest average feedwater temperature used in any of the runs. Had a higher feedwater temperature been used in this run the boiler efficiency would have undoubtedly been higher, as by a rule of thumb a saving of one per cent in fuel is obtained for each increase of 10 deg. fahr. in the temperature of the feedwater. This is one of the things about which marine engineers are particularly careful, and temperatures of from 220 to 230 deg. fahr. are the usual practice, and are obtained by having a back pressure of between 2 to 6 lb. gage on the auxiliary exhaust which is used to heat up the feedwater. Higher temperatures up to 240 deg. are sometimes used, but any temperature requiring an auxiliary exhaust pressure more than 10 lb. gage is not good practice. By carrying a high feedwater temperature there is a saving in fuel, and this temperature is easily read with a thermometer. The adjustment of the valves to carry the proper auxiliary feed pressure for the desired feedwater temperature is readily made and need not be changed ordinarily under constant working conditions.

The introduction of flue-gas analysis has been slow in marine work, probably due to the idea that it is a complicated process. It also requires chemicals of known strength, which are not readily obtainable everywhere, and some of them are liable to deteriorate if not kept properly. It is true that flue-gas analysis requires a certain knack to obtain proper results, but given a few simple instructions, it would seem that marine engineers would quickly learn to make accurate readings. After using this method to learn what is going on in the furnace, and making the required changes in the operation of the boilers to suit such an analysis, a very real saving in fuel would result in a large number of cases. The use of automatic CO_2 and CO recording instruments has not been possible, due probably to the delicacy of the instruments, which are so devised that they can only be used for stationary work.

Pyrometers are used in navy work to indicate the temperature of the gases as they leave the boiler. It seems that they would be equally valuable in merchant-marine work, and would afford the engineer some indication of how much heat is going up the stack and being wasted.

The marine engineer is also handicapped by not having a definite means provided for measuring the amount of water fed to the boiler, and when using coal for measuring the exact amount fired. Approximations may be used in both cases—for example, so many pounds of coal in a wheelbarrow—and with a well-made-up system of piping and no free escapes of steam the amount of make-up feed used is a fairly definite proportion of the water fed to the boilers. Also for a complete analysis of boiler conditions an instrument for determining the quality of the steam—if not superheated—would be required.

A further important thing in marine work is the use of a calorimeter for determining the fuel value of the coal or oil used. This would give the engineer an idea of the quality of the fuel he was using, and would also be of great value in its purchase. The recent high price of coal and its poor quality will undoubtedly hasten the use of a calorimeter for this work.

Such items as keeping the boiler clean by opening at the proper intervals, blowing the tubes regularly, keeping the boiler water slightly alkaline and not too salty, and all apparatus in good working condition, are too well known to need any discussion.

These, then, are the principal items in which it seems to the writer that this test differs from ordinary present merchant-marine practice. In addition he does not himself know of any case in marine work where the gases leaving the furnace are used to heat up the air fed to the boiler, but of course this system is valuable as far as the boiler efficiency is concerned.

Washington, D. C. Charles D. Shepard.

[Mr. Shepard's communication was placed before Mr. Jefferson, the author of the paper, from whom the following letter has been received.—Editor.]

To the Editor:

In regard to Mr. Shepard's letter commenting on the article on Scotch marine boilers, the writer would like to submit the following remarks:

1 *Feedwater Temperature.* All the efficiencies as listed in the heat balance of this test were determined from the equivalent of the evaporation figures which automatically take care of the feedwater temperature.

The writer has found it common practice in marine service to operate with 15 lb. back pressure, and on several of our best performers we have gone still further and installed a second feed heater which utilizes the auxiliary exhaust from such auxiliaries as are run on full boiler pressure, these auxiliaries being run at 35 lb. back pressure. The purpose of the second feed heater using the higher

back pressure is to boost up the feed temperature to about 270 deg. This has resulted in increased economies as high as 7 per cent of steam for our turbine-driven ships where the auxiliary steam being taken away from the main condenser permitted higher vacuums to be obtained on the main unit and the increased boiler-feed temperature resulted in reduced maintenance charges.

2 *Flue-Gas Analysis.* Mr. Shepard comments regarding the fact that the adoption of flue-gas analysis for the use of determining boiler efficiencies in marine practice has been somewhat slow. You are advised that we have found this only too true, and it is to overcome such conditions as this that the Fuel Oil School has been started at the Philadelphia Navy Yard. It is proper to say, however, that while there were practically no Orsats in use in our fleet a year ago, now practically 50 per cent of the vessels are equipped with this instrument and the *engineers are using them.*

3 *Use of Pyrometers.* The pyrometer has been installed for some time in merchant vessels, but in common with a great many other similar power-plant installations, proper regard has not been given to its location. In order to get really worth-while data for operating purposes, it is necessary that the pyrometer be installed as close as possible to the point where the gases leave the boiler. This in the Scotch boiler really means, on a three-furnace job, three pyrometers. When the pyrometer is installed in the stack halfway up the fiddley, the temperatures observed are not trustworthy for determining efficiency of operation as this temperature is generally affected considerably by minor leakage through breachings and uptakes.

4 *Use of the Fuel Calorimeter.* The writer's personal experience with the fuel calorimeter forces him to the conclusion that this is a laboratory instrument, and if used by inexperienced persons would lead to very erroneous conclusions.

5 *Use of Air Heaters.* Mr. Shepard states that he knows of no case where the gases leaving the furnaces are used to heat up the air fed to the boiler. This system of air heater was developed by James Howden a number of years ago and is in use on practically all Scotch boiler installations, as well as the majority of the large passenger vessels such as the *Leviathan,* etc.

New York, N. Y. C. J. Jefferson.

Locating Leaks in Underground Pipe Lines

To the Editor:

Locating leaks in underground steam and water lines is usually expensive. In the case of steam and return lines the first evidence appears as steam from the manholes or water or steam from the outlets of the underdrains. The exact location of the leak is determined by putting down one or more test excavations along the line until the leak is found.

The geophone, an instrument developed during the war for detecting vibrations of the earth due to tunneling, etc., was recently tried for locating leaks in underground piping systems of an eastern university with the following results:

The first leak was in the return of the heating system and was located accurately under 4 ft. of cover.

The second leak was in a domestic hot-water pipe encased in a concrete duct packed with mineral wool and under 4 ft. of cover. The line extended from a tunnel to a building 250 ft. away. The evidence of the leak appeared as warm water from the underdrain into the tunnel. The leak was located 200 ft. from the tunnel and proved to be a pit hole in the pipe about $^3/_{16}$ in. in diameter.

The third case was in a 5-in. steam line carrying 10 lb. steam pressure. The line is encased in a concrete duct. The leak was located at a point which proved to be $9^1/_2$ ft. underground.

In all these cases the leaks were plainly audible for ten or more feet each side of the point at which it was finally decided that the disturbance was loudest. In each case the first excavation put down centered on the leak.

The above trials indicate that the geophone can be very profitably used for locating leaks in like underground lines. [Its use in locating leaks in compressed-air lines was described in Mechanical Engineering, November, 1922, p. 741.—Editor.] The instrument and some of its applications are described in Technical Paper 277, Department of the Interior, Bureau of Mines.

Ithaca, N. Y. H. A. Ward.

A.S.M.E. Boiler Code Committee Work

THE Boiler Code Committee meets monthly for the purpose of considering communications relative to the Boiler Code. Any one desiring information as to the application of the Code is requested to communicate with the Secretary of the Committee, Mr. C. W. Obert, 29 West 39th St., New York, N. Y.

The procedure of the Committee in handling the cases is as follows: All inquiries must be in written form before they are accepted for consideration. Copies are sent by the Secretary of the Committee to all of the members of the Committee. The interpretation, in the form of a reply is then prepared by the Committee and passed upon at a regular meeting of the Committee. This interpretation is later submitted to the Council of the Society, for approval, after which it is issued to the inquirer and simultaneously published in Mechanical Engineering.

Below are given the interpretations of the Committee in Cases No. 412–417, inclusive, as formulated at the meeting of March 22, 1923, and approved by the Council. In accordance with the Committee's practice, the names of inquirers have been omitted.

Case No. 412

Inquiry: Is it permissible, under the Code, to use on boilers, pressed-steel nozzles having the upper or bolting flange of the Vanstone joint construction, with the bolt-flange made of steel?

Reply: While the form of construction proposed for a boiler nozzle embodying the use of the Vanstone joint, as outlined, does not conflict with the requirements of the Code, provided the flange, dimensions, etc., meet the requirements of the Code for pipe flanges, it is the opinion of the Boiler Code Committee that a rigidly attached form of nozzle flange is preferable.

Case No. 413

Inquiry: What is the permissible stress for screwed stays with ends riveted over less than 20 diameters in length, when such screwed stays are inserted in the sheets at an angle that is not truly radial in the case of curved plates, or in the case of flat plates is not normal to the plane of the plate?

Reply: It is impossible to formulate any logical requirement for a condition of that sort and it must be a matter of judgment. A revision of the Code has been proposed which reads as follows:

"All staybolts not normal to the stayed surface shall have not less than three engaging threads, of which at least one shall be a full thread."

The angularity in such case should not exceed 15 deg. to the stayed sheet. If the angularity is greater than 15 deg. it must be taken into account in calculating the permissible stress in the staybolt.

Case No. 414—(In the hands of the Committee)

Case No. 415

Inquiry: Where a boiler of the locomotive type is fitted with a form of removable drum, attached by bolted connection to the outlet nozzle, as is customary practice in the California oil fields, is it the intent of the Code that the requirements of Par. 194 shall apply to the construction of the drum, or can this construction be considered as a steam drum subject to the requirements of Par. 187?

Reply: It is the opinion of the Boiler Code Committee that the form of construction shown is not a boiler dome and therefore does not come under the requirements of Par. 194 of the Code, but must be considered as a steam boiler drum coming under the provisions of Pars. 187 and 188.

Case No. 416—(In the hands of the Committee)

Case No. 417

Inquiry: Is it the intent of the Code to require any particular design for suspension lugs to support horizontal-return-tubular boilers 78 in. or less in diameter?

Reply: It is the opinion of the Committee that it was not the intent of the Code to require any particular design for suspension lugs to support horizontal return-tubular boilers 78 in. or less in diameter, but that any such lugs should conform to the requirements of Pars. 324 and 325 of the Code.

MECHANICAL ENGINEERING

A Monthly Journal Containing a Review of Progress and attainments in Mechanical Engineering and Related Fields, The Engineering Index (of current engineering literature), together with a Summary of the Activities, Papers and Proceedings of

The American Society of Mechanical Engineers

29 West 39th Street, New York

Contributions of interest to the profession are solicited. Communications should be addressed to the Editor.

By Law: The Society shall not be responsible for statements or opinions advanced in papers or.....printed in its publications (B2, Par. 3).

Uniform Safety Legislation

Harris and Ewing
M. G. Lloyd

THE administration of industrial accident prevention in this country differs widely from state to state. Legislation is now in force in different states providing either: (1) a commissioner of labor statistics whose duty is to collect and report information; (2) statutory requirements for accident prevention; (3) statutory requirements for accident prevention supplemented by a staff of factory inspectors to enforce these requirements; (4) a board or commission having power to make detailed regulations—usually with reference to only one subject or industry; (5) officials or commissions with power to make detailed regulations for industries in general, with a staff of inspectors to enforce both statutory requirements and commission orders.

The experience which has now been obtained is sufficient to enable us to form a definite idea as to the type of legislation which will secure the best results, although this idea may have to be modified to some extent by local differences in political or industrial conditions. It should be noted that most of the prominent industrial states have adopted the method of delegating the legislative authority for enacting regulations to the administrative officials who are concerned with the enforcement of the regulations, and whose regular duties bring them into contact with working conditions as they are met in industry. There are now 17 states where such powers for industries in general have been given to an industrial commission or similar officials, and there are others where similar powers with respect to mining or public utilities reside in a separate commission. This may be regarded as the complete development of the system of protection for the worker against industrial accidents. This system has the advantage over statutory requirements that the regulations may be changed with comparative ease when experience, advancement in the arts, or wider knowledge of industries and processes shows such amendment to be desirable. It is then unnecessary to wait for a legislative session or to convince legislators, who are unfamiliar with the details of the matter and who are largely occupied with matters of a political nature, of the desirability of the change. It is also possible to cover additional industries or new conditions in old industries as soon as the subject may demand attention. It is also possible to give the detailed requirements much more extensive and more technical study than it is possible for legislators to give. The regulations are consequently likely not only to be more complete and more adaptable to conditions, but also more satisfactory both to the inspector and to those who must comply with them.

It would consequently seem desirable in future legislation on this subject that those who are attempting to improve present conditions should work toward the establishment of administrative authorities with full powers to make the detailed regulations which are to be enforced, and to combine with this the authority to amend regulations which have already been placed upon the statute books. In many cases such regulations have become obsolete before they have been repealed or amended by later statutes. This is one of the most objectionable features of detailed statutory requirements, which usually do not permit exercise of any discretion upon the part of the inspector or administrator.

M. G. Lloyd.[1]

The Pittsburgh Power Survey

TWO YEARS AGO public attention was attracted and the popular imagination fired by an announcement by the United States Geological Survey that a superpower system was being planned for the region between Boston and Washington. In its report on the subject the Geological Survey pointed out the possibilities of great economies in power production by interconnection and combination of power-producing facilities. The investigation on which the report was based was prompted by a far-seeing idea that economical power production must be the basis for future industrial expansion, and a requisite for the advance of our civilization.

In the discussion of papers on hydroelectric development at the Spring Meeting of the Society, William M. White called attention to the facts that the productivity of the workers of each country and the rates of wages paid to each worker bear a definite relation to the amount of mechanical power per worker. He also emphatically stated that the public must look to the engineer to point the way in developing nature's resources to minimize human toil. The utilization of power to meet the needs of our industries and to provide the many varied articles that make modern life possible is therefore a grave responsibility of the present generation of engineers. To bear this responsibility properly, however, the engineering profession must have facts, and many careful studies, such as those relating to the superpower system, must be carried on.

The investigation recently conducted in the steel industries in the Pittsburgh district, as reported in the leading article by Professors Ely and Rittman in this issue of Mechanical Engineering, furnishes important facts upon which principles for the more economical use of power and fuel may be based. An interpretation of the facts and trends of this paper lead to a much more thorough appreciation of the importance of power in all the American industries.

The effect of this survey in the Pittsburgh district itself must have been very helpful. It emphasized as the authors point out, the need for greater completeness and uniformity of power and fuel records in the steel industry. It has brought out coöperation between the various components of the steel industry and the producers of electrical energy in the district.

The results of the study bear witness to the confidence the industries of Pittsburgh place in the Carnegie Institute of Technology and in the authors. Such confidence must be the basis on which accurate statistics of this kind are developed.

The Engineer's Job

THE quotation on the cover of this issue of Mechanical Engineering is from an address delivered before the Engineers' Club of Philadelphia as reported in the January issue of *Engineers and Engineering*. Dr. Frank Aydelotte, the author of the quotation, in addition to being President of Swarthmore College, is American Secretary of the Rhodes Trustees, a trustee of the Carnegie Foundation for the Advancement of Teaching and a member of a number of educational and scientific bodies.

[1] Chief of Safety Section, Bureau of Standards, Washington, D. C.

World Power Conference

A WORLD Power Conference will be held in London next year to determine how the industrial and scientific sources of power may be adjusted nationally and internationally. This conference is to be held at the time of the British Empire Exhibition, but is an independent undertaking under the auspices of the British Electrical and Manufacturers' Association. General committees are being formed in Great Britain, France, Italy, Norway, Sweden, Czechoslovakia, Canada, and other countries, to arrange for participation in the conference. Members of engineering organizations in the respective countries are serving on these committees.

In the United States, a preliminary meeting was held on February 8 to consider participation by this country. A special committee, consisting of J. W. Lieb, Chairman, H. J. Pierce, Calvert Townley, W. H. Onken, Jr., F. R. Low, and O. C. Merrill, was appointed to draw up a plan of organization. Its report was submitted and approved at a second meeting on May 4. A final organization meeting was held in New York on June 20, at which engineering and technical societies, business associations interested in power, and government agencies were represented, making up the general committee. The organization for this country's participation was effected and an executive committee chosen to work out the details. Members of the national societies who are serving on the general committee are Peter Junkersfeld and George C. Orrok, A.S.C.E.; D. B. Rushmore, A.I.M.E.; and F. R. Low, D. B. Rushmore, and F. D. Herbert, A.S.M.E.

This important conference is one of a series of international events in which the American engineers are participating, all tending to strengthen the international bonds between engineers.

French Engineering Society Celebrates Seventy-Fifth Anniversary

IMPRESSIVE excerises marked the three-day celebration in Paris, May 4, 5, and 6, of the seventy-fifth anniversary of the founding of the Société des Ingénieurs Civils de France. The American Society of Mechanical Engineers was represented at the celebration by Past-President Jesse M. Smith and Laurence V. Benet, Honorary Vice-Presidents for the occasion by Council appointment.

Mr. Smith was selected by the Société to be spokesman for all the American societies represented at the opening reception and he delivered an appropriate and eloquent address.

The principal session on May 4 was presided over by M. Millerand, President of the French Republic. Two technical papers were presented: The Metallurgical Industry, by M. R. Jordan, and Large Electric Transmission Systems, by MM. Janet and Bizet.

The feature addresses, however, were delivered the following morning, when General Ferrie spoke on Hertzian Waves and Their Application, M. Soreau on Aeronautics, and M. Percheron on the Guidance of Airplanes by Radiotelegraphy. This session was followed by an excursion to Bourget, where the installation and organization of the greatest airport in the world were examined in detail. The regularity of the arrival and departure of mail- and passenger-carrying planes was most impressive, and the statistics given of the amount of mail and freight and the number of passengers carried during the past year without accident demonstrated that the air service has become an essential part of the transportation system of France.

Sunday morning, May 6, was marked by a reception to M. Eiffel given on the second platform of the Eiffel Tower. In spite of his 91 years, M. Eiffel delivered an address of welcome which was greatly appreciated by a large audience.

Several brilliant social affairs were held, the last of which was a banquet of about 400 covers addressed by delegates from all the foreign countries and by M. Le Troquer, a member of the French Cabinet. Here again Mr. Smith represented the United States of America, and his speech was warmly applauded. Sir Archibald Denny was Great Britain's representative.

Laurence V. Benet, one of the Society's representatives at the celebration, represented it twenty-five years ago at the fiftieth anniversary exercises of the French Société, and spoke then on behalf of American engineers.

Dr. de Margerie Honored by U. S. Engineers

A RECEPTION and luncheon in honor of Dr. Emmanuel de Margerie, second exchange professor from France to this country, was held at the Harvard Club, New York City, May 18, 1923. Arrangements were made by a committee of the A.S.C.E., A.I.M.E., A.S.M.E., and A.I.E.E., and the guests included present and past officers of those societies and their joint organizations; representatives of the seven universities on the exchange list; Dr. A. E. Kennelly, last year's exchange professor to France; Dr. Charles F. Scott, president of the Society for the Promotion of Engineering Education; Dr. Stephen Duggan, director of the Institute of International Education; M. Gaston Liebert, former consul-general in New York, now director of the French Bureau of Information in New York City; and M. Charles Baret, successor of M. Liebert as consul-general in New York, representating Ambassador Jusserand. Dr. A. R. Ledoux, chairman of the committee on arrangements, acted as toastmaster.

Dr. de Margerie, who during the past year has lectured at Columbia, Cornell, Harvard, Johns Hopkins, Massachusetts Institute of Technology, University of Pennsylvania, and Yale, is director of the Geological Survey of Alsace-Lorraine, and chief geologist of the Geological Survey of France. He is a member of and holds medals from leading American and French geological societies, the latest honor conferred upon him being the Mary Clark Thompson gold medal of the National Academy of Science of the United States.

Dr. Kennelly, who is now professor of electrical engineering at Harvard and M.I.T., introduced Dr. de Margerie, referring to his work, which carries him over the political boarders of France into other countries, as another illustration of what modern science is doing for us in linking us all together.

"Unity of thought" between the scientist and the engineer, the influence of the engineer in the development of the community, and the large number of educational institutions, are among Dr. de Margerie's impressions of America, as stated by him in a brief address at the luncheon. Both M. Baret and M. Liebert also spoke.

This occasion marked the close of the second year of exchange professorships in engineering and science between the United States and France. The plan, which was inaugurated by the late Dr. Maclaurin of M.I.T., purposes to bring about a closer relation of science and engineering between the two countries, through the influence of personalities as well as the exchange of ideas.

Rudolph Hering, Dean of Sanitary Engineers, Dies

RUDOLPH HERING, consulting hydraulic and sanitary engineer of New York City and an authority on municipal water supply, sewage, and garbage disposal, died on May 30, 1923. Mr. Hering was born in Philadelphia, Feb. 26, 1847. He was educated in Dresden, Germany, and was graduated from the Royal Polytechnic College of Dresden as a civil engineer in 1867. He returned to this country shortly afterward and became assistant engineer to the Board of Public Works of Philadelphia. In 1881 he visited Europe again to study sewage-disposal methods for the National Board of Health.

From 1883 to 1885 he was engineer in charge of the new water supply of Philadelphia, and during the next two years was chief engineer of the Chicago Drainage and Water Supply Commission. From 1888 until 1920, when he retired from active practice, Dr. Hering was engaged in consulting work for water supply and sewage works for practically all of the larger cities in the United States and Canada. As a member of a New York firm of consulting hydraulic and sanitary engineers for many years he served the Department of Water Supply, Gas and Electricity of that city.

Dr. Hering was the author of several technical books, and the recipient of the honorary degree of Doctor of Science from the University of Pennsylvania. He belonged to the American Society of Civil Engineers, the Canadian Society of Civil Engineers, the Institution of Civil Engineers, The Franklin Institute, the American Water Works Association, the New England Water Works Association and the American Public Health Association, and was a Fellow of the American Academy of Science. He became a member of The American Society of Mechanical Engineers in 1906.

Engineering Achievements of Pacific Coast Shape Program for Regional Meeting

Los Angeles Headquarters for Second A.S.M.E. Regional Gathering—California's Remarkable Progress in Engineering Described in Addresses and Viewed on Excursions

THE SECOND A.S.M.E. regional meeting, held in Southern California April 16–18, 1923, under the auspices of the Los Angeles Local Section, matched its predecessor, at Springfield, in success. The Hotel Alexandria, Los Angeles, was headquarters for the meeting and there, on the opening day, the first and only session designated as technical was held. After that the program demonstrated once again the fundamentally technical character of excursions which are opportunities for gathering scientific information rather than mere sightseeing expeditions.

An account of the technical session is given in succeeding columns. On the afternoon of April 16 an opportunity to study engineering work in the motion-picture industry was given in an address by Mr. Langey of the Pickford-Fairbanks studio, followed by an inspection of the studio in Hollywood.

On April 17 the meeting moved on to Pasadena where the morning was spent at the Norman Bridge Laboratory of Physics at the California Institute of Technology. Prof. E. C. Watson, who conducted the party about the laboratory, explained a number of interesting things, including the use of the special screen for vertical projection by showing the principles of wave motion as illustrated in a ripple tank; some slides of actual photographs of sound waves; the power of the circuits to the lecture room by means of an experiment on electromagnetic repulsion in which an aluminum ring was thrown to the ceiling; acoustics of the room as illustrated by sounds produced in large pipes by heat vibrations; some experiments with ultra-violet light, showing the peculiar fluorescence produced in many substances, etc.

Dome of 100-in. Hooker Reflecting Telescope, Mt. Wilson Observatory

The afternoon was spent at the laboratory and shops of the Mt. Wilson Observatory. One of the most interesting machines which the members were allowed to inspect was a ruling engine, perfected by one of the members of the staff, and representing many years of study. With this engine it is hoped that 100,000 lines to the lineal inch can be ruled. A sample of the work of the machine, carrying 15,000 lines ruled to the lineal inch, was an object of great interest.

Late in the afternoon the party motored to the top of Mt. Wilson, where the night was spent. In the evening Prof. Francis G. Pease, astronomer in charge of design at the observatory, gave details regarding the 100-in. Hooker reflecting telescope there installed, the most powerful instrument of its kind yet constructed. Extracts from his description are given later in this account. A heavy fog made impossible the demonstration of this and other instruments that evening, but early the next morning many of the party inspected the 150-ft. tower telescope used for studying the sun, and examined the powerful 75-ft. spectrograph.

By noon the engineers had reached Long Beach. Ralph Reed, chief engineer of the Union Oil Company, spoke briefly on oil-field tools and equipment, after which the oil fields of Santa Fe Springs and Signal Hill were visited.

A more detailed account of the excursions appeared in the May 7th *A.S.M.E. News*, and preceding issues carried descriptions of the engineering achievements at Mt. Wilson and other places visited by the engineers. Those who have had the opportunity to participate in such excursions where demonstrations and explanations are given and close inspection permitted can best appreciate their technical value.

Back in Los Angeles Wednesday evening the meeting closed with a banquet at the Hotel Alexandria, details of which are given on a following page.

Too much credit cannot be given to the committees in charge for the success of this regional meeting. The Regional Committee, Carl C. Thomas, chairman, and the Los Angeles Local Section Committee, George H. Rhodes, chairman, were assisted by committees on local arrangements, with chairmen as follows: finance, J. G. Rollow; professional events, G. H. Rhodes; printing and signs, H. L. Doolittle; entertainment, J. G. Rollow, excursions, Prof. R. L. Daugherty; hotels, H. R. Hilton; information and service bureau, H. L. Doolittle; publicity, R. W. Lawton; and reception, H. R. Hilton.

The Technical Papers and Addresses

Five papers were presented at the technical session held on Monday forenoon, namely, The Oil Venturi Meter, by E. S. Smith, Jr.; Flow of Crowds, by C. H. Benjamin; The Cross-Flow Impulse Turbine, by Forrest Nagler; Diesel-Engine Progress on the Pacific Coast, by H. W. Crozier, John Stigen, and C. E. Nagel; and Hydroelectric Development by the Southern California Edison Co., by H. A. Barre. The papers by Messrs. Smith and Nagler appeared in Mechanical Engineering for May, and the one by Messrs. Crozier, Stigen, and Nagel is printed in the present issue.

Dean Benjamin's paper dealt with the flow of crowds, which he likened to the flow of viscous liquids through pipes. The loss of energy by friction in passages, contracted openings, and bends was similar, and the absence of a pressure head was met by continuing muscular energy. The paper developed a simple formula for the flow. The constants used therein were determined by a series of experiments in a three-story college building with large rooms, halls, and stairways. The crowds (of students) were variously distributed and controlled, and the widths of doorways and stairways were adjustable. It was found that with normal men under control, moving as fast as practicable without crowding, about twice as many could descend stairways and pass through openings of a given width in a given time as had generally been estimated; but it did not follow from this that the old rule should be done away with, for crowds did not always comport themselves as well as those considered in the paper.

Mr. Barre, electrical engineer of the Southern California Edison Co., described the extensive program for power development now being carried out by that organization. This hydroelectric work is chiefly on the San Joaquin River, in the Big Creek district some 240 miles north of Los Angeles, where the conditions are such that it is possible to provide a complete coördinated scheme for the total utilization of the resources of that river—for irrigation as well as for power—in conjunction with the company's other water powers further south and the steam-plant resources which must necessarily accompany any water-power development. In the area under development about 1,400,000 hp. of commercial power is available, and the total cost of the new work involved will be in the neighborhood of $200,000,000. The development comprises two large tunnels, one 5 miles long and 21 ft. in diameter, and another 12 1/2 miles long and 15 ft. in diameter; and several storage reservoirs having capacities of 75,000 acre-feet and upward. When the development is completed the water will have been used through a total head of nearly 6000 ft.

On Tuesday morning, at the California Institute of Technology, Pasadena, R. W. Sorensen, professor of electrical engineering at that institution, described the million-volt 1000 kva. testing set to be installed in its new high-voltage laboratory. There was every reason to believe, he said, that potentials up to this value would be required in the very near future for the testing of standard apparatus used for electric power transmission, and in the meantime the set would be available for use in the investigation of high-voltage phenomena ahead of the commercial demand for high-tension apparatus. The Big Creek system of the Southern California Edison Co., described by Mr. Barre on Monday, had already raised their voltage from 150,000 to 220,000, thus doubling the amount of power they could transmit over their present lines, and many of the tests required by the 220,000-volt apparatus had called for testing potentials of from 450,000 to 500,000 volts. The transformer which Professor Sorensen had designed and which would shortly be installed would consist of four 250,000-volt units, each so constructed that one of its windings could be used to excite another transformer of the series. When the four 250,000-volt windings of these transformers were connected in series with one end grounded, a potential of 1,000,000 volts from line to ground would be obtained. This equipment would at the same time provide the laboratory with a 500,000-volt system with step-up and step-down transformers, four separate 250,000-volt testing sets, or, by use of three transformers Y-connected, a 433,000-volt three-phase transmission line to work with.

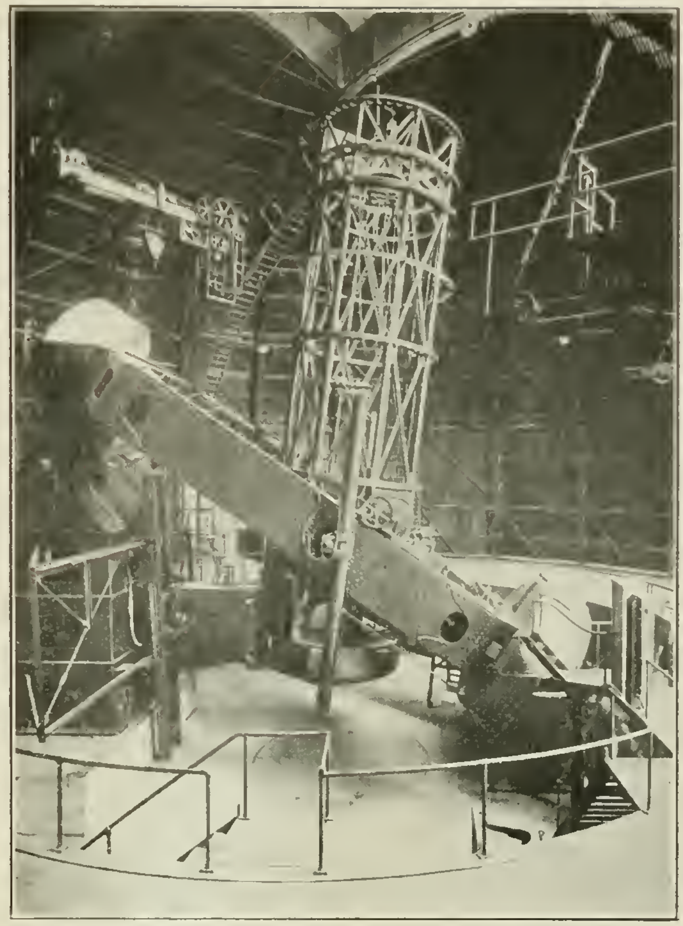
Extended extracts from the address by Professor Pease, referred to in a preceding paragraph, immediately follow.

The 100-Inch Hooker Reflecting Telescope of the Mount Wilson Observatory

The most powerful of all telescopes thus far constructed is the great Hooker telescope of the Mount Wilson Observatory, having a clear aperture of 100.4 in. and a primary focal length of 507.5 in. The telescope is now in actual use, the daily results proving the value of the instrument to be of the highest order.

The Hooker telescope is of the reflecting type wherein a parabolic mirror converges the parallel beam of light coming from the distant object to a focus. The image given is a real image, just as is given by a camera lens; it can be viewed with an eyepiece or photographed by placing a plate at the focal plane.

The mirror is 101.3 in. in diameter, 12 in. thick, and weighs 9000 lb. It is glass, cast in France by the St. Gobain works. Any internal strains likely to alter the curvature are eliminated by mounting the glass on large edge arcs supported on knife edges and supporting it horizontally on 12 pads, three of which are fixed, the remaining 9 counterweighted. The glass and its supporting systems lie in a massive steel cell which bolts to the lower end of an open tube 11 ft. outside diameter and 38 ft. long. The bottom section of the tube is composed of steel-casting rings, columns triangular in cross-section, of pressed-steel plates, and open panels of steel plate. Two massive castings are built into the section to carry the declination trunnions. The remaining sections, including the "cages" which carry the various auxiliary mirrors, are built of similar steel rings, columns of Shelby tube, corner castings of steel and diagonals of tire channel. Each section is assembled and then machined as a unit; the cages are interchangeable, fit a tapered ground point on the upper end of the permanent part of the tube and are locked in position by 8 lip bolts controlled by a single handle.



Interior View of Dome, Mt. Wilson Observatory

The weight of the tube is 35 tons; its center of gravity lies on the declination axis, so that it is always in balance. As some of the various attachments alter this balance, the change in moment is compensated for by the motion of two 1400-lb. weights in the large tubes at the side. Two additional counterweights are placed under the mirror cell to provide for adjustment about the axis of the tube.

The declination bearings are spherical in shape to allow for any flexure of tube or yoke; these spheres serve to align the axis while the bulk of the weight at each bearing is taken up by two systems of roller and ball bearings, one axial, the other radial; these systems are counterweighted by a series of levers extending downward along the yoke and actuated by a common weight.

The tube is suspended in a massive yoke, the polar axis, 16 ft. across and 32 ft. long, on the ends of which are trunnions supported by massive bearings. The axis of the yoke lies parallel to the earth's axis and is inclined at an angle of 34 deg. 13 min. to the horizontal, pointing to the north pole of the heavens.

The yoke consists of four members, built of structural steel with a massive steel casting at each end; their weight is 10 tons each and after assembling each was machined as a unit. Their average cross-section is 2 ft. wide by 4 ft. deep; hollow steel trunnions are bolted on the end members, and to these in turn are bolted the large steel flotation drums. The weight of the moving parts of the telescope is 100 tons. This mass is driven at just such a rate (1 revolution in 24 hours) as to equalize the diurnal motion of the earth, consequently every provision is made to reduce friction to a minimum. To define the polar axis there are two spherical bearings, and to relieve the friction two liquid flotation systems, consisting of hollow steel drums fastened to the trunnions, which float in tanks of mercury supported by the north and south pedestals. The drums are bolted at their upper ends and their insides relieved about an inch so that sleeves fastened to the south faces of the

tank reach nearly to the upper faces of the drums, thus increasing the depth by many inches. The south drum displaces 60 tons and the north 40 tons. There is a ball ring thrust bearing at the lower face of the south bearing to define the position of the axis longitudinally. The instrument is driven by a "driving clock" through a worm and worm wheel which clamps to the south trunnion.

Rapid motions are provided for setting the telescopes in right ascension and declination as well as slower motions to enable the observer to correct for errors in speed, refraction and bad seeing.

The worm wheel, which is 200.53 in. in diameter, has 1440 teeth accurately cut on the circumference and so ground that there is no periodic error as great as 0.00001 in.

The driving clock connects directly to the worm with a double Hooke's joint to eliminate any periodicity due to the worm and clock shaft not being truly adjusted. The speed of the worm can be altered by the observer by means of a motor mounted on the last shaft of the clock. The declination, quick, and slow motions are mounted on the yoke beside the tube and operate on it, the former through a sector, the latter through a long screw and arm. The range given by the two motions is from 30 deg. to $2^2/_3$ min. arc per minute of time.

The telescope stands on a hollow concrete pier 33 ft. high, bringing the intersection of the polar and declination axes at elevation 50 ft.

Since variation in temperature alters the figure of the mirror with consequent distortion of the image, the mirror and its cell have been surrounded with an inch of corkboard and means provided to control the temperatnre within the enclosure. Brine, the temperature of which is automatically controlled by a thermostat within the enclosure, is circnlated from a tank in the pier through coils lying under the mirror; fans circulate the air all around the mirror and coils. The brine is heated by electrical coils in the tank and cooled by ammonia expansion coils. Eight interconnected leaves, motor-operated, fold open in front of the mirror when in use.

The housing is a dome 100 ft. in diameter and 100 ft. high, all above 28 ft. rotating on tracks on the lower fixed part. The dome is of structural steel and sheathing throughout, and double-walled to insure more uniform temperature inside. The upper part is carried on 28 trucks with conical wheels and is traction-driven by two $7^1/_2$-kw. motors at opposite points. Its weight is 550 tons, while that of the fixed part is 250 tons. A slot 20 ft. wide extends from elevation 44 ft. to the peak of the dome, providing an opening through which the telescope is pointed, and is covered with a shutter formed by two halves moving along horizontal tracks.

To reach the primary focus of the telescope an observing platform is placed across the shutter opening, which travels up and down the main girders, its level being automatically regulated at the hoisting drum. To reach the secondary or Cassegrain focus on the north side of the tube, there is a platform which travels across and up and down the south face of the north column.

All motions of the instrument and dome are motor-driven and nearly all the circuits are "remote control." The settings can be made from a deck just beside the south pedestal and from auxiliary controls at the three foci. There are altogether 40 motors used in the dome, with an aggregate of 50 hp., and about 14 miles of wiring.

A 10-ton crane travels along the main girder opposite the shutter opening and handles all cages and instruments about the telescope.

The telescope is situated upon Mount Wilson near Pasadena, California, 5800 feet above sea level, where the atmosphere is free from the lower clouds and dust and where it can be operated a large part of the year to excellent advantage.

Looked on as an engineering problem, no serious difficulty was met with in the construction of the Hooker telescope, and a machine of double the aperture might well be built before one was seriously at the limiting factors of the materials of today.

Speakers at the Banquet

The banquet with which the regional meeting closed gave those attending it an opportunity to meet and hear speak a number of the men who have done much to advance the engineering profession, either in California or other sections of the country. Carl C. Thomas, as chairman of the Committee on Arrangements, made the address of welcome and introduced the toastmaster of the evening, John A. Britton, first vice-president and general manager of the Pacific Gas & Elec. Co., of San Francisco.

The welcome of the city of Los Angeles to the Society and its guests was expressed by Captain John D. Fredericks, past-president of the Chamber of Commerce of Los Angeles, and C. E. Cook, now head of its publicity department. Captain Fredericks, an eloquent speaker, voiced the praise and love of many for the Pacific Coast. "Out here," he said, "where the Pacific has been singing the sunset song of the nation for a great many years, we have learned that it is a wonderful place to live and a wonderful place to dream; but we have also learned that it is a wonderful place to work." He called attention to some of the great engineering feats that have been accomplished and some yet to come. He referred particularly to the protection of the Imperial Valley from the flow of the Colorado, and to the reclamation of some two million acres of unproductive land lying just back of it, and to the building of a great harbor for Los Angeles.

Mr. Cook, who personally conducted the first excursion of the A.S.M.E. to California, back in 1892, described that trip and similar ones, for other groups.

John Lyle Harrington, president of the Society, spoke of the difficulties which engineers have had to overcome in developing California and urged that the strength, the knowledge, experience, and idealism which have been gained thereby be contributed in ever greater measure to the upbuilding of a unified engineering profession. He urged also that the engineer participate more largely in the business and government of the country, stating emphatically that "it is highly essential that the engineer come to take more than a technical part in the work of the development of the nation."

Dr. Ira N. Hollis, past-president of the Society, who recently resigned the presidency of Worcester Polytechnic Institute, a follower for many years of the sea, used a number of his stock of sea stories to drive home the importance of the solidarity of the engineering profession. He spoke briefly of the ties which bind the states of the Union together and praised the engineer for the part he has played in establishing these ties, and for his achievements in other countries, particularly in Egypt. He disagreed with those who feel that the engineers are praising their profession too much, because "it is pride in our profession that will enable us to do the best work."

The growth of the manufacturing industries of Los Angeles was surveyed by Henry M. Robinson, president of the First National Bank of Los Angeles. He believed that her possibilities as a point for assembling raw materials for manufacturing and distribution to the Atlantic seaboard cities were very great. He referred specifically to cotton, copper, pig iron, and steel.

R. H. Ballard, vice-president and general manager of the Southern California Edison Co., pictured what prosperous public utilities mean to communities, and discussed the share of the communities in making their utilities prosper. "The prosperity of any section," he said, "depends upon having a good, active, energetic, and prosperous public utility or a number of utilities." He discussed the ownership and regulation of public utilities, pointing to the advantages of private ownership with public support, the method now in general practice.

William Mulholland, chief engineer of the Bureau of Water Works and Supply of Los Angeles, spoke of the responsibility of the engineering profession as an agency in the advancement of man. "Every step in the progress of man," Mr. Mulholland said, "is marked by his ability as an engineer. All the implements or early instruments that go back to the earliest history of mankind, are evidences of his ability as an engineer. The advancement of man parallels the development of tools."

D. W. Pontius, vice-president and general manager of the Pacific Elec. Ry. Co., spoke briefly on interurban transportation. He discussed the enormous amount of traffic in California and the steps being taken to handle increasing traffic in the future.

The final speaker, Dr. Robert Sibley, who for years has closely followed hydroelectric developments, particularly on the Pacific Coast, gave an illustrated lecture on the subject, which was of great interest to his listeners. It is planned to publish his address in the August issue of Mechanical Engineering.

Fluctuations in Student Enrollment in Engineering Courses

Data Furnished by Twenty-One Typical American Universities and Colleges Show Trends in Interest in Engineering Education During Past Ten Years

MANY engineers and educators are of the opinion that the interest in engineering as a profession varies with the commercial prosperity as well as with the normal growth of the country. Educators have reached the conclusion that the scholastic mortality of engineering students is high. The first of the above conditions would appear to be a natural sequence of human events; the second would indicate an error in choice by the student, a lack of sufficient and sound preparation, or a faulty program.

In order to determine conditions and trends in interest in engineering and in the mortality in engineering courses, comprehensive enrollment figures of engineering students in twenty-one American colleges, universities, and institutes have been secured, the institutions being selected with due respect to geographical distribution. The data were collected and this report prepared by Alan Bright and W. F. Rittman, registrar and professor of commercial engineering, respectively, of the Carnegie Institute of Technology.

Fig. 1 (*a*) shows the numbers and changes in total enrollment of engineering students in the twenty-one institutions under consideration. It is frankly recognized that these total numbers fall far short of the total enrollment of students in engineering in America. It is believed, however, that the trend is definitely in harmony with that of the entire country. The curve clearly shows that during the world war and immediately following, the number of engineering students increased at a rate unprecedented theretofore and reached a maximum in 1920. The 1920 enrollment is nearly 80 per cent greater than the somewhat constant registration existing in 1913 and 1914.

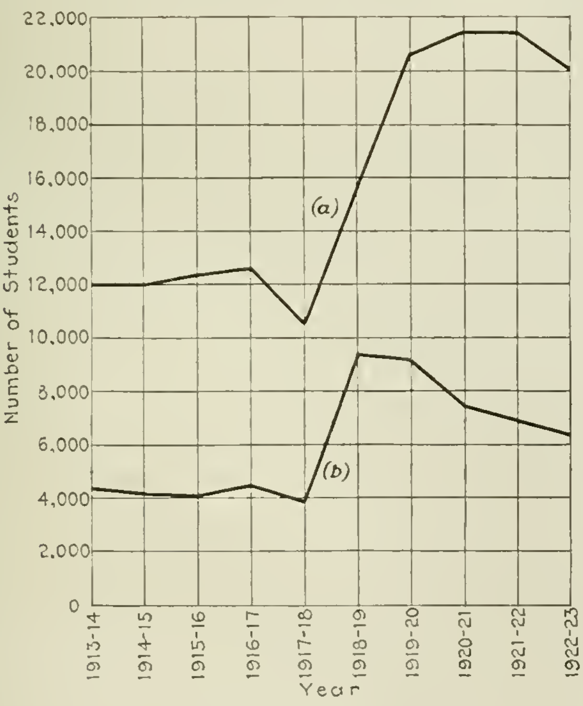


Fig. 1 Total Enrollment (*a*) of All Students and (*b*) Freshmen in 21 Engineering Schools, 1913–1922

Fig. 1 (*b*) shows the numbers and changes in freshman enrollment of engineering students of the institutions. It is believed that this curve shows the attitude and changes in attitude of the general public toward engineering as a profession. The world war appears to have given a tremendous impetus to public interest in the study of engineering. This impetus is very probably the result of the fact that modern warfare is almost entirely a matter of applied engineering in all its branches. Never in the history of the world were engineers of greater importance and in greater demand than during the period from 1915 to 1920. The dropping off in the enrollment of freshman engineering students from 1919 to 1922 was but a natural reaction from the abnormal increase of 1918 and 1919, aided by the industrial depression of 1920 to 1922. Added to these conditions there was a decreased demand for engineers. These figures, also, are not absolute totals for the country, but it seems evident that they do definitely represent trends.

Fig. 2, expressed in terms of percentage, show the ratio of engineering freshmen to seniors. These percentages vary from as high as approximately 80 per cent to as low as approximately 20 per cent of those who enter as freshmen and who remain until their senior year.

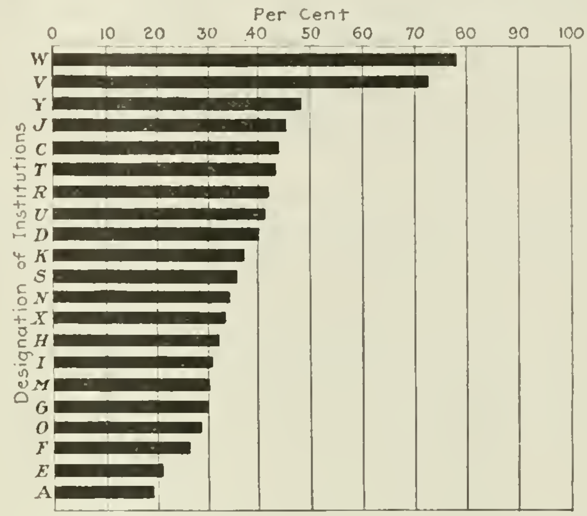

Fig. 2 Ratio (expressed in percentage) of Seniors to Freshmen in 21 Engineering Schools, 1913–1922

Certain institutions receive a large percentage of their upper-class students from the academic colleges who register with advanced standing. As a matter of economy many students, especially in the Middle West, prefer to attend an institution near home for one or two years and then enter a more distant engineering school, even at the expense of spending five years in college. It is not infrequent that heads of engineering schools urge those who can afford it to graduate from an academic college before entering an engineering school. This tendency accounts for the lower mortality in the upper years at certain institutions.

TABLE 1 AVERAGE CLASS ENROLLMENT IN ENGINEERING COURSES IN 21 TYPICAL INSTITUTIONS, 1913–1922

Institution	Freshmen	Sophomores	Juniors	Seniors
W	525	504	471	412
V	157	141	131	114
Y	222	163	128	108
J	298	228	178	136
C	351	245	211	156
T	310	207	157	136
R	224	136	111	99
U	187	134	105	80
D	120	81	60	48
K	551	365	253	205
S	231	163	107	85
N	396	307	199	138
X	161	99	75	56
H	173	87	56	58
I	582	258	233	180
M	370	251	163	112
G	143	80	53	43
O	320	189	115	93
F	304	187	103	81
E	173	108	57	37
A	270	139	82	53
Average	289	191	145	117

Table 1 gives the average number of students, during the years 1913–22, in each of the 21 institutions under observation, and the averages for them all, from which the percentages of loss may be easily computed.

Meetings of Other Societies

American Institute of Electrical Engineers

The operation, control, and protection of transmission and distribution systems was selected this year by the American Institute of Electrical Engineers as the keynote of its spring convention, held in Pittsburgh, Pa., April 24–26, 1923. Of the five technical sessions, including in all some twenty papers and a good deal of valuable discussion, one on the morning of the second day of the convention held the greatest interest for mechanical engineers.

Three of the papers at this session dealt with electric-furnace problems. F. V. Andreae, chief engineer for the Southern Manganese Corpn., Anniston, Ala., stated his belief, formed after careful observation of electric-furnace operation, that the transformation of electrical energy into heat energy in the furnace takes place in an arc passing through an atmosphere of vapors under pressure. He derived a general equation for the three-phase furnace and took up specific examples of its application, showing how the unbalance can be taken care of in several ways. His final conclusion was that the general performance of the three-phase furnace can be determined in advance with a high degree of accuracy by using the simple equations of the balanced three-phase system, where the only thing that is necessary is the previously determined reactance per phase.

A paper by Frank Hodson, president of the Electric Furnace Construction Co., dealt with the development of the large electric melting furnace, the limitations of large electrode furnaces, and the design and construction of the 80-ton furnace at the Ford River Rouge Plant. The advantages of correct heat application, the influence of the new Soderberg continuous electrode on furnace design, and the possibility of using large electric furnaces as an intermediate process for the manufacture of cheap steel were other subjects discussed by Mr. Hodson. The new Soderberg electrode to which he referred consists of a thin metallic casing the size of the electrode to be used, into which the electrode paste or mix is dropped. The actual baking of the electrode is done in the furnace.

The other paper on electric furnaces was by A. N. Anderson and B. D. Saklatwalla, both of the Vanadium Steel Corpn. It discussed electrical factors to be considered in the design of leads for ferroalloy electric furnaces in order to achieve the highest input efficiency.

At the same session A. H. Babcock, electrical engineer for the Southern Pacific Railroad, presented a paper on Some Fuel Determinations on the Southern Pacific System, and C. T. Guildford, of the Westinghouse Elec. & Mfg. Co., one on Heating a Cotton Weave Shed by Electricity. Mr. Babcock gave test data on a representative mountain railway on the West Coast showing the fuel consumption of an average mountain-type locomotive burning oil, beginning with firing up at the engine house and including consumption while testing brakes, during acceleration, running up and down various grades, holding the trains on sidings, and finally running down hill over stretches of steep grade. The overall efficiency determined by the test was 5.57 per cent, but the author stated that the data apply only to the specific conditions and should not be applied indiscriminately to all conditions of operation.

Mr. Guildford described the electric heating system at the St. Croix mill of the Canadian Cottons Co., Ltd., Milltown, New Brunswick, Canada, which operates nearly 57,000 spindles and over 1400 looms, and told how to estimate the quantity of heat required for such buildings. The method of heating employed at the St. Croix mill is the Sturtevant hot-air system with groups of electric heating units instead of steam coils in the fan room. The weave shed, which is a one-story building 480 ft. long by 180 ft. wide, requires 1600 kw. consumption at 15 deg. below zero. Electric heat may be adopted with economy in mills where surplus hydroelectric power is available. To be on a parity with coal at $10.50 per ton, the electric heat should cost $0.0025 per kw-hr. where the average heating-season temperature is 22 deg. In the case of the plant at Milltown a return of more than 37 per cent on the investment for the electrical equipment is shown.

Subjects discussed at other sessions of the convention were grounding devices, the technical features of surges and arcing grounds, relay schemes and illumination, reactors, lightning disturbance, and insulators.

American Welding Society

A comprehensive program, reviewing progress in all the phases of welding, was presented at the annual meeting of the American Welding Society, held in New York, April 24 to 27. The majority of the sessions were devoted to committee reports, only two including the presentation of papers.

Four speakers summarized new developments in the welding field, as follows: W. L. Warner, General Electric Co., Schenectady, N. Y., Electric Welding; G. O. Carter, consulting engineer, Linde Air Products Co., New York, Gas Welding; Hermann Lemp, General Electric Co., Erie Pa., Resistance Welding; and J. H. Deppeler, chief engineer, Metal & Thermit Corpn., Jersey City, N. J., Thermit Welding.

Mr. Warner reviewed the work of the American Bureau of Welding, which is the welding research department of the American Welding Society. Standard tests for welds and welding-wire specifications have been made and a large amount of general research work carried on. Enumerating some interesting applications of the welding process, Mr. Warner spoke of hammer forging as being highly valued for improving the strength, ductility, and fatigue resistance of metal deposited by the electric arc. High welding currents are now being used, he stated, 300 amperes sometimes being employed with coated electrodes for large thermal capacities, and the arc welding of brass with a flux-covered type of copper electrode is already commercial in England. Malleable-iron welds, although possible and sometimes necessary, are not sufficiently strong to justify frequent use. Mr. Warner stated that arc welding has been found economical for the repair of machinery in steel mills, and that the arc welding of monel metal is possible when the proper reducing flux is used. Referring to arc-welding apparatus, the speaker described a safety switch which cuts the power from the welding line and primary circuit whenever the arc is not being drawn. The voltage at all times during welding is limited to a harmless value.

The welding of long stretches of steel pipe was emphasized as an outstanding feature of the past year by Mr. Carter, who gave details of a 140-mile line of 8-in. pipe welded by the Prairie Pipe Line Co. There are three intermediate pumping stations and the line has been welded into a continuous tube from one station to the other, no coupling joints being used. The line carries 750 lb. maximum oil pressure. Mr. Carter suggested the welding of the barrels of concrete mixing machines instead of the usual riveted instruction, outlined the further extension of oxy-acetylene welding to maintenance and repair work, and reported that many valuable applications of the oxy-acetylene process of cutting cast iron have been made. The correct methods of handling cast-iron welding, however, are not so well known.

Mr. Lemp, outlining developments in resistance welding, said that the progress has been made in extending the application of the process with existing apparatus. Among the newer applications which he mentioned were the successful welding of the halves of steel castings and forgings, the welding of cast-iron valve heads to steel shanks, and the welding of tungsten and copper cable for radio apparatus.

The fourth speaker, Mr. Deppeler, gave the results of a research to eliminate blowholes in steel, which is accomplished by permitting the gases to escape through the molds. He also spoke of developments in the rail-welding field and described a new and more efficient design of preheater recently developed.

At a second technical session Dr. H. L. Whittemore, of the Bureau of Standards, Washington, D. C., outlined the method and results of tests made by the Bureau on unfired pressure vessels. These tests were conducted in coöperation with the pressure vessel committee of the American Bureau of Welding for the information of the A.S.M.E. Boiler Code Committee, which is now working upon a code for the construction of unfired pressure vessels. A hydrostatic and hammer test was used and 40 tanks have been tested to the point of destruction. The shells of most of the tanks were 6 ft. long by 2 ft. in diameter and made of $^3/_8$-in. mild-steel plate. Both electric and oxy-acetylene welding were used. It was found that the welded pressure vessel, according to the regular formula for working pressure, has a factor of safety of about 6. The results of the tests are now in the hands of the Boiler Code Committee.

At the same session J. C. Wright, of the Federal Board of Vocational Training, chairman of the committee on training of welding

operators of the American Bureau of Welding, explained a training course for oxy-acetylene welders developed by his committee. The analysis of the work of an oxy-acetylene or gas welder presents various types of jobs with a statement of the operations necessary to perform each, and the information and skill which the operator must possess in order to be an efficient worker.

American Foundrymen's Association

For the third time in its history the American Foundrymen's Association selected Cleveland for its annual convention. The first of its meetings there, which was also the occasion of its first official exhibition of foundry equipment and supplies, took place in 1906; the second occurred ten years later; and the third, which was the 27th annual meeting, in conjunction with the 17th exposition, was held April 28 to May 4, inclusive.

A commendable feature of the technical program was the great reduction in the number of papers presented, as compared with previous conventions, permitting more extensive discussion and promptness in closing sessions. The business session was brief. The election of G. H. Clamer as president to succeed C. R. Messinger was announced. Mr. Clamer is first vice-president and general manager of the Ajax Metal Co., Philadelphia, and is well known not only for his work as a non-ferrous metallurgist but also for his investigations of alloys and inventive work in connection with electric furnaces. Mr. Messinger, the retiring president, Dr. George K. Burgess, newly appointed director of the Bureau of Standards, and Dr. H. Ries, of Cornell University, were elected honorary members of the association in recognition of their services to it.

There were two joint sessions with the Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers, both on the subject of non-ferrous foundry practice. A feature of the first, held on April 30, was the presentation of the annual exchange paper from the Association Technique de Fonderie. In the absence of the author, M. de Fleury, Mr. Clamer read the paper, which was on the application of the aluminum alloy alpax in the foundry. Alpax was described as being an alloy of aluminum and silicon which when treated with certain alkaline salts is said to have unusual properties. Because of its lightness, strength, and low coefficient of expansion and contraction it has been developed for automotive parts particularly, being used for cylinders, pistons, and connecting rods. Other properties and uses of the alloy were also discussed. Emile Ramas, president of the Association Technique de Fonderie and director of the Société Francaise Metallurgique, was a guest at this session and spoke briefly.

R. J. Anderson, of the U. S. Bureau of Mines, Pittsburgh, Pa., was another prominent figure at these joint sessions. At the first he presented a paper on the linear contraction and shrinkage of light aluminum alloys, giving results of a series of experiments at the Bureau to obtain data for use in making pattern allowances. The linear contraction was found to vary between 0.95 and 1.80 per cent. He was also co-author of two papers presented at the second joint session. One gave additional data secured by the Bureau of Mines, dealing with the linear contraction of brasses and bronzes, showing that in general high-temperature pouring causes less contraction than low-temperature pouring. The other discussed the effect of heat treatment on release of stress in bronze castings. E. G. Fahlman, National Smelting Co., Cleveland, and C. L. Eldridge, Metropolitan Museum of Art, New York, were respectively co-authors of these papers.

Among other papers presented at this session was one by F. L. Wolf and W. Romanoff, Ohio Brass Co., Mansfield, Ohio, abstracted by Dr. Paul D. Merica, International Nickel Co., New York. It discussed various shop problems encountered in making castings of brass and bronze, and gave data on pouring temperatures, furnaces, properties of castings, fluxes, etc. It was concluded that the pouring temperature should be as low as possible, consistent with the sizes of the castings.

There were also two sessions on steel foundry practice. Major Minton, U. S. Ordnance Dept., Watertown Arsenal, Watertown, Mass., dealt with the production of links and grousers for army tractors. The physical and chemical properties which these castings must have was given and their heat treatment described. Slides depicted the method in use at the Watertown Arsenal for testing these castings.

A paper illustrated by slides and a motion picture showed a process for the centrifugal casting of steel developed by William McConway, of McConway & Torley, Pittsburgh, Pa. The paper was presented by Harvey Allen of the McConway company. The steel is cast, revolved under hydraulic pressure until it is solidified, conveyed to the soaking pit, and then broken down on the forging presses to produce various sections.

H. A. Lorenz, Bucyrus Co., South Milwaukee, Wis., brought out the fact that the heat treatment of steel castings emphasizes the good and bad qualities of the original casting. He mentioned particularly the bad effects of non-metallic inclusions, dendritic structure, and improper density. He presented data on heat-treating practice on chrome-nickel-steel castings and recommended further research on special alloy steels.

An investigation to determine specifically the proper thermal treatment to apply to electric steel castings of 0.20 to 0.32 per cent carbon was described by H. A. Neel, Michigan Steel Casting Co., Detroit, Mich.

Several papers on gray iron were presented, one of particular interest to mechanical engineers being on gray iron for automotive castings, by H. B. Swan, Cadillac Motor Car Co., Detroit. It contained the results of a questionnaire sent to twenty-five automotive-castings plants, giving data on iron mixtures and cupola practice in producing cylinders, pistons, crankcases, and various small castings. The author reviewed the effects of carbon and other elements upon the physical properties of automotive castings, and commented upon the lack of standard cupola practice and of tuyere ratios.

At a session on malleables a paper by E. D. Smith, Lakeside Malleable Co., Racine, Wis., read by E. J. Lowry, of Hickman, Williams & Co., Chicago, showed that there are great possibilities in hardening and tempering malleable castings. It described experiments conducted to determine the feasibility of hardening malleable-iron parts, the nature of the hardened product and the processes best adapted to hardening, and suggested further fields for research on this subject.

Other papers at this session dealt with the application of fuel oil to the malleable air furnace, describing furnace construction and methods of operation which have been successful; the adaptation of continuous tunnel annealing furnaces to the malleable-iron industry, with details as to the construction, operation, and control of the furnaces; and a method for reducing the amount of scrap in a malleable foundry.

Two sessions on sand research, reclamation, conservation, testing methods, and geological survey work were of great interest to members interested in these phases of foundry work. Several committees reported, bringing out considerable discussion, and a number of papers were presented. Much of the discussion centered about methods of determining the bonding strength of molding sands. Dr. Ries described experiments at Cornell based on the Doty method, but with a different process of ramming the sand specimen.

Industrial engineering, dealing principally with employment, cost accounting, foreman training, compensation, and apprentice ship courses, has in recent years received considerable attention at the foundrymen's meetings. This year the subject of industrial education was presented for discussion in the form of a symposium of eleven papers on training foundry workers. The speakers represented not only state and educational institutions but also manufacturers who have inaugurated foundry courses. It was the consensus of opinion that the successful apprentice course must be based on a policy to give thorough training to the apprentice, and at the same time afford a sufficient monetary reward during the period of apprenticeship.

Two sessions characterized as dealing with new developments in the foundry industry complete the technical sessions. Leon Cammen, associate editor of Mechanical Engineering, traced the history of centrifugal casting and outlined its possibilities. He explained the mechanics of centrifugal casting on horizontal, vertical and inclined axes respectively, and touched upon the temperature of mold surfaces, comparing warm molds, water-cooled, and hot molds. The process of hot-mold centrifugal casting, which he himself has devised, he said makes possible the production of thin sections $^3/_{16}$ in. and up in considerable lengths

and in comparatively small diameters. Heating the mold to a high temperature obviates the rapid chilling of metals that results when they are poured at temperatures only a little above the melting point. It has been found that a $^3/_{16}$-in. wall of steel poured against a mold having a temperature of 1700 or 1800 deg. fahr. takes about 45 sec. to harden completely, which is sufficient to produce clean metal. Becket metal analyzing 0.50 per cent carbon, 26 to 28 per cent chromium, 0.40 to 0.60 per cent silicon, and 0.60 per cent manganese is most suitable for the hot molds, and for best results the surface of the mold should be lapped as smooth as glass.

Dr. Richard Moldenke, Watchung, N. J., presented a paper at each of these sessions, one on the desulphurization of cast iron, in which he discussed various methods for reducing the sulphur content of iron, and one on the development of a new long-life mold. G. K. Elliott, The Lunkenheimer Co., Cincinnati, spoke on gray cast iron from the point of view of the electric furnace, outlining the main features of the acid and basic electric furnaces and then sketching the general operating features of both the cupola and the electric furnace. The manufacture of synthetic foundry iron in the electric furnace was discussed in a paper by C. E. Sims, C. E. Williams, and B. M. Larsen, all of the Northwest Experiment Station of the U. S. Bureau of Mines, at Seattle, Wash. They described the production of cast iron from almost any kind of ferrous scrap by the use of a carburizer. They recommended a dense, pure form of carbon for the carburizer and stated that this should be charged under the metal and the melting conducted from the bottom up.

Recent developments in British foundry practice were summarized in a paper by Dr. Percy Longmuir, director of research for the Institution of British Foundrymen. This paper was the annual international exchange paper contributed by the British foundrymen and may be characterized as supplementary to addresses by Dr. Longmuir before the A. F. A. over twenty years ago, in which he declared that the future of all foundry work depended upon the development of scientific methods. His paper, read by Mr. McPherran of the Allis-Chalmers Mfg. Co., showed how the growing use of such methods is making the British foundrymen more efficient.

An extensive exhibit of foundry supplies and accessories was held simultaneously with the convention at the new Auditorium. This exhibit deservedly attracted the attention of the foundrymen present, and was of considerable interest in many ways. While it did not show any striking new developments or sensational improvements in machinery, it went along way toward proving the high state of the development of the mechanical accessories now at the service of the American foundryman.

There were numerous exhibits of material-handling equipment, the demand for which is rapidly growing with the increasing scarcity of labor, as well as of sand mixers, molding machines, crucibles, welding apparatus, heating and small melting furnaces, etc.

American Electrochemical Society

The annual spring meeting of the American Electrochemical Society was held in New York, May 3 to 5, 1923, under the auspices of the New York section. A symposium on the production and use of rare metals was the main feature of the convention. Dr. F. M. Becket, Carbide & Carbon Co., New York, who secured the contributions, was presiding officer and opened the meeting with an address on an investigation conducted by the research department of his company under his direction to determine the effect of zirconium in steel. It presented some revolutionary facts, made public for the first time, showing the definite effects of the use of a silicon-zirconium alloy in the production of steels of various kinds, among which may be mentioned its scavenging and desulphurizing properties, as well as a remarkable effect which it has on the rolling properties of steel when the actual sulphur content is high.

One of the important papers of this symposium was descriptive of experiments with rare-metal steels using uranium, boron, titanium, zirconium, cerium, and molybdenum, by Dr. H. W. Gillett and E. L. Mack, of the Bureau of Mines, Ithaca, N. Y. A large protion of the paper was devoted to a discussion of molybdenum in steel. Molybdenum was said to be a real alloying element and more potent in its effect than any other element, except possibly carbon. Attention was called to the air-hardening properties, particularly the depth thereof, which molybdenum bestows upon steel, and to the changes which it brings about in the critical range, an effect which vanadium does not have. Dr. Gillett, who presented the paper in abstract, stated as his belief that the presence of molybdenum in steel results in good strength combined with extra good ductility.

The present status of the production of rarer metals, the effect of alloying elements in steel, the preparation of metallic uranium, and platinum metals were other subjects included in the symposium.

Miscellaneous subjects were covered at other sessions, among them being heat-insulating materials for electrically heated apparatus, methods of handling materials in the electric furnace and the best type of furnace to use, electric-furnace detinning and production of synthetic gray iron from tin-plate scrap, and a new process called "chromizing," analogous to calorizing and sherardizing. F. C. Kelly, who is connected with the research laboratory of the General Electric Co. at Schenectady, N. Y., described this process, which involves the introduction of chromium at temperatures above the ordinary into the surface of iron, forming more or less of a superficial alloy or covering. He stated that chromizing may be used to prevent the flow of a metal like copper on iron at a temperature above the melting point of copper, as well as to prevent corrosion.

Important to A.S.M.E. Members Interested in Stress Analysis

At the 1922 Annual Meeting, under the auspices of the Railroad Division, an extremely valuable paper dealing with stresses in locomotive frames was presented by R. Eksergian. The paper gives a lengthy and complete discussion of the analytical methods to be followed in determining stresses in locomotive frames.

In view of the fact that there was a great wealth of material presented at the last Annual Meeting and that the Committee on Publication and Papers was compelled to reduce the size of Transactions to the minimum, it was decided to omit Mr. Eksergian's paper from the annual volume, but to print pamphlet copies of the complete paper with the discussion on it, and supply copies to members who might desire to have them. The number of copies printed will be limited to the number of requests for it received before September 1. Requests for this pamphlet should therefore be sent to the Secretary's office before that date.

A synopsis of the paper follows. Members of the Society are requested to study this carefully and determine whether the subject-matter would be of value in their work. It may be stated that the analytical methods developed by Mr. Eksergian should prove of value to all engineers engaged in the study of stresses howsoever set up.

Synopsis of R. Eksergian's Paper on Stresses in Locomotive Frames

This paper is essentially a preliminary analysis of the major reactions brought on a locomotive frame, as well as of the nature of frame action as regards variation of bending moment, shear, etc., for differently supported types of frames.

A careful analysis has therefore been made of the various methods of equalization, spring design, and the nature of cab supports in electric locomotives. This is followed by a section dealing with the dynamics of the steam locomotive, where the variation of torque and a quantitative investigation of the various oscillations are discussed in detail. Further, a careful analysis of the variation of side-rod loads and journal-bearing loads is included. The succeeding section deals with electric-locomotive drives and the major reactions brought on the frame. This section includes the dynamics of the electric side-rod drive, which discussion augments the previous one on side-rod loads in steam locomotives. The next section discusses the dynamics of braking, its change in load on the equalization, and the reactions brought on the frame. In this section is included a brief discussion of bumping loads and dynamical loads on the drawbar.

For a more quantitative investigation of the effects of vertical loads the bar frame has been approximately treated as a continuous beam under equalizer-applied loads and boiler supports, and the variations of bending shear, etc., for the U. S. Standard Pacific locomotive are computed in detail in Appendix No. 1. Following this is a careful analysis of the stresses resulting from longitudinal loads due to traction, etc.

Finally, the nature of the lateral reactions and the dynamics of lateral oscillations on entering a curve, etc., are discussed, a short recapitulation of the static reactions while on a curve being also given.

A brief outline of methods of analysis coördinating with future experimental work is discussed in Appendix No. 2

Engineering and Industrial Standardization

The Lumber-Standardization Program

AT THE first American Lumber Congress, in 1919, steps were taken to inaugurate simplification and general standardization of lumber sizes and grades. Since that time the Engineering Bureau and the Bureau of Lumber Economics of the National Lumber Manufacturers Association, at the request of the American Lumber Congress, have been continuously engaged in a thorough study of lumber standards.

The lumbermen of the United States have assumed the responsibility of establishing and maintaining the lumber trade upon a high plane of efficiency and of ethical practice, and to accomplish this they have established the "Central Committee on Lumber Standards," representing the entire organized trade from producer to consumer and created by a general conference of lumber manufacturers, distributors, and consumers in July, 1922. This Central Committee on Lumber Standards is composed of

John W. Blodgett, *Chairman*, representing National Lumber Manufacturers Association
W. E. Hawley, *Vice-Chairman*, representing the Association of Railway Executives, and the construction engineers
John H. Kirby, representing the Southern Pine Association
Chas. A. Goodman, representing lumber manufacturers
Dwight Hinckley, representing American Wholesale Lumber Association
John E. Lloyd, National Retail Lumber Dealers Association, representing lumber retailers
Sullivan W. Jones, representing the American Institute of Architects
W. L. Saunders, representing lumber manufacturers.

Its declared function is to act as a steering organization to draft and submit to its constituent associations its best judgment of suitable ways and means to accomplish in practice the simplification of lumber grades; the standardization of lumber sizes, the certification of quantity and quality, and the enforcement, by means of association inspection service and, if practicable, by grade marking of definite standards of lumber sizes and grades.

The National Lumber Manufacturers Association with which, prior to the appointment of the Central Committee, the initiative in further development of the standardization program had been lodged by the lumber trade, turned over to the Committee the results of its three-year investigation of lumber standards, together with an outline of definite proposals for the Committee's consideration. These were made the basis of the suggestions for lumber standards now being submitted by the Committee to the lumber industry.

One of the first acts of the Central Committee was to arrange for the establishment and maintenance of permanent headquarters and offices in Washington, D. C., under the direct charge of R. C. Merritt, who it appointed to be its executive secretary. Its next important act was the creation of the following Consulting Committee to prepare in behalf of its constituents appropriate data and suggestions for the consideration of the Central Committee:

Wilson Compton, *Chairman*, National Lumber Manufacturers Association

Group Chairmen

George Gerlinger, representing manufacturers
W. T. Murray, representing manufacturers
Harry J. Meyers, representing retailers, Brown-Borhek Lumber & Coal Co.
C. V. McCreight, representing wholesalers, Ricks-McCreight Lumber Co.
C. E. Lindsay, representing railroads, New York Central Lines
Wm. A. Babbitt, representing wood-using industries, National Association of Wood Turners, Inc.
E. S. Hall, representing architects and general contractors, American institute of Architects
Dr. Hermann von Schrenk, representing engineering and technical organizations
A. W. Newton, representing engineering and other technical organizations.

Other Members

Guy Gray, representing retailers, Gray Lumber Company
Adolph Pfund, representing retailers, National Retail Lumber Dealers Assn.
Charles Hill, representing manufacturers, A. C. Tuxbury Lumber Company
L. Germain, Jr., representing wholesalers
John Foley, representing railroads, Pennsylvania Railroad System
E. A. Frink, representing railroads
Henry Ericsson, representing general contractors
Arthur E. Lane, representing American Wholesale Lumber Association
E. J. Curtis, representing wood-using industries
R. E. Brown, representing the Society of Automotive Engineers
J. M. Pritchard, representing Hardwood Manufacturers Institute.

As a result of one of the important decisions of a recent meeting, Mr. Compton, as chairman, will assign to individuals and groups of individuals, selected from the membership of the Consulting Committee, various phases of the problem of lumber standardization and simplification for investigation and recommendation. Their findings will be reported to the whole Consulting Committee.

Although conclusions regarding standardization in lumber-grading nomenclature and the marking of standard grades on lumber must necessarily await conclusions on grade standardization, they are now a subject for the consideration of the Consulting Committee. Grade marking can be undertaken on the present grades without awaiting conclusion of more uniform standards. Similarly improved and more uniform inspection service is closely related to grade standardization. These are, however, matters of immediate concern to lumber manufacturers and shippers and as a consequence may not require the consideration of the entire Consulting Committee.

The outline of immediate activities of the Consulting Committee includes careful consideration of the following:

1 Yard Lumber Sizes
2 Molding Patterns
3 Standard: (*a*) species; (*b*) use; (*c*) size; (*d*) manufacturing classifications of lumber.
4 The Forest Products Laboratory plan for investigation of softwood shop, and hardwood, lumber grading; and such consideration as the Consulting Committee may desire to give to the following:
5 Application to grading rules of Suggested Basic Rules for Grading Softwood Yard Lumber and Structural Timbers
6 Grade Marking
7 Use of Tally Cards
8 Inspection Service
9 Standard Names for Lumber Grades.

The suggested provision in lumber-grading rules for the admissibility of certain percentages of short lengths and odd lengths of lumber has been submitted to the constituent associations together with an analysis of information, and opinion thereon, prepared by the executive secretary.

Standardization in the Marine Field

THE general committee on Standardization recently formed by the American Marine Association has adopted a plan of organization which will enable it to establish standards in the marine field comparable with the work of similar organizations in other fields both here and abroad but entirely independent of them. The purpose of this movement is to give the marine industries of the United States the benefit of established and recognized standards for hull details and operation details. Both of these will reduce the cost of ship construction and operation and will thus help to place competition with foreign shipping on more equal terms.

The third meeting of the general committee was held in New York on April 17 with Captain R. D. Gatewood, U. S. N., as acting chairman. At this meeting it was resolved that the standardization and simplified-practice project in the marine field be carried on under the name of the "American Marine Standards Committee."

The purpose of the American Marine Standards Committee is in line with the movement inaugurated by Secretary Hoover of the Department of Commerce to eliminate waste and reduce costs. The extension of this work to the marine industries was proposed by him at the annual Marine Exposition in New York last Novem-

ber and was taken up by the American Marine Association with the support of the Department of Commerce and the United States Shipping Board Emergency Fleet Corporation.

In order to carry out the work expeditiously and economically, the committee has adopted a plan of organization in which the American Marine Standards Committee will act as the executive committee, all details and correspondence being carried out through the office of its secretary in the Division of Simplified Practice of the Department of Commerce in Washington.

The work of the organization will be administered primarily by three committees as follows:

A Organization, Membership and Finance
B Constitution and Rules
C Publicity and Relations.

The policies of these committees will be carried out by the secretary.

The following were appointed as members of the three administrative committees:

Committee A

Col. E. A. Simmons, *Chairman*, President, American Marine Association
Capt. C. A. McAllister, *Vice-Chairman*, Vice-President, American Bureau of Shipping
Charles F. Bailey, Engineering Director, Newport News Shipbuilding and Dry Dock Company
Hugo P. Frear, Naval Architect, Bethlehem Shipbuilding Corpn., Ltd.
E. H. Rigg, Naval Architect, New York Shipbuilding Corpn.

Committee B

William F. Gibbs, *Chairman*, President, Gibbs Brothers
E. H. Rigg, *Vice-Chairman*, Naval Architect, New York Shipbuilding Corpn.
Capt. John F. Milliken, Secretary, Neptune Association
John W. Gray, Newport News Shipbuilding and Dry Dock Company
Capt. C. A. McAllister, Vice-President, American Bureau of Shipping.

Committee C

Capt. C. A. McAllister, *Chairman*, Vice-President, American Bureau of shipping
Capt. R. D. Gatewood, *Vice-Chairman*, U. S. N., United States Shipping Board Emergency Fleet Corporation
Col. E. A. Simmons, President, American Marine Association
John W Gray, Newport News Shipbuilding and Dry Dock Company
Capt. John F. Milliken, Secretary, Neptune Association.

Under Committee A (on organization) three technical supervisory committees will be created as follows:

1 Committee on Hull Details
2 Committee on Engineering Details
3 Committee on Ship Operating Details and Consummable Supplies.

Through each of these technical supervisory committees there will be formed a large number of subject committees to which will be assigned the task of studying and formulating a standard for such specific items as will from time to time be designated by the executive committee. At the April meeting the committee confirmed the appointment of A. V. Bouillon as its secretary.

LIBRARY NOTES AND BOOK REVIEWS

Sampling and Analysis of Coal, Coke and By-Products

Sampling and Analysis of Coal, Coke and By-Products. Methods of the U. S. Steel Corporation. Second edition, 1923. Published by The Carnegie Steel Company, Pittsburgh, Pa. Leather, 5 × 7¾ in. 184 pp., illus., tables, $3.

Reviewed by C. P. Menges,[1] New York, N. Y.

This little book contains a collection of the methods of sampling and analysis of coal and its derivatives to be used as a guide for its evaluation as a fuel or by-product, and compares very well with the best literature on this subject.

The methods chosen are those which have recently been found to be the most accurate and rapid and which can be followed out in most analytical laboratories. Numerous standard methods outlined in this volume were taken from the proceedings of the American Society for Testing Materials and the Bureau of Mines, where both chemical and physical tests on this subject have been carefully investigated. Also a number of special tests by different authors are quoted.

In reviewing that part of the work in which no outside references are made, a similarity of methods is noticed to those found in the best chemical literature and textbooks from which the fundamental methods were taken, with the addition of such tests and apparatus as special investigators on this subject have found to be of additional value in the examination of these various products.

Alternative methods are frequently given, so that there is a choice as regards the kind of apparatus at hand and the time required to make the analysis.

In conclusion it may be said that the book is complete in itself. The preparation of the standard solutions necessary to make the analysis are described in detail, and also the various tables required for the calculations are included, so that the necessity of consulting other books is eliminated.

Automobile Chassis. By Ben G. Elliott. McGraw-Hill Book Co., New York and London, 1923. Cloth, 5 × 8 in., 233 pp., illus., $2.50.

A textbook for students of automotive engineering. Treats all parts of the gasoline automobile, except the body, the power plant, and its immediate accessories. Particular stress is put upon fundamental principles. These are illustrated, as far as possible, by examples from modern practice, so that the work is useful for reference as well as for instruction.

[1] Chemist, New York Edison Company.

Business Cycles and Unemployment. Report and Recommendations of a Committee of the President's Conference on Unemployment. McGraw-Hill Book Co., New York and London, 1923. Cloth, 6 × 9 in., 405 pp., charts, tables, $4.

Report of an investigation of the whole problem of unemployment and of methods of stabilizing industry so that business depressions would be prevented. This volume contains also the report of an investigation made, at the request of the Committee, by the National Bureau of Economic Research. The latter report discusses the relation of business cycles to unemployment, cyclical fluctuations in employment, and proposed remedies for cyclical unemployment.

Consolidated Textile Catalogs, 1923. Compiled by *Textile World*. Bragdon, Lord & Nagle Co., New York, 1923. Cloth, 9 × 12 in., 531 pp., illus.

This catalog is intended to provide firms engaged in the textile industry with a conveniently arranged collection of catalog information, similar to that available for other lines. The book describes a large proportion of the textile machinery built in this country, the material being arranged under such heads as cotton machinery, wool and worsted machinery, knitting machinery, machinery for dyeing, drying and bleaching, power-plant equipment, mill supplies, building construction, etc. An index of firm names and an index of products are provided, together with a catalog of books on textiles.

Cosgrove's Handbook of Woodworking Machinery. Cosgrove Company, Owosso, Mich., 1923. Loose leaf, fabrikoid, 8 × 11 in., $15.

Buyers of woodworking machinery will find in this handbook descriptions of the machines and equipment manufactured in this country, prepared in uniform manner and classified so that the different machines may be easily compared. The descriptions explain the principles of each machine, tell the sizes made and their capacities, state the power and floor space which they require, and give the names of the manufacturers. An index and a directory of manufacturers are included. The book is issued in loose-leaf binding, to permit the insertion of new matter.

Elasticity and Strength of Materials Used in Engineering Construction. Section 2. Theory of Simple Flexure. By C. A. P. Turner. Minneapolis, Minn., 1923. Cloth, 6 × 9 in., 108 pp., diagrams, $5.

The second section of Mr. Turner's work deals with the theory of flexure. The development of the exact theory of flexure will prove interesting to the profession, the author believes, as will also the simplified formulas. These are developed in such form that they can be remembered and used without reference to a handbook. The discussion of the stress analysis of beams shows clearly the relation of shear distortion to shear resistance, a relation frequently not understood.

Electric Cranes and Hauling Machines. By F. E. Chilton. Isaac Pitman & Sons, London and New York, 1923. (Pitman's technical primers.) Cloth, 4 × 6 in., 114 pp., illus., diagrams, $0.85.

The object of this book is to describe a number of the more generally used types of electric cranes and hauling machines, together with a few of the accessory specialties used with them, and to explain their methods of operation. The subject is treated in a simple, descriptive manner, on broad general lines. Only the most modern and commonly used appliances are included.

Electric Motors, vol. 1. Chiefly Concerning Direct Current. By Henry M. Hobart. Third edition. Isaac Pitman & Sons, London and New York, 1923. Cloth, 6 × 9 in., 412 pp., illus., diagrams, tables, $4.50.

An advanced treatise by an experienced designer, in which matters of theoretical and practical interest are discussed. The present edition has been completely revised and rewritten. While this volume is mostly about direct-current motors, the author has made no attempt to separate alternating- and direct-current questions sharply, and has included certain important matters in the second volume.

English and Engineering. By Frank Aydelotte. Second edition. McGraw-Hill Book Co., New York and London, 1923. Cloth, 5 × 7 in., 415 pp., $2.

Dr. Aydelotte sets forth the purpose of his book to be to teach the student to write by stimulating him to think for himself about his own problems, about his work, and its place in the world.

The range of the thirty-eight essays in the book embraces many kinds of men and many kinds of writing—from the works of Macaulay and Ruskin to the writings of living engineers and advertisements of manufacturers.

Financial Incentives for Employees and Executives. By Daniel and Meyer Bloomfield. 2 vols. H. W. Wilson & Co., New York, 1923. (Modern Executive's Library.) Cloth, 5 × 8 in., $4.80.

A handy compilation of articles on wage systems, bonus plans, thrift plans, and other plans for rewarding employees, classified and arranged for convenient reference. Part of the material is reprinted from periodicals and reports, the remainder is original with the authors. The work covers a wide field and gives the practice of many firms.

Hutte, des Ingenieurs Taschenbuch, vol. 1, 24th edition. By Akademischer Verein Hütte, Berlin. Wilhelm Ernst & Sohn, Berlin, 1923. Cloth, 5 × 7 in., 1308 pp., diagrams, tables, $2.

The present volume has been thoroughly revised to bring it abreast of modern practice. The section on the mechanics of rigid bodies has been entirely rewritten; that on the mechanics of fluids has been enlarged. Improvements have been made in the section on heat, especially in the chapter on combustion, and in the section on the strength of materials. The chapters on lubricants and on belts and belt conveyors have been rewritten. The section on machine elements has been rewritten and enlarged. Nearly 250 pages in all have been added to the book. A change has been made in the method of selling the book, so that the individual volumes can now be bought separately.

Industrial Electric Heating. By J. W. Beauchamp. Isaac Pitman & Sons, New York and London, 1923. (Pitman's technical primers.) Cloth, 4 × 6 in., 118 pp., illus., diagrams, tables, $0.85.

The primary object of this book is to bring together, for the benefit of the engineer and student, information on the applications of electric heating, particularly to other purposes than furnace and welding work. The book is intended to suggest possible applications and thus to stimulate further inquiry by manufacturers and others who could use electric heating, by calling attention to the variety of uses which it now has.

Interior Wiring and Systems for Electric Light and Power Service. By Arthur L. Cook. Second edition. John Wiley & Sons, New York, Chapman & Hall, London, 1923. Fabrikoid, 4 × 7 in., 458 pp., illus., diagram, tables. $3.

Intended as a guide to modern practice in electric lighting and power applications, and in the design and installation of the wiring for these purposes. Written particularly for superintendents of electrical installations and for wiremen who may be called upon to extend or change existing installations and who need definite information upon the best method of procedure. It is also intended as a textbook for students in trade schools and as a handbook for architects.

Kalender und Handbuch fur Betriebsleitung und Praktischen Maschinenbau, 1923. By Hugo Güldner. 2 vols. H. A. Ludwig Degener, Leipzig, 1923. Limp cloth, 4 × 6 in., diagrams, tables, $1.

A pocketbook designed to meet the wants of engineers engaged in management and operation, or in the manufacture of machinery, rather than in design. Issued in two parts, the first containing the greater part of the text and discussing the materials of machines, machine parts, prime movers, power transmission and auxiliary machinery. Volume two treats of management and also contains mathematical tables. The work is published in inexpensive form and is revised each year.

Mechanical Testing, Vol. 2; Testing of Prime Movers, Machines, Structures and Engineering Apparatus. By R. G. Batson and J. H. Hyde. E. P. Dutton & Co., New York, 1923. (Directly useful technical series.) Cloth, 6 × 9 in., 446 pp., illus., diagrams, tables, $10.

This book, the concluding volume of this treatise on testing, deals with methods and apparatus for testing prime movers, machines and structures. The text is confined to descriptions of mechanical methods of testing, except in certain important cases where hydraulic, electrical, or optical means are employed to supplement mechanical means. Types of testing apparatus for the standard tests, suited for use both in the laboratory and the factory, are also described. Prominence is given to details of importance in the success of test apparatus.

Moedebeck-Taschenbuch fur Flugtechniker und Luftschiffer. By R. Süring und K. Wegener. Fourth edition. M. Krayn, Berlin, 1923. Boards, 5 × 7 in., 920 pp., illus., diagrams, tables, $3.60.

This volume, intended to serve as a concise account of the present state of aerial navigation, suitable for ready reference. Its seventeen chapters are each prepared by an authority and are liberally illustrated with diagrams and photographs; many have short bibliographies. A collection of tables is appended to the book.

Origin and Development of the Quantum Theory. By Max Planck. Oxford University Press, American Branch, New York, 1922. Paper, 6 × 9 in., 22 pp. $1.20.

This is the Nobel Prize address delivered before the Royal Swedish Academy of Sciences, June 1920. It sketches briefly the history of the origin of this important theory and gives a short account of its development and its influence on present-day physics. A brief bibliography is given.

Professor Coker's Apparatus for Determining the Distribution of Stress in Structural and Machine Members. Made by Adam Hilger, London.

This pamphlet is a trade publication describing the apparatus devised by Prof. E. C. Coker for using polarized light to determine the distribution of stress in parts of machines and structures by observations on models made of transparent materials; a method that makes it possible to measure the stress distribution under any system of loads, in any body that can be represented by a plate model stressed in its own plane. As the measurements obtained on models with this apparatus have been found to represent accurately the stresses in metals, the experimental results can be immediately applied to engineering materials. A bibliography is included.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 117-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AIR FURNACES

Oil-Burning. Melts with Oil in Air Furnace, D. J. Dobson. Foundry, vol. 51, no. 11, June 1, 1923, pp. 436–437 and 466, 1 fig. Coal-burning furnaces used to melt malleable with slight changes in combustion chamber; figures given showing relative cost of coal and oil firing; oil consumption recorded.

Jet Propulsion. Jet Propulsion for Airplanes, Edgar Buckingham. Nat. Advisory Committee for Aeronautics—Report, no. 159, 1923, 18 pp., 8 figs. Discusses method for propulsion by reaction of internal-combustion jet; only hope of success is said to lie in thrust augmentors.

Low-Powered. The Low-Powered Aeroplane, W. H. Sayers. Aeroplane, vol. 24, nos. 18, 19 and 20, May 2, 9 and 16, 1923, pp. 323–324, 343–344 and 363–366, 2 figs. General consideration in light of present developments. May 9: Speed and power; cleanness; weight; wings and body resistance. May 16: Effect of 1 gal. fuel limit; effect of body; engines for light airplanes.

AUTOMOBILE ENGINES

Triumph-Ricardo. Novel Cylinder Block and Crankcase in New British Light Car, M. W. Bourdon. Automotive Industries, vol. 48, no. 20, May 17, 1923, pp. 1078–1080, 6 figs. 4-cylinder engine designed by Ricardo for Triumph car; masked inlet valve and slipper pistons are features; two-bearing crankshaft, splash lubrication, and integral inlet and exhaust manifolds used; bore, $2^1/_2$ in. and stroke, $4^3/_8$ in.

AUTOMOBILES

Wheels. Making Welded Pressed-Steel Automobile Wheels. Machy. (N. Y.), vol. 29, no. 10, June 1923, pp. 757–761, 8 figs. Methods and equipment employed in making automobile and truck wheels by new process.

BLAST FURNACES

Linings, Disintegration of. Solving Furnace Lining Problems, C. E. Nesbitt and M. L. Bell. Iron Trade Rev., vol. 72, no. 22, May 31, 1923, pp. 1603–1607, 7 figs. Laboratory tests are conducted on firebrick for blast furnaces to determine cause of disintegration and its prevention; hard burning is helpful but not desirable; iron-free clay must be used. (Abstract.) Paper presented at Am. Iron & Steel Inst.

BOILER FURNACES

Design. The Influence of Radiant Heat on Furnace Design, A. G. Christie. Power, vol. 57, no. 22, May 29, 1923, pp. 851–854. By simple analogies author pictures behavior of radiant heat waves and their effect on various substances, leading up to analysis of radiant heat in boiler furnaces; suggests designing furnace with maximum amount of boiler-tube surface exposed to fire in order to take up greater amount radiant heat.

BRAKES

Kunze-Knorr. The Kunze-Knorr Air Brake. Ry. & Locomotive Eng., vol. 36, no. 5, May 1923, pp. 143–147, 10 figs. Describes recent German development based on principle of single-cylinder automatic compressed air brake. See also editorial, pp. 149–150.

CAMS

Internal-Combustion-Engine. Internal-Combustion Engine Cams, B. B. Low. Engineering, vol. 115, no. 2995, May 25, 1923, pp. 641–644, 12 figs. Gives mathematical analysis of cams most generally used in internal-combustion engines and considers definite examples showing relative merits as regards average lift, spring strength, noise, etc., of different types.

CENTRAL STATIONS

Diesel-Powered. The Diesel-Powered Central Station. Power, vol. 57, no. 22, May 29, 1923, pp. 856–858, 6 figs. Cites examples where Diesel engine has shown economies impossible with steam units. There are 1100 oil-engine-powered light plants in United States.

COAL

Carbonization. Coal Carbonization as Applied to Power-Plant Practice, V. Z. Caracristi. Power, vol. 57, no. 22, May 29, 1923, pp. 831–836, 4 figs. Low-temperature system of coal distillation; working temperature of oven 1200 deg.; distillation completed in five minutes; coke obtained suitable for boiler firing, powdered fuel or briquetting into domestic fuel.

COST ACCOUNTING

Overhead. Taking the Guesswork out of Overhead Costs, Dale S. Cole. Indus. Management (N. Y.), vol. 65, no. 6, June 1923, pp. 324–326, 1 fig. Shows simple, inexpensive method which permits of more intelligent estimating by small plant, laying particular stress on items of "contributory overhead."

DIE CASTING

Dies. Die-Casting Dies and Their Design, Charles Pack. Machy. (N. Y.), vol. 29, no. 10, June 1923, pp. 804–806, 7 figs. Describes most important points of design and construction in number of die-casting dies, showing methods that may be employed for die-casting white metals into parts of various designs.

DROP FORGINGS

Coarse-Grained. Coarse-Grained Drop Forgings—Their Detection and Correction, L. S. Cope. Am. Soc. Steel Treating—Trans., vol. 3, no. 8, May 1923, pp. 808–823, 28 figs. Review of factors which chiefly contribute to coarse-grained structure, most important of which are excessively high forging temperatures with insufficient amount of mechanical work; discusses methods of detecting coarse-grained fractures and describes method devised by author which has proven satisfactory; importance of proper furnace design, heating temperatures and reductions in hammering metal into dies.

ELECTRIC FURNACES

Gray Iron. Melts Gray Iron by Electric Furnace, G. K. Elliott. Iron Trade Rev., vol. 72, no. 21, May 24, 1923, pp. 1535–1537. Outlines main features of acid and basic electric furnaces, sketches effects upon principal elements of cast iron in comparison with effects obtained through cupola, and discusses problems of cast iron that have arisen through introduction of electric furnace for treating cast iron. (Abstract.) Paper read before Am. Foundrymen's Assn.

ELECTRIC LOCOMOTIVES

4000-Hp. New Electric Locomotives for the Norfolk & Western R. R., T. C. Wurts. Ry. & Locomotive Eng., vol. 36, no. 5, May 1923, pp. 153–155, 4 figs. Features include cab structure carried by side frames; four pairs of drivers in single truck per cab; single 1000-hp. motor per jack shaft; oil-insulated force-cooled transformer; unique arrangement to reduce torque on any motor to present slipping. See also description in Ry. Elec. Engr., vol. 14, no. 4, May 1923, pp. 137–140, 5 figs.

ELECTRIC WELDING, ARC

Manufacturing Purposes, Use for. Arc Welding as a Manufacturing Asset, J. F. Lincoln. Elec. World, vol. 81, no. 20, May 19, 1923, pp. 1147–1148, 1 fig. Points out that arc welding can be of greatest service in manufacture of parts which are usually made of cast iron, and gives examples; also enumerates the advantageous features of properly arc-welded joint.

EMPLOYEES, TRAINING OF

Plans. How Labor Can Be Made More Productive, Harold C. Smith. Am. Mach., vol. 58, no. 22, May 31, 1923, pp. 793–796. Educational activities of Nat. Metal Trades Assn. Five plans for training workers; purpose of industrial training.

EMPLOYMENT MANAGEMENT

Personnel Practice. Present Tendencies in Personnel Practice, Robert F. Lovett. Indus. Management (N. Y.), vol. 65, no. 6, June 1923, pp. 327–333, 2 figs. Study of personnel procedure in 74 industrial and commercial concerns.

FACTORIES

Building Planning. Buildings from The Manager's Viewpoint, G. L. H. Arnold. Management Eng., vol. 4, nos. 5 and 6, May and June 1923, pp. 329–333 7 figs., and 417–421, 10 figs. May: Foundation, floors, and ceiling for well-planned factory. June: Planning roof; partitions, doors, and equipment.

FLOW OF WATER

Electrical Measurement. Electrical Measurement of Velocities of Flow in Pipes, Ivan E. Houk. Engineering, vol. 115, no. 2995, May 25, 1923, pp. 644–645, 3 figs. Describes typical method of measurement based on principle of sudden change in electrical properties of fluid which occurs when charge of salt is inserted; method consists of observing time required for such charge to pass through measured length of pipe, adding salt at intake end, or some other convenient place. Method was used by Miami Conservancy District.

FURNACES, HEAT-TREATING

Electrically Heated. Heat Treat to Remove Strains, Pat Dwyer. Foundry, vol. 51, no. 11, June, 1 1923, pp. 429–432, 5 figs. Large turbine frames and other castings of similar character are heat-treated in special electrically heated oven in which casting is raised to approximately 700 deg. Fahr.; describes foundries of General Electric Co. at Schenectady, N. Y.

GEARS

Automobile Non-Metallic. Study of Material and Methods Needed in Non-Metallic Gear Production, J. Edward Schipper. Automotive Industries, vol. 48, no. 20, May 17, 1923, pp. 1084–1086, 4 figs. Quiet gear-driven front end obtained; tests with typical product indicate blanks are more expensive than metallic type; fewer tear-downs and easier inspection offset extra cost.

HYDRAULIC TURBINES

Draft Tubes. Results of Tests on Five Types of Draft Tubes. Power, vol. 57, no. 22, May 29, 1923, pp. 859–862, 6 figs. Tests conducted for purpose of securing comparison of performance between older forms of elbow draft tubes, type of recently developed and new symmetrical types of draft tubes.

HYDROELECTRIC PLANTS

Automatic. Automatic Plants Aid Western Water-Power Development, E. R. Stauffacher and Gustaf Clinwald. Elec. World, vol. 81, no. 22, June 2, 1923, pp. 1257–1259, 3 figs. Nine semi-automatic generating plants, with total rating of 14,655 kw. now in operation on Southern California Edison system; operating costs reduced approximately 45 per cent.

INDUSTRIAL MANAGEMENT

Cost Control. Managerial Control Through Costs, J. P. Jordan. Management Eng., vol. 4, nos. 2, 3, 4, 5 and 6, Feb., Mar., Apr., May and June, 1923, pp. 81–86, 169–176, 235–240, 335–340 and 399–404, 10 figs. Feb.: Managerial control with direct personal knowledge, without either direct or indirect personal knowledge, and with indirect personal knowledge. Mar.: Cost control. Apr.: Use of general expense accounts. May: Use of departmental burden accounts. June: Keeping up cost reduction.

Greater Production. How Management Can Be Made More Productive, Acheson Smith. Am. Mach., vol. 58, no. 23, June 7, 1923, pp. 831–834. What "greater production" means and why it is necessary; influence on prosperity of scarcity of labor; specific lines of effort that management should follow.

LOCOMOTIVES

Oil-Burning. Mountain and Mikado Types for the 'Frisco. Ry. Age, vol. 74, no. 24, May 19, 1923, pp. 1207–1208, 2 figs. New oil-buring locomotives based on U. S. R. A. designs modified to suit railroads' standards.

OIL ENGINES

Hot-Bulb. The Penney-Porter Heavy Oil Engine. Engineering, vol. 115, no. 2995, May 25, 1923, pp. 652–653, 6 figs. Describes two-cycle engines of hot-bulb type for land and marine use.

Solid-Injection. A Solid-injection Crude Oil Engine. Engineer, vol. 135, no. 3516, May 18, 1923, pp. 523–524, 3 figs. New horizontal type of crude-oil engine, working on 4-stroke cycle, and made with single and twin cylinders in several sizes; feature of engine is facility with which it can be changed over for working with gas instead of oil as fuel.

OPEN HEARTH FURNACES

Reversing Valves. New Type of Open-Hearth Reversing Valve, John Nelson. Iron Age, vol. 111, no. 22, May 31, 1923, pp. 1560–1561 and 1610, 3 figs. Isley combination air and gas-reversing valve is self-contained and all above ground; permits regulation of gas and air supply; without internal moving parts.

PRODUCER GAS

Metallurgical Use. Making Efficient Producer Gas, Waldemar P. G. Dyrssen. Iron Trade Rev., vol. 72, no. 23, June 7, 1923, pp. 1677–1682, 2 figs. Practice as it concerns production of fuel for metallurgical use; theoretical and actual results are compared; modern types of producers designed to provide gas in constant volume and quality. (Abstract.) Paper presented at Am. Iron & Steel Inst.

STEAM-ELECTRIC PLANTS

Detroit Edison Co. New Marysville Plant, Detroit Edison Co., C. Harold Berry. Power, vol. 57, no. 22, May 29, 1923, pp. 824–830, 8 figs. Contains two turbo-generators, one of 10,000-kw. and other of 30,000-kw. capacity, served by four boilers, each having 28,212 sq. ft. of effective heating surface.

Hell Gate, New York. Operating Methods at Hell Gate. Power Plant Eng., vol. 27, no. 11, June 1, 1923, pp. 555–564, 12 figs. Large boiler units impose certain limitations on operating methods; heat-balance control under one operator; station records and test facilities are unusually complete; coal-handling system serves seceral stations; ash handling by sluices.

STEAM POWER PLANTS

Benson Super-Pressure. The Benson Super-Pressure Plant—Its Scientific Basis, P. W. Swain. Power, vol. 57, no. 22, May 29, 1923, pp. 842–846, 6 figs. Study of scientific principles underlying this and other systems for production and utilization of high-pressure, high-temperature steam; Mollier and temperature-entropy diagrams are used in investigating possibilities of various methods of operation.

STEEL MANUFACTURE

Waste-Heat Utilization. Reducing Waste in Steelmaking, H. T. Morris. Iron Age, vol. 111, no. 22, May 31, 1923, pp. 1600–1602. Utilizing heat waste in steel works is said to offer possibilities for improved efficiency; electrification an important factor in eliminating driving energy losses; standardization a valuable method of fighting waste. (Abstract.) Paper read before Am. Iron & Steel Inst.

Acceptance for mailing at special rate of postage provided for in section 1103, Act of October 3, 1917, authorized on January 17, 1921.

Robert Sibley

H. G. Acres

Myron A. Lee

Peter Payne Dean

F. L. Kallam

Contributors to This Issue

Robert Sibley was born at Round Mountain, Ala., in March, 1881. He was graduated from the University of California in 1903 with the degree of B.Sc., and during the next four years was professor of mechanical and electrical engineering and head of the School of Engineering at the University of Montana. In 1907 he opened an office in Missoula, Mont., as consulting engineer in hydroelectric investigations in the Northwest. He returned to California in 1911 as associate professor of mechanical engineering at his Alma Mater, becoming professor the following year and remaining in that capacity until 1915. He was given a doctorate degree in electrical engineering by that institution last year.

During the next year Dr. Sibley travelled in Japan, China, the Philippines and various industrial centers in eastern and southern parts of the United States. July, 1916, found him back in California once more, as editor of the *Journal of Electricity*, and in 1920 he was appointed president of the McGraw-Hill Company of California. He resigned these positions early this year to become executive manager of the University of California Alumni Association, but still serves the McGraw-Hill Co. as Pacific Coast Consultant.

Dr. Sibley is a vice-president of the A.S.M.E. and a fellow of the A.I.E.E. He is not averse to boosting California's climate on occasion, but his voice is heard more frequently on the subjects of fuel oil for steam-electric generation, and the hydroelectric developments of the Pacific Coast, on both of which he is an authority.

* * * * *

Charles E. Brooks, whose paper on the Recent Development of the Motor Coach is included in this issue, was born at Constantinople in July, 1886. He received his B.Sc. from McGill University in 1908, and soon afterward entered the employ of the Grand Trunk Pacific Railway. He served this railway in various capacities, finally as superintendent of motive power, having supervision over all work in connection with maintenance of locomotives, cars, and shops. When the Canadian lines were recently merged into the Canadian National Railways, Mr. Brooks was appointed chief of motive power of the new organization. The preparation of the paper in this issue at a time when he was assuming the manifold duties of a new position, as well as transferring his headquarters from Toronto to Montreal, is in itself no small achievement.

* * * * *

H. G. Acres writes on the subject of Modern Hydraulic Turbines of Large Capacity. Mr. Acres was born in Paris, Ontario, in 1880. He was graduated by the Faculty of Applied Science, University of Toronto, with the class of 1903. After a short term in the engine room of Canadian Pacific Railway liners between Montreal and Liverpool, he entered the employ of the Canadian Niagara Power Company.

In the Spring of 1905 Mr. Acres went to Arizona as assistant to the chief engineer of the Arizona Copper Company, working on railroad and mill construction. In the Fall of that year he returned to Canada as hydraulic engineer of the Hydro-Electric Power Commission of Ontario, which position he still holds.

Mr. Acres is a member of the Engineering Institute of Canada, the A.S.C.E., and the A.I.E.E. We cannot resist remarking that for a young man Mr. Acres has covered a good deal of ground.

* * * * *

Myron A. Lee was born in Auburn, N.Y., in March, 1887, and was educated in the public schools there and at Cornell University. After his graduation he took the engineering-apprentice course offered by the Western Electric Company and was then employed by that company as equipment engineer. He returned to Cornell, first teaching machine design and then industrial engineering. He took his M.M.E. degree during this time.

Professor Lee left Cornell to accept a position with the Thomas-More Aircraft Corporation, and was assistant superintendent in their plant during the war. He returned to college teaching after the armistice, and is now assistant professor and head of the Department of Industrial Engineering at Cornell.

* * * * *

Peter Payne Dean, who was responsible for the complete design and carrying out of the valve test conducted by the Public Service Electric Co. at their Essex station, Newark, N. J., was born in Staffordshire, England. He attended the Birmingham Technical School and the City and Guilds of London Institute. He served his apprenticeship with Vickers' Sons & Maxim, and then became assistant engineer with the Sturtevant Engineering Co., of London. In 1909 he came to the United States as sales engineer for the Diehl Manufacturing Co. of Elizabeth, N. J., and during his association with this company he completely developed an electrical dynamometer extensively used in the scientific testing of internal-combustion engines.

In 1914 Mr. Dean became associated with the Cutler-Hammer Manufacturing Co., which took over his patents on valve control. Since then he has devoted his time to the design and manufacture of valve-control systems and remote-control devices for central-station use.

* * * * *

F. L. Kallam, who has been awarded an A.S.M.E. prize for his paper on the Thermal Conductivity of Liquids, received his A.B. from Leland Stanford Jr. University in 1921, and his M.E. in 1922. He has been connected with several iron and fuel companies in California since graduation, and is now engaged in the natural-gas-gasoline industry with the Shell Company of California, as gas engineer.

Making America Independent in the Air

Fundamental research in the problems of flight must be the basis for adequate development of air service, either commercial or military. The National Advisory Committee for Aeronautics is in charge of an extremely valuable research program which will be treated in the leading article in the September issue of MECHANICAL ENGINEERING. Many interesting problems and their successful solutions will be described.

The Electrical and Industrial West

A Commercial and Industrial Empire Looks to the Engineer for Its Upbuilding by the Utilization of Its Vast Waterpower Resources

By ROBERT SIBLEY,[1] BERKELEY, CAL.

THE PURPOSE of this article is to give to the reader a conception of some of the unusual engineering feats that are being accomplished west of the Rocky Mountains and to point out some of the reasons why they have been attempted—and in a word to call to the attention of fellow-engineers the vision of the future that prevails among our engineering brothers in that great section of America lining the Pacific.

Due to the scarcity of coal and the necessity for irrigation combined with proper control of flood water and its economic application, the West stands preëminent in irrigation, in flood control, and in hydroelectric development as regards other sections of the world. Hence the engineer here is largely concerned with the var ous ramifications of water and the utilization of hydroelectric power down through the industries. Nature seems to have foreseen in its bounteous provision for our citizens west of the Rockies the crying need for the service of water. In the eleven states west of the Rockies, constituting but 8 per cent of the population, we find 70 per cent of the great undeveloped water powers of the nation. Already great strides have been made in the utilization of this great natural resource. West of the Rockies the average use of electrical power per capita is twice the per capita consumption of the nation as a whole, while in hydroelectric energy the citizen west of the Rockies uses six times the hydroelectric energy consumed by the average citizen of the nation, and in hydroelectric power still undeveloped he has a per capita possibility of twenty-two times that of the average citizen of the nation, even though the East has its great Niagara, Muscle Shoals, and other large power resources.

The general conception of hydroelectric power as it has been developed to date in the West is depicted graphically in Fig. 1. There are no great Niagaras in this empire west of the Rockies, hence the engineer has found it necessary to create artificial waterfalls. His general method is to go up into the mountain gorges, build a dam to store the water, convey this water through a ditch or tunnel, often ten to fifteen miles around the mountain side, at a gradient less than that prevailing in the main run of the stream, and thus create an artificial waterfall of 1000, 1500, and often even greater than 2000 ft. vertical drop. Through giant pipes these waters are dropped against water wheels often of record proportions, thereby developing electrical power which in turn is transmitted to the farm, to the mine, to the home, and to the various industries in the great cities of the West.

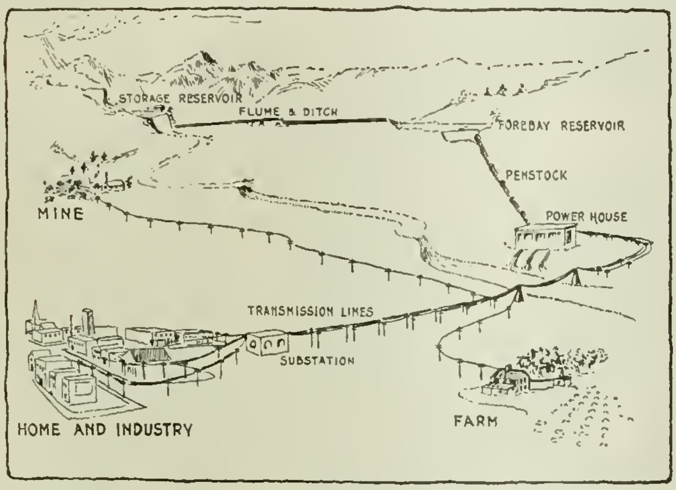

Fig. 1 Sketch Illustrating a Typical Modern Hydroelectric Power System on the Pacific Coast

Let us by pictures follow through some of these record-breaking installations. Fig. 2 is a view of Mt. Shasta in Northern California, the head of a vast drainage area for future power development. Fig. 3 shows some of the many volcanic springs existing to the east of this great drainage area which make possible a constant source of water for power development. The Pacific Gas and Electric Company has undertaken the development of some 600,000 hp. in this region, known as the Pit River development. This company, the largest of its type in the world, ties in with five other great power companies of California, in an interconnected network of approximately a million and a half horsepower, over an area greater than that of New York State, Pennsylvania, and all the New England states combined. Last year the total generated energy of this network was in excess of 4,300,000,000 kw-hr. Assuming the daily work of a human being as the equivalent of one kilowatt-hour, this means that the harnessing of California's mountain streams made possible last year the delivery of energy equivalent to a day's work of four billion, three hundred million people or two and a half times the entire population of the world today.

The view on the cover of the present issue shows the exterior of Pit River Power Plant No. 1. To the left will be seen the power lines which transmit hydroelectric energy at the record-breakage tension of 220,000 volts. This line is 202 miles in length and journeys southward to San Francisco and the industrial centers of central California.

Fig. 4 shows the interior of this power plant constituting the largest 60-cycle generator yet put into commission. The total output of each generator is 46,000 hp.

Fig. 5 is a close-up view of the 220,000-volt transmission line. In the building of this line the copper required for the conductors amounted to 10,000,000 lb., the largest amount ever placed in a single order in an engineering development of this nature.

Many interesting world records have been established in the construction of such great transmission lines as this. One of them is the well-known span at Carquinez Straits near San Francisco, where we find a single span of wire over 4600 ft. in length. Another is the submarine transmission of power from Berkeley, Cal., into San Francisco, through a cable beneath San Francisco Bay, a distance of 7 miles, at 11,000 volts.

In the southern portion of California the Southern California Edison Company is likewise breaking many world records in engineering achievement. The Big Creek Development which is being financed and engineered by this company, has as its goal the ultimate development of 1,400,000 hp. on the various tributaries of the San Joaquin river; particularly, however, on the tributary known as Big Creek. This company has the distinction of having in its interconnected system the successor to the old San Antonio

power plant, built in 1892, which in its day held the world record for hydroelectric transmission and was the first to transmit power commercially at a higher voltage than that at which it was generated. The length of the transmission line was 20 miles and the voltage of transmission 10,000. Today the giant lines of this same company are transmitting power from this Big Creek Development on the San Joaquin river into Los Angeles, a distance of 240 miles, at a voltage of 220,000.

Records of other California companies are also interesting. It must be remembered that California is a state of such proportions that if the northern boundary could be placed at the Woolworth Building in New York City the southern boundary would be somewhere near Jacksonville, Florida. The Southern Sierras Power Company, flanking the eastern slope of the Sierras in California, which delivers its energy to the deserts to the south in and about the Mexican border line, transmits its power at 87,000 and 55,000 volts over the record distance of 539 miles.

Fig. 13 Beautiful Hetch Hetchy Valley, the Source of San Francisco's Future Water Supply

In the matter of sizes of turbine units, interesting records have been established. The two 30,000-hp., 1008-ft. head units in the Caribou plant of the Great Western Power Company in Northern California comprise the largest high-head impulse turbines thus far put into commission.

Fig. 6 shows an exterior view of Big Creek Power House No. 1, of 64,300 hp. installed capacity, which uses water under a total head of 2130 ft. and is the highest-head hydroelectric plant in America. It will be interesting and instructive to follow in some detail the difficult and unusual processes necessary in the engineering construction and installation of this great record-breaking accomplishment.

Fig. 7 shows the difficult road construction necessary in the San Joaquin River canyon between power houses Nos. 8 and 3 of the Big Creek project. Miles upon miles of such construction are often necessary before installation work proper can be undertaken in western hydroelectric power development.

Fig. 8 shows half of the stator for one of the generators in Big Creek Power House No. 3. This stator is for a generator of 25,000 kw. capacity and is shown in the process of being lowered on an incline down to the power house.

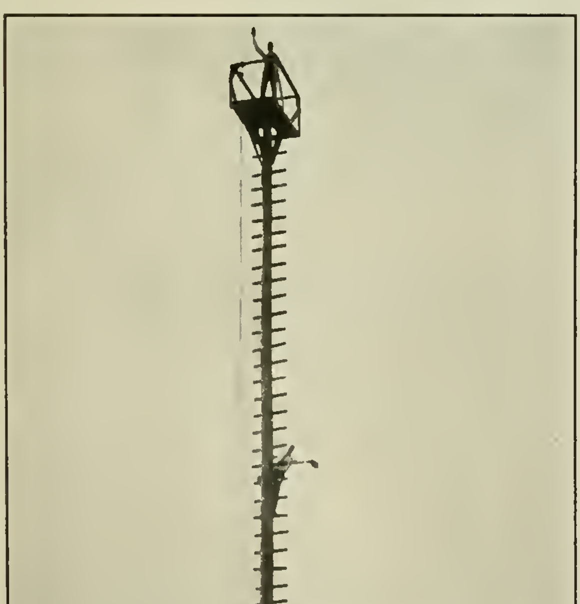

Fig. 12 Temporary Lookout from Which Engineers Take Photographs Daily Showing Progress of Work

Fig. 9 shows the interesting background of Big Creek Power House No. 8, in which may be seen the surge chamber and penstock of this great development.

Fig. 10 gives a view of the third 16,000-kw. hydraulic unit now being installed at Big Creek Power House No. 1. It shows the generator in the middle with the two overhung tangential water wheels plainly in view.

Fig. 11 shows the record-breaking banks of auto transformers at the Big Creek Power House No. 1, used to step up the voltage from 150,000 to 220,000 volts. Each bank is rated at 52,500 kva.

Fig. 12 indicates how the western engineer constructs a temporary lookout near installations of this character, in order that day by day photographs may be taken and a proper history of each day's constructive efforts may be recorded.

Often the mountain scenery encountered in this work is of an exquisite nature. Fig. 13 shows the famous Hetch Hetchy valley, where the city of San Francisco has been expending many millions of dollars in building a great dam near the tree shown in the foreground on the right of the picture. Today this great dam, together with the tunnels and the Moccasin Creek power house of 80,000 hp. capacity in the river 50 miles below, is nearing completion.

After a careful survey of developments now under way, the total program of hydroelectric development in the West as it has progressed from 1910 to date and may be expected to progress to 1930, may be summed up as follows:

	Horsepower Capacity		
Year	Hydroelectric	Steam	Total
1910	800,000	277,300	1,077,300
1911	886,910	324,690	1,211,600
1912	943,010	412,220	1,355,230
1913	1,051,540	467,251	1,518,791
1914	1,175,800	512,870	1,688,670
1915	1,332,430	542,580	1,875,010
1916	1,433,050	545,200	1,978,250
1917	1,566,390	554,680	2,121,070
1918	1,673,350	558,800	2,232,150
1919	1,701,546	619,344	2,320,890
1920	1,826,164	671,586	2,497,750
1921	2,116,500	742,350	2,858,850
1922	2,366,650	823,740	3,190,390
1923	2,728,670	861,330	3,590,000
1924	2,957,900	911,590	3,869,490
1925	3,210,040	943,760	4,153,800
1926	3,352,530	970,570	4,323,100
1927	3,630,280	973,260	4,603,540
1928	3,978,000	978,620	4,956,620
1929	4,177,740	978,620	5,156,360
1930	4,370,770	981,305	5,352,075

To indicate how undisturbed is the forward movement of hydroelectric development in the West, Fig. 14 is shown. By examination of this chart it will be seen that the upper portion of the black line, indicating the total power consumption in the State of California, has been at an even upward trend for many years past in spite of earthquake, pestilence, world war and financial depression. Hence we can predict with a considerable degree of accuracy the future of hydroelectric development in the years immediately ahead.

Two factors control this growth. Fig. 15 shows California's growth in mining, farm products and manufactures, according to figures from the United States census over a period of 40 years past. From this chart it is seen that farm products have long since outstripped mining. On the other hand, few have thought of California as an industrial state. It was as a consequence with much interest and surprise that its citizens heard recently of the

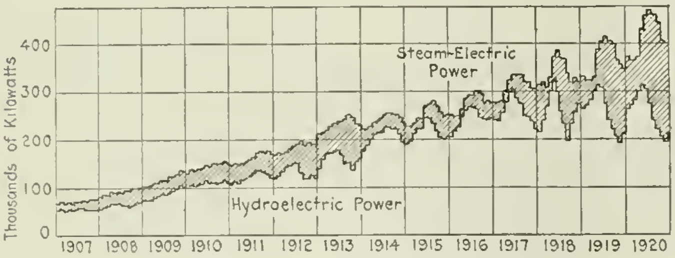

Fig. 14 Chart Showing the Steady Growth in Demand for Electric Power in California Since 1907

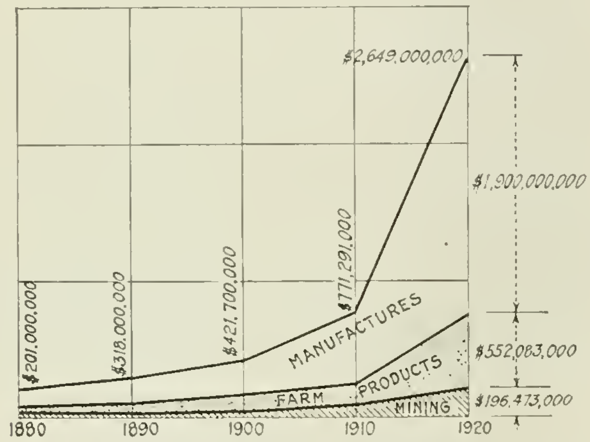

Fig. 15 Chart Showing Growth from 1880 to 1920 of Basic Industries Using Electricity in California

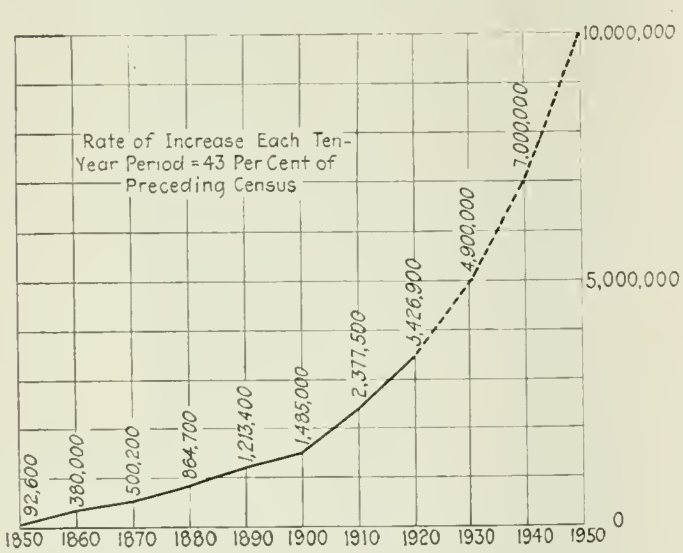

Fig. 16 Chart Showing Increase in Population of California Since 1850, and Predicted Increase for the Next 30 years

announcement by the Census Bureau at Washington that California had taken its place as eighth among the great manufacturing states of the Union, and was the fifth in rank as regarded the number of industrial establishments. In 1920 the value of California's industrial products amounted to one billion, nine hundred million dollars, and today their value is far in excess of this figure.

The other factor that controls California's growth is the matter of population. Fig. 16 shows her increase in population during the past 70 years together with predictions for the next 30 years. According to the census of 1920, California far outstripped any other state in the Union in this regard, her growth in population being 44.1 per cent. There is every reason to believe that, due to the present unexampled growth in the southern portion of the state, California is at present growing at an even more rapid rate; but assuming that her growth continues for the next 27 years as was maintained from 1910 to 1920, California will have a population in the generation immediately ahead of over 10,000,000 people; in other words, she will have a population by 1950 as great as we find today in New York, Pennsylvania, Ohio and Illinois.

A vision of the future takes us to the Pacific Ocean and the countries whose shores it washes, where now live over one-half of all the people of the world. With the vision of daring, enthusiasm, and constructive leadership in the developing of her great natural resources, the West has a destiny of service beyond comprehension, and with her vast waterpower resources she looks to the engineer for the upbuilding of a commercial and industrial empire such as the world has never before witnessed.

Small Electric Plants and Large Systems

The engineering reasons for the advantages of the grouping of many small plants into larger groups are generally known, but may be repeated. There are also similar large advantages to be gained from combining a number of small groups of plants to form a large *system* favorable to economic power supply, financing and management.

To use an illustrative analogy, quoting from the Economic Values of Electric Transmission by F. G. Baum, the large electric system may be compared to a bank in its economic function, and the electric medium of transmission may be compared to money, the medium of property exchange. If we had no money we would have to trade by direct exchange of property, and if we had money but no banks in which to deposit our funds from which those of us who need it might draw, the difficulties of doing business may be imagined. Without a central power-distributing system each consumer must develop his own power and have some surplus power. Hence, there is no medium of exchange, no means of "banking" the total power of all on the transmission system, and no drawing at such points and in such amounts as may be needed from time to time. Electric transmission provides the elastic medium for exchanging any one form of mechanical power to any other form of mechanical power at some point on the system.

Now if one hundred isolated power plants are connected together by a transmission system, and their power-producing possibilities thus concentrated on the system, we will then be able to supply the demands of the one hundred original consumers and have a fair-sized surplus always on hand. That is, by "banking" the individual energies through the medium of the transmission system, we can get all the convenience of the power facilities, and the system will be able to meet the demands of all its patrons—*and carry a surplus.* This is because we have concentrated the surplus of the several plants and because the individual needs do not all come at the same time. This surplus power is principally due to the fact that the diversity of interests now supplied from the one system is such that the system as a whole has a more uniform load, a better "load factor," than the individual plants when operating separately. In general, the more varied the interests which draw power from the lines the more uniform will be the demand, and the better for the transmission system.

Having now connected the hundred small plants by an electric-transmission system with a large power demand, we find we can no longer afford to operate the one hundred small plants, but instead, we install a few large power units to supply the entire system, and by this means produce a large saving in operating expense. The economies resulting from large power systems with large central stations in is in this way working a revolution in America, especially in California, and also in other countries. That this revolution is progressing from economic reasons which are fundamentally sound is certain, and therefore larger and larger electric power systems may be expected. (From Atlas of U. S. A. Electrical Power Industry by Frank G. Baum.)

Recent Developments of the Motor Coach

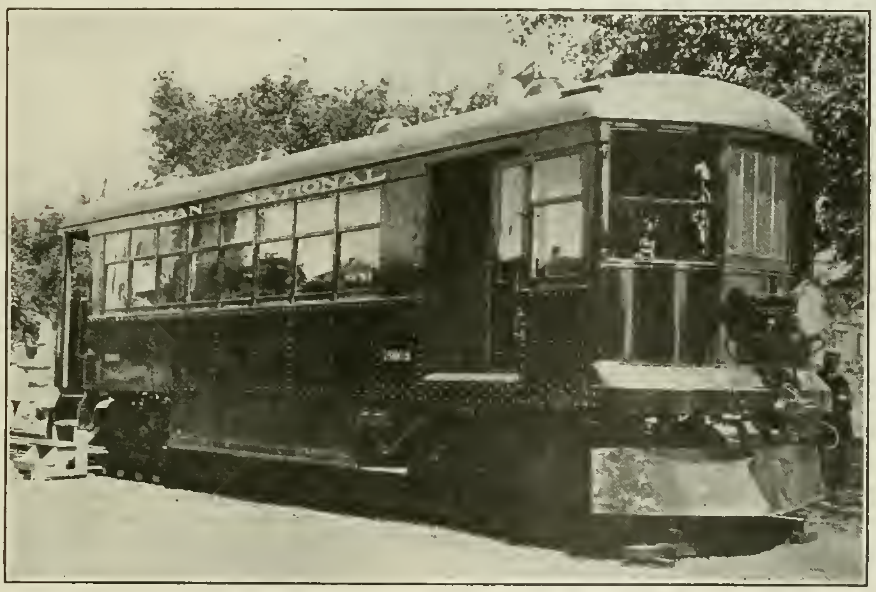
The Renewed Interest Taken in This Type of Equipment and the Reasons Why Railway Officials Have Been Forced to Turn to It—Advantages and Disadvantages of the Various Types of Gasoline-Engine, Storage-Battery, Steam and Gas-Electric Cars—Performance Data

By C. E. Brooks,[1] Toronto, Ont.

THE motor coach is not a new departure in railway work but is instead a branch which on most railways has sunk back from a promising start 15 years ago into obscurity due essentially to high maintenance and operating costs and to the general idea that the motor car was a toy only. During the past three years, however, interest in the subject has been actively revived as a result of

- *a* The ever-increasing encroachment of the motor bus on railway earnings
- *b* The improvement in the design of the motor and its appurtances, and
- *c* The attitude of the public, which the automobile is rapidly convincing that plush seats are not necessary when traveling short distances.

In order to enter into a discussion of present-day developments it will be necessary to outline briefly the service requirements, and in doing so the author must be pardoned if he presents the motor coach as a "unit car" and not as a train of cars or a driving car hauling a trailer. The latter methods of operation may be possible on small interurban or suburban lines, but for practical transportation purposes they are not being considered by many large railways. The reason for this is that up to the present time it has not generally been found to be economical to replace a necessary train service with a motor coach hauling one or more trailers on account of motor-capacity limitations.



Car Fitted with Edison Storage Batteries

On the other hand, high train-mile costs for small returns have forced railway officials to turn to the motor coach for relief in the following classes of service:

- *a* Giving a frequent passenger service on sparsely settled branch lines or parts of main line adjacent to market towns or junction points
- *b* Connecting junction points on important main lines with the town or small city situated within a few miles of the main line
- *c* Giving a group of towns situated on a main line or important branch lines a frequent connecting service over and above through main-line trains
- *d* Connecting small summer resorts, golf clubs, etc., to branch-line or through main-line service
- *e* Handling milk of a limited amount to a distributing or connecting point
- *f* Providing connections to small suburbs.

Among the first real developments of the motor coach was the gas-electric car, the use of which spread rapidly fifteen years ago but which unfortunately did not solve these problems successfully on account of the high maintenance cost of the heavy-duty gasoline motor driving the generator, the very uncertain service, the complications of the equipment, and the great weight of the motor coach itself. Indications are that the gas-electric system with a modern gasoline-engine generating plant is making another bid for this class of work, and a brief description of such a unit is given further on in the paper.

About the same time steam units having very considerable weight and all the complications of the locomotive appeared, but were discarded for much the same reasons as the gas-electric car.

Classification of Present-Day Developments

Present-day developments are generally to provide for traffic requirements, which for the purpose of discussion are subdivided as follows:

Class A—A seating capacity of from 24 to 40 persons and provision for approximately 100 sq. ft. of baggage space. The light weight of such a car to be from 18,000 to 30,000 lb. maximum, or in other words, not to exceed 750 lb. per single seat (with baggage space) or 500 lb. per seat if no baggage space is allowed. In some classes of service the baggage space is given up and seating accommodation substituted.

Smaller cars have been made and are in daily use, but considering the rapid development of traffic after cars are put into service, it is believed that the above-mentioned limits are reasonable.

Class B—Units seating from 40 to 60 passengers and providing for baggage space a minimum of 100 sq. ft. and maximum of 200 sq. ft. As constructed these cars weigh from 800 to 1200 lb. per single seat, but it is thought that the weight must be kept down to the same limits as those prescribed for Class A in order to get fuel economy and keep maintenance costs at a reasonable figure.

Speed Requirements. Schedule speeds of 15 to 25 miles per hour, including stops. Consider a 5-mile run between stops and 1 min. for stops: Acceleration from 0 to 30 m.p.h. in 2 min. on level track, 30 to 35 m.p.h. at end of third minute, an average speed of 35 m.p.h. for the next $3^3/_4$ miles and 0.5 min. to travel 0.21 mile and come to a stop, means that in order to run 5 miles and make one stop the elapsed time is 10.9 min., or an average schedule speed including stops of $27^1/_2$ m.p.h. This allows nothing for loss of time on gradients, slow orders, etc.

Generally speaking, Class A units have been gasoline-driven, and the experience of many railways goes to show that this class of equipment is an economical and lasting development which will be improved to the point of high-grade automobile reliability within a very short time. Already in many places these cars have retrieved business which had been lost to bus lines on the highways and also to the privately owned car, and it has been the usual thing to find that passenger traffic develops to a marked extent after a service has been instituted.

---

[1] Chief of Motive Power, Canadian National Railways. Assoc-Mem. A.S.M.E.

Presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Slightly abridged. All papers are subject to revision.

The failures have been rather heavy due to conditions described later in this paper, to the overexacting requirements of time tables, and to non-realization of the limitations of the gasoline motor.

For the purpose of description Class B units may generally be subdivided into (*a*) storage-battery, (*b*) steam, (*c*) heavy-duty gasoline-engine, and (*d*) gas-electric cars.

Class A Cars

The Gasoline-Engine-Driven Motor Coach. For Class A cars weighing approximately 30,000 lb. light weight, the general practice has been to use a high-grade 4-cylinder truck engine running at a maximum speed of approximately 1600 r.p.m. and developing a maximum of 70 hp. Wherever this type of engine has been used it has transmitted its power through clutches, transmissions, and universals to gears, most of which are of standard truck or even heavier design.

Service Car

A general description of a typical power plant such as mentioned above is as follows:

Engine, 4-cylinder, $4^3/_4$ in. by 6 in.
Pressure oiling system
Pump water-cooling system
Primary and secondary transmission
Primary ratio: first speed, 4 to 1; second speed, 1 to 1.
The secondary increases the ratio from 26 m.p.h. for normal engine speed to 35 m.p.h. The first provides for ruling-grade and the second for level-track conditions.

To a much less extent the automobile-type six-cylinder engine of the following general description has been experimented with:

Engine, 6-cylinder, $3^3/_{16}$ in. by 5 in.
Pressure oiling system
Gear ratio, 4.7 to 1 between engine and wheel
Nominal engine speed at 30 m.p.h., 1450 r.p.m.
Horsepower developed, 50 at 2200 r.p.m.
Maximum speed, 2200 r.p.m.
Pump water-cooling system.

In general its power has been transferred through standard automobile clutches, transmissions, etc., which are used with the same type of engine in automobile service.

So far as the actual power plant is concerned, it is the opinion of many that the automobile engine has in almost every way demonstrated its superiority over the truck engine for Class A cars and for general service because of its ability to run over rated speed without serious loss of balance and consequent excessive vibration, and its economy under light load conditions. The first of these reasons undoubtedly embraces conditions which are vital to the successful maintenance of any machine or engine, and it is the author's intention to attempt to explain this from the every-day point of view arrived at through experience rather than from the dynamics of the problem.

Practically any high-grade automobile engine designed for a rated engine speed of approximately 1450 r.p.m. at 30 m.p.h. with a gear ratio between 4 to 1 and 5 to 1 may be driven at engine speeds of 2200 r.p.m. and car speeds of from 50 to 60 m.p.h. without any noticeable vibration of a serious nature. Experience indicates that a similar flexibility cannot be expected from truck engines for any length of time without serious engine trouble developing and possibly resulting in a complete breakdown of the service.

When a motor coach is being operated on a railway where there are schedule connections to make and where there are meeting points designated by train orders and by the time card, it is certain that, regardless of the framing of a schedule, which should not develop an engine speed over that coinciding with the rated speed of 35 m.p.h., the operator will frequently exceed this by 15 or 20 m.p.h. in order to meet the requirements of the service after a delay of any kind. There is nothing parallel to this in highway work with either the automobile or the truck, but it is such an accepted fact on a railway that the only safe course is to provide the type of power plant which will meet these requirements daily without breaking down; in other words, the power plant must be moved out of the sphere of ordinary usage and into what might be called the outer edge of racing conditions. Railway gradients even accentuate this condition, as there is practically no opportunity for letting the engine cool off as there is on the highway.

The automobile engine has been designed not only for easy and economical low-engine-speed conditions, but also for those outlined in the preceding paragraph, and the experience of several railways in this country with a number of cars operating under extremely different conditions seems to bear this out, which leads to the conclusion that the light-weight, high-speed gasoline engine is a satisfactory power plant for the light-weight cars described as Class A.

Class B Cars

The Storage-Battery Car. The general data of a typical unit are as follows:

Car. Interior arrangement, to suit purchaser; weight, 60,000 lb.; length, 53 ft.

Trucks. Two 4-wheel standard M.C.B. axles, except that journals are fitted with roller or ball bearings.

Electric Motors, Etc. Four 25-hp. motors (250–300-volt) mounted with a gear ratio of 16 to 91. Standard series and parallel controller and circuit breaker installed at each end and in baggage compartment; provided with voltmeter, ampere-hour meter, underload circuit breaker and switches for control of air compressor and lighting.

Storage Batteries. 250 cells, capacity 450 amp-hr. at 300 volts, or 135 kw-hr. (580 amp-hr. have been obtained with a minimum of 150 volts).

Battery Charging. Direct current at 250 or 500 volts may be used for charging, and the car is equipped with switches for arranging the battery cells in either series or parallel. Normal rate of charging, 90 amp. Time required for a normal full charge, 5 to 7 hr. A higher rate of charging may be employed provided temperature of battery does not exceed 115 deg. fahr.

Radius of Operation. Maximum 140 miles on a full charge, figuring on level or rolling grade. Recommended not to exceed 100 miles without obtaining a boosting charge.

Power Consumption. Power required, 35 watt-hr. per ton-mile. Acceleration, $^1/_2$ m.p.h. per sec. Maximum speed, 45 m.p.h. on level track. As the car weighs approximately 60,000 lb., 35 watt-hr. per ton-mile is equivalent to 1.05 kw-hr. per car-mile for level track and normal conditions.

Within the above-mentioned radius of operation this car has been extremely satisfactory and is being operated successfully under low-temperature conditions with no appreciable trouble. Its tractive effort of 2400 lb. makes it possible to use a trailer if necessary. The cost of operation, including all maintenance and transportation charges, power, etc., is 17 cents per car-mile. The maintenance has been extremely light, and all indications are that the life of the batteries will be eight to ten years at least.

Steam Cars. The steam power plant was probably the first of any kind to be tried for self-propelled cars, but unfortunately its development has not kept pace with requirements. Medium-pressure (300 to 400 lb.) boiler plants with comparatively low superheat (100 deg. fahr.) were introduced to a considerable extent in continental practice several years ago, but the use of the steam car has not developed, due principally to the excessive weight and general complications of the equipment, and the inefficiency of the boiler plant.

Recent developments indicate that while the seriousness of these defects has been noted and improvements have been made, they have not yet been overcome to the point where steam power may

be considered to be the most satisfactory unit car power, and it may be well to consider these defects more in detail as they appear to exist in modern equipment.

Insufficient boiler capacity is a defect directly coupled with excessive weight of equipment. Boiler plants of approximately 70 boiler hp. nominal rating have been applied to cars with a total net weight in running order of from 50,000 to 60,000 lb. and providing for 100 sq. ft. of baggage space. The total live load will bring this equipment up to a gross weight of approximately 65,000 lb. or a load of 650 lb. per boiler hp.

Experience indicates that for a boiler of this capacity the weight should be reduced by approximately 15,000 lb., and the author has no hesitation in saying that this should be possible as the entire power plant may be carried on the leading (driving) truck and the remainder of the body lightened proportionately. Total absence of vibration should be a very great advantage in lightening the car equipment.

Practically all the first cars of continental make indicated that high pressure and high superheat were necessary in order to provide for a gear ratio sufficient for starting and at the same time for a piston speed of 800 ft. per min. at 40 m.p.h. The engine developed to meet these conditions has no doubt been a great mechanical success, but the boiler plant supplying it has not yet been developed to the point where it can exceed the schedule previously outlined, even under the most favorable conditions. The causes of this deficiency appear to be due to

a Insufficient header volume, resulting in carrying over an emulsion into the superheater units, with a consequent total loss of superheat and excessive water consumption, and

b Unequal distribution of heat to all generating units, resulting in steam pockets and thereby destroying both circulation and evaporative qualities.

The problem of providing sufficient surface-condenser capacity for hot-weather conditions coupled with protective appliances which will be operated by thermostat in cold weather has not been solved, with the result that under maximum conditions the water loss is as high as 45 lb. per car-mile, necessitating replenishing at frequent intervals and a consequent loss of time.

Automatic control of the oil flame has been highly developed but is not yet perfected. Generally speaking, this automatic feature must have two distinct functions: namely, (*a*) cutting off or reducing the fuel supply when maximum boiler pressure is reached, and (*b*) cutting off fuel under low-water conditions. The first-named is undoubtedly perfectly developed but the second is not, due to the varying quality of the steam coincident with the condition (maximum load) which most often causes low water.

The least considered of all conditions in connection with the steam car are probably those affecting the comfort of the operator, and in this respect it is unpopular on account of the extreme heat which may be experienced and also the noise of the oil flame. The latter is by far the most serious, and it is apparently impossible to control it when using high-velocity jets of steam for atomizing.

Space does not permit a further study of the steam plant, but the following general data of a steam car now being tested may be of interest.

Space required for boiler plant, sq. ft.	640
Heating surface of boiler, sq. ft.	385
Heating surface of superheater, sq. ft.	44
Gross weight of car, lb.	60,000
Net weight of complete power plant without oil and water, lb.	13,000
Quantity of water supply, U. S. gal.	200
Quantity of oil supply, U. S. gal.	180
Gallons of oil per car-mile, average	1
Boiler pressure, lb. per sq. in.	800
Superheat, average, deg. fahr.	200
Engine dimensions	6½ in. bore by 8 in. stroke
Gear ratio between crankshaft and axle	1 to 1.46

The Heavy-Duty Gas Car. The general data of a car of this type are as follows:

Car. Length, 55 ft.; weight, 66,000 lb. loaded.

Engine. 6-cylinder, 6¾ in. stroke. Power, 116 hp. at 800 r.p.m. and 225 hp. at 1600 r.p.m.

Transmission. Four speeds forward, three reverse; geared to give 56 m.p.h. forward at 1400 r.p.m. in high and 37 m.p.h. in third speed.

This class of car has not been tested to the point where any accurate data may be given, but it is evident that the gasoline consumption will be at least twice that of a Class A car per car-mile. The problem of handling through transmission and clutch the mechanical drive from a heavy-duty gasoline engine of possibly 200 hp. has not yet been solved unless it may be through the medium of the oil transmission so successfully used in navy work. However, the extreme complication of this transmission or magnetic control makes it doubtful at the present time whether gasoline power plants will successfully exceed 70 hp. in capacity.

The Gas-Electric Car. Mention has already been made of the car of this type which came into prominence about fifteen years ago and which was practically discarded on account of its unreliable power plant and general complication of equipment.

Car Equipped with Six-Cylinder Automobile Engine

The first-mentioned cause of failure has undoubtedly been overcome and reliable constant-speed units are now in general use for generating purposes. If it were possible to eliminate the starting troubles when using types of engines suited for low-grade and cheap fuels, there would be no doubt about the general use of this type of equipment on account of unit power costs. The difficulties mentioned are such an important factor in the successful operation of a motor coach in certain localities that we must necessarily turn to the gasoline engine for generating power.

The gas-electric system provides double-ended control and an efficient starting torque but still retains all the complications of a dual power plant.

The general data of a modern gas-electric car may be stated as follows:

Car. Length, 55 ft.; width, 10 ft.; seating capacity, 54 with 100 sq. ft. of baggage space; weight loaded, 65,000 lb.

Engine. 6-cylinder, governor-controlled, 7 in. bore by 8 in. stroke; develops 150 b.hp. at 900 r.p.m. and drives a 100-kw. 700-volt generator which in turn drives two motors on forward truck. Fuel consumption (estimated), 0.25 gal. per mile.

It is thought that there may be a possibility of employing a smaller-capacity constant-speed gasoline engine (average running power consumption approximating 25 hp. for cars weighing 60,000 lb. loaded) which will drive a generator charging a limited battery capacity. Theoretically this might provide the starting torque desired and at the same time eliminate the undesirable features of the large power plant, but it could not be an economic consideration where cheap power could be purchased.

Ball and Roller Bearings have been one of the most important factors in the development of the motor coach. Exhaustive tests indicate that the ball bearing has reduced starting friction under summer conditions to approximately 15 per cent of that of plain bearings, or in other words has reduced friction of approximately 20 lb. per ton to 3 lb. per ton. At the same time the average rolling friction at speeds up to 30 miles per hour has been reduced by approximately 40 per cent, or from 3.6 lb. per ton to 2.2 lb. per ton.

Experience in this country indicates that the ball bearing is

suitable for Class A cars, but that the areas and sizes for designed industrial work should be at least doubled for railway work due to excessive shocks and side thrusts. It is not possible at the present time to say whether side thrusts are more destructive than vertical rail shocks, but it is certain that for poor rail conditions the bearings should have a side-thrust capacity of 100 per cent of the vertical load.

For Class B equipment it may be necessary to use roller bearings for vertical loads in connection with special bearings for side thrusts.

Transmission and Type of Drive for Gas-Driven Cars

While it has been stated earlier in this paper that the automobile engine is most suitable for the light motor coach, it must nevertheless be admitted that experience indicates that standard automobile transmissions, clutches, universal connections and driving gears are entirely inadequate for motor-coach service and are the cause of probably 75 per cent of the breakdowns. Similar parts which have been developed for truck engines are generally much superior due to their greater size and strength per horsepower transmitted.

The argument has been advanced that the parts are designed for the engine and will handle all the power developed by it; but this contention is not sound, because the greater inertia to be overcome at starting requires a momentary torque much in excess of anything experienced in automobile work.

Account must also be taken of the fact that in this country and the northern part of the United States cars have to be operated in snow storms, resulting in clutch slippage and shocks to transmission which are much in excess of those experienced in automobile service.

The method employed in transmitting the power to the wheels has generally been one of the following:

1 Through a standard transmission to one driving axle which supports the entire two-wheel rear truck and which can move in a vertical plane only. While this is the simplest method of driving, it is not the opinion that it will ever be generally acceptable to the railways as railway experience indicates that safety and good riding qualities are almost proportionate to the number of wheels in the trucks. This is particularly applicable to cars operating on cheaply maintained lines.

2 To both axles of the front four-wheel truck by gearing and universal connections from a transmission located behind the truck. Experience on some railways goes to show that this method is very successful, and although the number of universal connections is not reduced the shafts are all short and the driving forces are entirely removed from the passenger-carrying part of the cars, thereby reducing vibration.

3 To a transmission located at about the center of the car and from there to nearest axle of each four-wheel truck or to both axles of two-wheel trucks. The advantage claimed for this method is that the entire weight of the car is available to give good adhesion (where the trucks are of the two-wheel type), but general experience indicates that this is not necessary and is harder on the engine than an arrangement where part of the momentum of rotating parts may be taken up by slippage. Where four-wheel trucks are used this method has been found to give better adhesive qualities than connecting to both axles of one truck, but the advantage seemingly is not sufficient to warrant the extra complication of transmission.

4 To the leading axle of rear four-wheel truck. The chief advantage of the drive to the rear truck is that the engine may be aligned in such a manner as to have its shaft center line pass through the center line of the main driving axle, thus reducing wear on the universals and friction to a minimum. The disadvantage is that it necessitates the use of one or more supplementary bearings between the engine and the point where the drive shaft is coupled to the front universal. The maximum lateral motion of a truck of 48-in. wheel centers and 18-in. truck centers on an 80-ft. radius curve is shown by road check to average $^3/_4$ in. at a radius from the center of 24 in., so that it is apparent that the swing of the truck has but little effect on the universals. The torque arms supporting the housings of such an arrangement should have both vertical and lateral swing. Only when the load on the main axle is not sufficient for adhesion it may be conceived that driving power acts on the second axle. Under ordinary conditions transmitting power to the second axle generates no more friction than that due to the weight of rotating parts.

Methods of transmitting power from the front axle to the rear axle of rear truck may be subdivided as follows:

a Chain Drive. Chain drive has the disadvantage of rapid wear, noise, and the complication of shields and covers which more than overcome the advantage of the straight drive to the rear truck.

b Gear Drive. Gear drive to the second axle no doubt appears to be the best mechanical means of transmitting power, but it has all the disadvantages of rapid wear due to difficulty of adjustment of contact and the maintenance of extra universals.

c Side Rod and Cranked Wheels. Side-rod drive to the second axle, along with many other locomotive developments said to be crude and inefficient, in actual practice is a thoroughly reliable and easily adjusted and inspected arrangement, and is operating successfully at high and low speeds and with no appreciable friction.

d Miscellaneous, including oil transmissions that are still being experimented with.

Summary

The author realizes that no doubt a very great difference of opinion exists among railway men regarding what type of motor coach will fulfil the requirements of the service best. It is apparent to any engineer that there will be important developments in railway motor cars, both as regards design and field of service, and therefore the following conclusions may be considered as preliminary only.

Class A Cars (30,000 lb. max. light weight), driven by automobile-type, 6-cylinder gasoline engines, should have the following general characteristics and limiting conditions: 1.6 hp. per 1000 lb. light weight of car at engine speed of 2100 r.p.m., giving a car speed of 35 to 40 m.p.h. Rolling friction, 2.2 lb. per ton of weight on rail, and wind resistance of 5 lb. per sq. ft. cross-sectional area of car at 40 m.p.h. Weight of car per passenger seat, maximum 750 lb.; weight of car per maximum hp., 600 lb. Gear ratio between engine and wheel for ruling grades not exceeding 1.25 per cent, 4.7 to 1. (In hard operating conditions this may be increased to 5.5 to 1.)

Class B Cars. It is difficult to come to a general conclusion with regard to this class of equipment, as it appears that only one class of car has actually passed out of the experimental stage. One of the Canadian railways has found the battery car to be a thoroughly reliable and economical unit to operate, provided that the schedule will permit of charging time. Severe weather conditions have had but little effect on the operation, and the simplicity of the power-controlling devices eliminates any chance of opposition from the operators.

The chief obstacles in the development of this type of unit are the first cost and, in some regions, high power costs, but it is felt that the great advantage it possesses of double-ended operation without complication more than offsets any serious disadvantages.

In conclusion, it seems safe to say that there is a fairly large field for the motor coach in railway work and that it will not be developed from without but rather from within—slowly, conservatively, by motor manufacturers and railway engineers, as the traveling public will never tolerate from the railway companies the difficulties and disappointments which have been visited on them personally by the automobile manufacturers. The railway engineer to do his part in this problem must be familiar not only with operating conditions but also with the labor problems which are sure to arise in such a development, making it necessary and advisable to give consideration to the employee operating this equipment and to the public using it.

Discussion

L. Klopman,[1] who opened the discussion, said that he agreed with all that the author had said in favor of the storage-battery

[1] Gen. Mgr., Railway Storage Battery Co., New York, N. Y.

car, but that the paper did not go quite far enough in presenting the proved utility and service of the storage-battery unit.

The author had divided self-propelled cars into two classes placing the storage-battery car in the heavier class (B) but excluding it from the lighter (A), or that for cars having a seating capacity of 24 to 40 passengers, a baggage space of approximately 100 sq. ft., and a car weight of from 18,000 to 30,000 lb. maximum. Storage-battery cars answering this description had been in successful operation since 1917 on the Chattahoochee Valley Railway in Georgia, on the Long Island Railroad in New York since 1914, and elsewhere, which had a seating capacity of 32 to 40 passengers, a baggage space of 80 sq. ft., and a weight, including battery, of 28,000 lb. These cars had been equipped with two 25-hp. 175 to 250-volt motors, double and series-parallel control with a gear ratio of 5.29 to 1, and 150 A-12 Edison cells.

There was no reason why a storage-battery car such as this could not meet every test which had been successfully met by the gasoline-engine-driven motor coaches designated by Mr. Brooks under Class A, and not only meet these conditions, but more economically and with greater reliability in operation than the gasoline car.

It was a matter of common knowledge that the ordinary overhead-trolley car stayed in constant daily service with little or no repair so far as the motors were concerned for periods as long as 20 years.

Assuming the average daily operation of a car in the Class A group to be 100 to 125 miles per day, it was well known that in interurban work the trolley motor performed this service day in and day out, year after year, with only nominal motor repairs and practically no "out of service" conditions.

It was equally well known that no automobile engine would do 100 miles per day continuously, 36,500 miles per year, without considerable repairs and replacement of parts. All automobile owners knew the necessity of frequent regrinding of valves to insure good operation, to say nothing of replacement of piston rings, pitted cylinders, worn gears, transmission shaft, etc., which meant a car frequently out of service for many hours. With such engine equipment the liability existed of complete power failure, and when this happened it necessitated at great expense, annoyance and delay to traffic, substitution by steam service.

The multiplicity of troubles and complete failures which were inevitable with any kind of combustion engine and drive after considerable service necessitating shopping of equipment and consequent substitution, were matters worthy of serious thought. It was generally conceded that the second-hand value of an engine which had run 36,000 miles, or about the equivalent of one year's continuous daily operation, was a very nominal amount, which indicated the large depreciation per annum which must be charged against such a type of car.

This was to be compared with the simple, effective electric motor and control of the storage-battery car, which was as nearly absolutely foolproof as any mechanism yet devised. The four-motor drive permitted in the remote contingency of failure of even two motors, of the remaining two motors' propelling the car. A mechanical or electrical failure of the battery in this service was so remote as to require no consideration. Its initial cost was admittedly higher than that of a gasoline tank, but in a comparatively short period of operation the low cost of maintenance both for the battery and the electric motors soon equalized the difference in initial cost.

The life of the storage battery of which he was speaking had proved to be over ten years in this class of service and, in fact, cars were now in operation in Canada the batteries of which had been installed as far back as 1914. The condition of a gasoline engine started in the same service in that year could be easily imagined.

It was to be remembered that all storage-battery cars were equipped for double-end control, which meant both economy of time and money in operation. The author had cited the use of these cars to connect junction points, small summer resorts, golf clubs, etc. This service would hardly warrant the cost of installation of a Y or turntable such as the one-end operation of a gasoline motor car made necessary, and it would easily be seen that it was only fair that the cost of such installation be deducted from the initial cost of storage-battery operation for both Class A and Class B service.

So far as Class B cars were concerned, he would call attention to the fact that in stating the maximum radius of operation, the author had limited himself to the statement that its maximum radius of operation was 140 miles on a full charge. This statement was correct as far as it went, but in Canada, as well as elsewhere, cars of this size had made and were making up to 235 miles a day where facilities were available and operating schedules permitted the time for intermediate charging. This would give the storage-battery car a mileage which, for all practical purposes, was equal to that afforded by a gasoline-engine-driven car.

R. G. Gage[2] said that one of the chief items that should be watched in connection with storage batteries was the first cost—not perhaps in the car itself, but in the different facilities for making low cost of operation. The charging facilities sometimes were different to procure. The question of operation of the storage-battery car in Canada was important. At certain times of the year, with the temperatures which they had, it was absolutely necessary to start the car out properly charged, but in such cases it had been his company's experience that there was very little trouble. That was one of the serious things that must be given consideration as regarded the proper scheduling, which those having to do with transportation were not always very ready to realize.

J. A. Shaw[3] stated that the railway company with which he was connected had installed four gasoline-engine-propelled cars, which were still in service, to transport passengers from the station to its hotel. They operated for four months each summer and carried all the supplies and fuel as well as passengers. By their installation the use of 200 horses had been done away with and the cost of gasoline for operation per annum was about $1000, which was small.

He had investigated a number of cases where electric cars could be operated. The street-railway company approached was willing to furnish the power required at a very low rate, with practically no charge for auxiliary equipment.

The author, in closing, said that the chief reason why he believed that the gasoline-driven car was the most suitable to fulfil the requirements outlined for Class A cars was the requirements of the service.

These small units were often used in very sparsely settled parts of the country where the only hope railway companies had of making anything out of the service was in its frequency. His company had driven cars fitted with automobile engines on regular schedules which necessitated covering 360 miles per day, up to 50,000 miles before any appreciable repairs had been necessary to the engine.

It was necessary, he said, to differentiate between experience derived from highway-run service and mechanical equipment driven on steel rails. He felt sure, from what he had seen, that the life of a gasoline car motor running on steel rails would be five or more times that of a gasoline automobile motor on highway service.

It was necessary to remember, the author said, that in Canada, where car batteries had to be imported, their cost would run close to $20,000. If necessary, the complete gasoline power plant in one of the Class A cars could be junked every year for practically the interest on that amount alone, without repayment of the cost of the batteries. It might appear at first that it was wise to figure on writing off the value of an automobile engine driving one of these small units after, say 50,000 miles. Experience had indicated, however, that it would be proper to allow 150,000 to 200,000 miles on that kind of service. But even if conditions were such as to make it advisable to junk the engine at the end of 50,000 miles, he still thought it would be better to do this rather than to incur the very heavy expense for the storage battery, which necessitated a large investment in the charging equipment where cheap power could not readily be tapped. He appreciated the value of the storage-battery car, but felt that for certain classes of service it was necessary to have something a little cheaper and a little more flexible.

Modern Hydraulic Turbines of Large Capacity

A Discussion of the Subject with Special Reference to Refinements in Design, Increased Efficiency, Improved Test Methods, and Advances in the General Art Which Make the Use of Large Turbines Possible

By H. G. Acres,[1] Toronto, Ont.

On New Year's Day of 1905, in the plant of the Canadian Niagara Power Company, it fell to the author's lot to bring up to speed, for the official inspection of the Provincial Park Commissioners at Niagara Falls, Ontario, two 10,000-hp. turbines, the largest units ever built up to that time. Almost exactly seventeen years later it was again his privilege to turn over the first of the five 55,000-hp. turbines now installed in the Queenston plant of the Hydro-Electric Power Commission at Niagara, the largest-capacity units at present in operation. It was this more or less fortuitous combination of circumstances which suggested a subject for discussion.

Not in any sense as a precise definition, but for the purpose of placing a reasonable limit on the scope of discussion, a hydraulic turbine of large capacity may be defined as one having a capacity of not less than 25,000 hp. and a revolving weight, with the generator rotor, of not less than 200 tons, exclusive of hydraulic thrust.

The above limitation on capacity and revolving weight will serve the double purpose of eliminating from the discussion any consideration of low-head installations and at the same time giving prominence to certain problems which become increasingly serious as the operating head ranges upward from 70 or 80 ft. As units of the class which has just been defined above are rarely installed under heads as low as this specified minimum, the discussion is therefore more or less limited to medium- and high-head plants.

Where a high operating head is involved, there is always present the problem of controlling high static pressure in the interests of safety; and in most cases there is also the problem of controlling and utilizing the flow characteristics of long pipe lines to insure not only safe but practicable operation. Finally, where a copious water supply is associated with a high head, there enter the problems of safely and efficiently controlling a heavily energized water column, and handling the immense revolving weight of the modern super-turbine.

Static-Pressure Control

Control of static pressure involved in super-turbine water supply is a vital factor in relation to a maximum degree of safety and convenience in operation, and in continuity of plant output. Obviously the mechanism to exercise this function is a valve, and such a valve, for super-turbine service, must have the following general specifications:

a It must be built in any size necessary to accommodate any conduit, however large.

b It must be designed to operate under any static head, however high.

c Its operation must at all times be safe, sure, and positive, in opening under full static pressure, and in closing under the most serious plant emergencies, such as the breakage of a wheel case or a runaway resulting from failure of governor control.

d It must open and close rapidly, and should have an automatic closing feature to meet the above-mentioned emergency conditions.

Obviously such a specification could not be met by any valve of the ordinary type, nor was it met until the advent of the Johnson automatic plunger valve. This is now an indispensible adjunct to super-turbine installation, and constitutes one of the advances in the general art which contributed to the possibility of present-day super-turbine development.

Flow Control

In the majority of cases the development of a high head involves the use of some type of closed pressure conduit of considerable length. In the case of an automatically governed plant where the ratio of head to length of conduit is more than about 1 : 10, certain phenomena become manifest which constitute a serious menace to safe and practicable operation. The continuous rejection and pulling on of load increments causes recurrent surges throughout the length of the conduit, which, if not damped out or relieved, will sometimes multiply and become superimposed to such an extent as to cause pressures enormously in excess of the static head. This condition, in conjunction with the conversion of pressure into velocity head for acceleration purposes, when a large increment of load is pulled on will impose a duty on the governors which they are not intended to perform, and where long closed conduits are used with turbines gated beyond the point of maximum efficiency, as they nearly always are, a condition may obtain which is entirely beyond the regulating function of the governor.

The power-discharge curve for the ordinary turbine will show a maximum production per second-foot at the point of best efficiency and the first derivative of this curve will show a rapidly decreasing rate of production per second-foot from that point to full gate. Consequently, every horsepower pulled on in excess of best-efficiency capacity will require a rapidly increasing amount of water to produce it. If, therefore, the turbine is operating at or beyond the point of maximum efficiency, when the system demands a large increment of load there will be a falling off in production per unit of water supplied, and coincident therewith a loss of effective head, due to the absorption of such velocity head as is necessary to accelerate the water column. It is therefore evident that during the period when the water column is accelerating, a condition may obtain where the power output is actually falling off while the water input is increasing, the result being that the governor may open the gates full stroke in response to the falling speed, at which point its controlling function will cease, until either the system wr^2 holds the unit, with dropping frequency, for the space necessary for the governor to gradually resume control on rising speed, or until the generator drops its load and the turbine jumps to runaway speed at full gate, with possible disastrous consequences.

In so far as the control of surge pressures is concerned, it is evident that if no practical limitations are placed upon it in the matter of diameter and height, the ordinary standpipe would be an ideal corrective agency. It is clear, however, that in the case of a super-turbine installation unrestricted scope in design is wholly impracticable from the standpoint of both cost and space limitation. On the other hand, a simple standpipe, feasibly designed and located, may at times actually make more acute the conditions it is designed to correct or alleviate. This is due to the fact that the simple standpipe can only passively absorb surge pressure, with its recurrent phases, and for this reason often acts as an agency for superimposing, one upon the other, pressure waves generated by successive changes in load.

Another obvious expedient under this head is to limit the range of velocity change in the conduit by means of a synchronous bypass, actuated by the governor mechanism. This contrivance can be adjusted to prevent the occurrence of disruptive pressures in the conduit, and also to supplement the influence of the system wr^2 in holding the unit within the regulating range of the governor when the unit is pulling on or rejecting load. In this connection it is to be noted that the condition under discussion has not necessarily to do with the maximum conduit velocity at any one time, but with the *range of change* in conduit velocity over a short period of time, and with the absorption and building up of head energy induced by these changes, within their low and high limits.

[1] Chief Hydraulic Engineer, Hydro-Electric Power Commission of Ontario.

Presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Slightly abridged. All papers are subject to revision.

The synchronous bypass therefore has a useful function, but in the case of a high-head super-turbine installation its usefulness would be largely discounted by its cumbersome dimensions, its waste of water, and an added mechanical complexity which should be avoided whenever possible as a matter of principle.

The discussion under this head has now reached a stage where it is possible to define the specifications of an ideal surge-control agency.

a It should have the effectiveness of a simple standpipe of very large dimensions, without its cost and space requirements.

b It should be capable on the one hand of preventing or counteracting the effect of any undue absorption of head energy when load is pulled on, and, on the other hand, of preventing or counteracting the effect of any serious recurrent surge pressures arising from load rejections, whether isolated or successive.

c The water surface should be sufficiently active to prevent freezing in ordinary low temperatures, and the dimensions should be such as to allow feasible and effective frost protection against extraordinarily low temperatures.

d It should operate without wasting water.

e It should be mechanically simple, with a minimum of moving parts and adjustments.

f It should be entirely dissociated from the governor mechanism, leaving the governor free to perform its own peculiar and highly important function, which is to control the speed of the generator, and not the vagaries of the water column.

This specification has been met with a large degree of effectiveness by one of the most wholly original and at the same time most useful contrivances ever developed in the field of hydraulic engineering, namely, the Johnson differential surge tank. Ample published data are available concerning its structural details and operating principle, and it is only necessary to state here that this contrivance constitutes another of the essential advances in the hydraulic art which have made possible the development and safe operation of the super-turbine.

Revolving Weights

The handling of the revolving weight of a modern super-turbine is governed largely by consideration of efficiency, a matter which will be discussed later, only the mechanical aspect of the problem being considered at this time.

In the early days of hydraulic-turbine development the step bearing, a form of combined thrust and guide bearing located under the runner, was used almost exclusively for the support of revolving element. The subsequent gradual increase in the efficiency, speed, and capacity of turbine runners then began to introduce problems of pressure intensity, depreciation, and accessibility, which the designers of that day solved, not by improving the step-bearing principle, but by abandoning it and inaugurating, as a result, the era of the horizontal-shaft turbine. This led to advanced development in bearings of the pillow-block type, together with the introduction of marine-type thrust bearings to take up unbalanced runner thrust, a double requirement which gave rise to serious problems when the development of electrical generation and transmission called for continuously increasing turbine capacity and speed.

The original turbines installed in 1896 by the Niagara Falls Power Company represent the first reversion to the primitive basic principle. They were the super-turbines of that period, and were of the vertical-shaft type. The revolving weight of these units was partially suspended from and partially superimposed on a step bearing located above the runner and immediately below the generator, thus removing one of the main disadvantages of this type of bearing, that of inaccessibility. A further important innovation was the application of external pressure to a film of oil which was forced in between the moving and stationary elements of the bearing.

The oil-pressure thrust bearing had a vogue of many years' duration, and some bearings of this type are still in operation. Their disabilities are: expensive investment and maintenance cost, mechanical complexity, and high temperature, resulting in low oil viscosity and high energy losses. Also, even a momentary failure of the pressure-oil supply usually results in the loss of the bearing.

Finally there came the ultimate conception, based on the simple and true embodiment of a basic principle first established by the experiments of Tower in 1883 and afterward mathematically demonstrated by Reynolds. It remained for Kingsbury to exemplify this principle in a mechanism which is one of the most outstanding examples extant of the simple and efficient application of a natural law.

The Kingsbury-type thrust bearing has the following characteristics which distinguish it from its oil-pressure prototype and make it an eminently suitable mechanism for supporting, in motion, the revolving weight of the modern super-turbine:

It can be adapted to safely support the revolving weight of the heaviest turbine, within feasible dimensional limits.

The source of oil supply is static, and integral with the bearing itself.

The oil supply is "unlimited" in the sense necessary to conform with the laws of motion of viscous fluids, as enunciated by Reynolds.

The formation of the "pressure wedge" is not induced by any external agency but by the motion of the bearing itself, and by providing for a very slight lack of parallelism between the stationary and moving elements.

The wedge pressure is a direct function of the speed of the moving element, and the thickness of the oil film is a direct function of the degree of viscosity of the fluid, and consequently of fluid temperature, which can be regulated within any desired limits by the simple expedient of water-cooling coils.

Apart altogether from their very material contribution to operating efficiency, the mechanisms above discussed introduce a factor of safety and dependability, either singly or in combination, without which the present-day status of super-turbine development would have been unattainable.

Refinements in Design

The items above classified as essential advances have been radical departures from contemporary practice, and have actually opened up the possibilities of super-turbine development, whereas the turbine governor has been enlarged and improved more or less synchronously with the enlargement and improvement of the hydraulic turbine, and to meet the constantly increasing importance of the duty it has been called upon to perform.

Governors. As the primary requirements of governor operations are precision and reliability, the natural trend of design has been in the direction of simplicity in principle, the reduction of lost motion by the use of minimum of moving parts, and precise shop work. An interesting development along this line is the White shaft governor, where the centrifugal element is attached direct to the main turbine shaft, thus obviating the complication of a belt or gear drive for the flyballs.

The double compensation principle, with the restoring mechanism and load-limiting attachment, appears to meet all requirements of super-turbine governor control adequately and safely, and speed regulation is assured within safe operating limits for all gate movements up to the full stroke of the servomotors.

Remote switchboard control has also been developed to such a stage that there is considerable latitude as to the location of the actuator, which in some cases in now placed directly over the servomotor cylinders, in others on the machine-room floor, and sometimes on the switchboard gallery.

A useful adaptation of the Johnson valve principle has been devised by Taylor for interchanging governor and hand control. Two sets of plunger valves are used, one set on the governor and one on the hand control, and the throwing over of one hand lever will simultaneously close all the governor valves and open all the hand-control valves, or vice versa. This operation can be carried out in such a short interval of time that there is little or no chance of losing control of the turbine, and no chance whatsoever of interfering with the proper sequence of operation.

One of the latest innovations in governor design is a motor-driven centrifugal element, the motor being located on the flyball spindle and synchronously actuated by the main generator. This device serves the same purpose as the shaft governor in that it eliminates the belt or gear drive.

Draft Tubes. The activity which has manifested itself during the last four or five years in draft-tube investigation is directly

traceable to the vogue of the super-turbine. There are two main reasons for this: first, the large concentration of power in a super-turbine permits an appreciable increment of useful power to be reclaimed as the result of a gain of only a fraction of one per cent in overall efficiency; and second, the vibration resulting from vortex action and unsteady vacuum becomes magnified in the super-turbine to such an extent as often to cause serious inconvenience in operation. The pioneer development under this head was the White hydraucone, which marked a distinct advance in this branch of the art.

Briefly, the twofold object of recent draft-tube experimental research has been to regain as much as possible of the whirl component of the velocity head in the runner discharge, and to devise means of so training the combined axial and whirling flow, through appropriately designed water passages, as to minimize conditions giving rise to vibratory effects. All experiments carried on along this line by the principal turbine builders have definitely proved the inadequacy of all forms of the elbow-type tube, and have developed a series of types, more or less correlated, which have given satisfactory results when tested under operating conditions. Of these types the Moody spreading tube seems to conform most nearly to one's conception of the conditions to be met. This is particularly the case in respect of a cone in the center of the Moody tube which extends from the invert to the lower extremity of the runner hub. Inasmuch as this cone solidly fills the region of maximum turbulence, it seems entirely reasonable to assume, even without experimental confirmation, that it will be effective in preventing cavitation and the formation of vortices, with their resultant vibratory effects. Serving this purpose it also naturally follows that it must affect a useful conversion of the hitherto wasted whirl energy of the central zone, realizing thereby a gain in efficiency as well as a betterment in operating conditions.

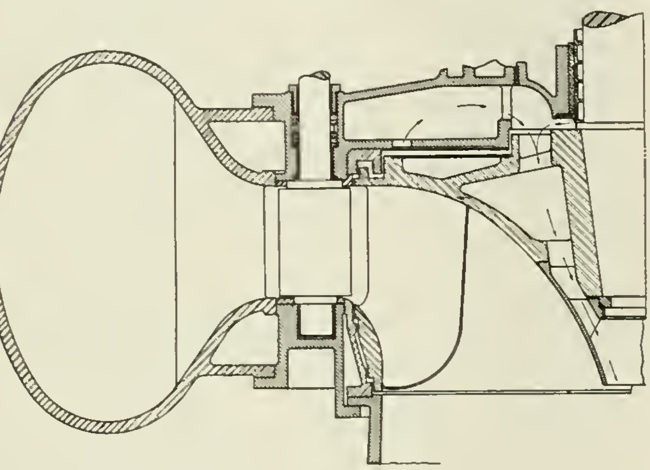

Fig. 1 Showing Application of Labyrinth Seal and Overn Disk to Hydraulic Turbine for Reduction of Leakage

Leakage Prevention. In a small high-head plant with which the author had something to do the turbine showed 85 per cent efficiency on acceptance test. A year later the efficiency had dropped to 67 per cent by reason of excessive leakage through the runner clearance spaces. The head in this case was 550 ft. and the circumference of the clearance spaces was about 14 ft. In the case of the 55,000-hp. turbines at Queenston the head is about 250 ft. less, but the circumference of the runner clearances is about 65 ft. It is evident, therefore, that in the case of a runner of this size, under such a head, the leakage factor is a serious matter. As a matter of fact, two of the most recent refinements in turbine design have been devised for the express purpose of meeting this condition: namely, the so-called "labyrinth seal" for preventing leakage through the runner clearance space, and the Overn disk for preventing leakage through the gate clearances.

Instead of the ordinary simple seal consisting of a straight annular passage past the crown of the runner into the space under the head cover, and a similar passage past the runner band into the draft tube, the labyrinth seal, Fig. 1, consists of a series of alternately expanded and contracted passages which destroy the velocity head and reduce the head on the final free jet to one-third of its initial value.

The Overn disk, Fig. 2, functions by introducing into the clearance space between the end of the gate vanes and the distributor plates an obstruction to the leakage flow considerably greater than the diameter of the gate shanks, thus effectively reducing the leakage at these points.

Taylor Sectional Scroll Case. Where the head is sufficiently high to require the use of a cast-steel scroll case, a serious problem is introduced which has to do with the cantilever strain on the radial joints between the speed ring and the scroll case. With the ordinary design, efficient bolt distribution is not practicable, and in the shop pressure test, where the scroll is not supported by a surrounding mass of concrete, the bolts are sometimes stressed beyond the elastic limit, with resultant serious leakage. This disability can be largely overcome by casting the speed-ring stay vanes integral with the scroll sections, but the pouring and annealing of such a casting is a most difficult piece of work and the results are not always certain. The Taylor sectional scroll case is just as effective and largely removes any uncertainty as to the quality of the casting. Taylor's method, see Fig. 3, is to cast the speed-ring stay vanes integral with a small radial section only of the scroll, and connect later by means of a joint to the main section of the scroll. This joint is so located as to permit of a heavy flange and efficient bolt spacing, and the castings are of such shape and dimensions that there is every assurance as to their quality after leaving the annealing furnace.

The showing made by the sectional scroll case under shop pressure test indicated that no undue risk would be involved in setting the scroll in the open, with only so much concrete as might be necessary to secure a stable anchorage.

With regard to the pitting and erosion of runners, it may be said that super-turbine development has now reached a stage where this condition is no longer primarily a problem of design but of economics. In other words, if the customer so specifies, the manufacturer can select a specific speed and supply, at a price, a turbine in which the runner will have as long a period of useful life as the other major elements of the installation.

Such a specification on the part of the customer would, of course, involve additional capital expenditure for the generator as well as for the turbine, but as against this aspect of the situation it must be realized that the modern super-turbine frequently has a capacity which enables it to earn upward of \$2500 every twenty-four hours. Consequently the lost revenue charge against runner replacement in a fully loaded unit may easily run as high as \$25,000. If this were necessary every two years, it would be equivalent, on a 6 per cent basis, to a capital charge of \$200,000. Such being the case, it is evident that the choice of a proper economic specific speed is a matter deserving the most careful and mature consideration, being a factor of at least equal importance with proper gateage and elevation relative to tailwater.

Fig. 2 Showing Application of Overn Disk to Guide Vanes for Reduction of Leakage

Efficiency

The overall maximum efficiency of the Queenston units is well beyond 90 per cent, and within their maximum efficiency range they deliver about 32 e.hp. to the switchboard for every second-foot of water supplied under 305 ft. of net head. Under such conditions a variation of one per cent, one way or the other, on one of these 55,000-hp. units would mean either the lack, or the availability, of sufficient power to meet the requirements of an average community of 2000 population. This statement should serve to emphasize the significance of high efficiency as related to super-turbine practice.

The primary factor making for high efficiency is a minimum of obstruction to the direct flow of water from forebay to tailrace. This consideration involves water passages of ample section, with changes in direction of flow eliminated wherever possible, and where unavoidable, careful proportioning and transitioning. These requirements constitute the general definition of high efficiency, and are exemplified in the carefully designed annular water passages in the Johnson valve, in the wheel case, speed ring, runner, and draft tube of the modern super-turbine, and also in the total elimination of one change in direction of flow entering the wheel case, by vertically suspending the revolving weight from a Kingsbury-type bearing. Secondary but none the less significant factors are the elimination of leakage, low power loss in thrust and guide bearings, and expert shop work.

The proper handling and correlation of these various factors is exemplified in the results illustrated in Fig. 4, which shows the efficiency and power-discharge curve for one of the Queenston turbines. The matters of interest in connection with these curves are as follows:

1 The maximum efficiency is $93^1/_2$ per cent.

2 The efficiency at the point of maximum discharge is 88 per cent.

3 The turbine has a capacity range of 32,000 to 63,000 hp. at efficiencies of 90 per cent or over, and a capacity range of 37,000 to 60,000 hp. at efficiencies of 92 per cent or over.

Fig. 5 illustrates the overall switchboard efficiency curve of the same unit, and indicates a maximum overall efficiency of 91 per cent.

The outstanding fact in connection with these results is that the modern super-turbine is capable of converting into mechanical energy all but 7 per cent of the gross potentiality of the water supplied. Extreme conservatism in the fixing of specific speed, and the combined effect of further small refinements in the design of water passages, may possibly raise this efficiency another per cent in the future, and may give the curve a slightly more advantageous shape, but it would really appear that the super-turbine of the present day embodies the ultimate in respect of water economy at the point of best efficiency.

Fig. 6 is an interesting curve representing the first derivative of the power-discharge curve of one of the Queenston turbines. As its name implies, this curve is derived by plotting the amounts of horse power per second-foot produced, in various regions of gate opening at and beyond the point of maximum efficiency, by a very small opening movement of the gates. In other words, it shows, not the gain, but the rate of gain in power for increasing water input.

It will be seen that when operating at the point of maximum efficiency with a water input of 1600 sec-ft. the gain in power for one additional second-foot supplied is 32 hp. On the other hand, at full gate, when the turbine is taking water to the extreme limit of gate opening, the gain in power for one additional second-foot supplied is only about 10.5 hp.

The two extremes above cited serve to illustrate the significance of previous statements made under the head of flow control, and also to confirm the truth of the following statement: that under high heads, where the gross potentiality per second-foot of water

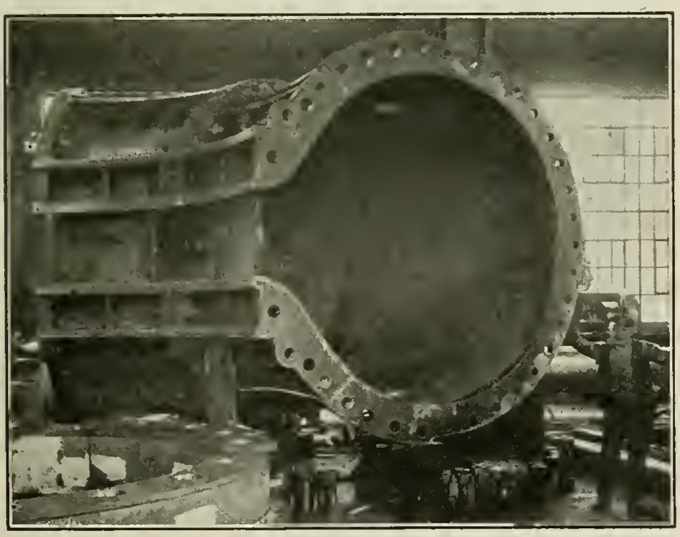

Fig. 3 Section of Taylor Sectional Scroll Case Showing Integral Cast Stay Vanes and Joints Subdividing Sections

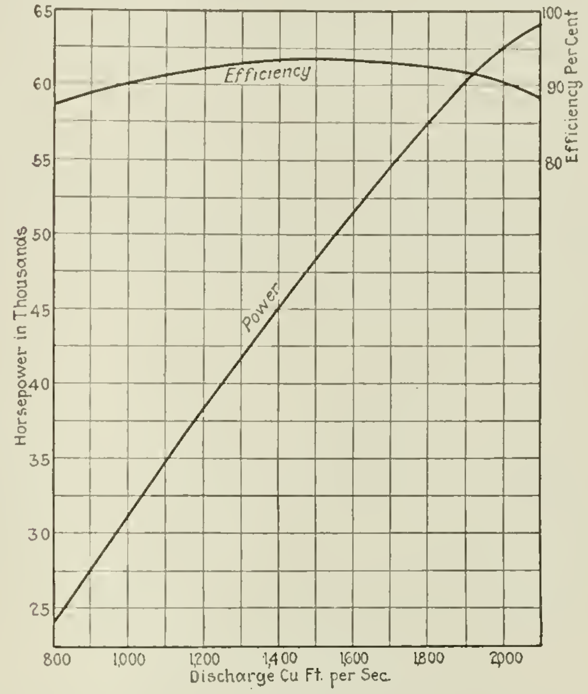

Fig. 4 Power-Discharge and Efficiency Curves of one of the Queenston Turbines

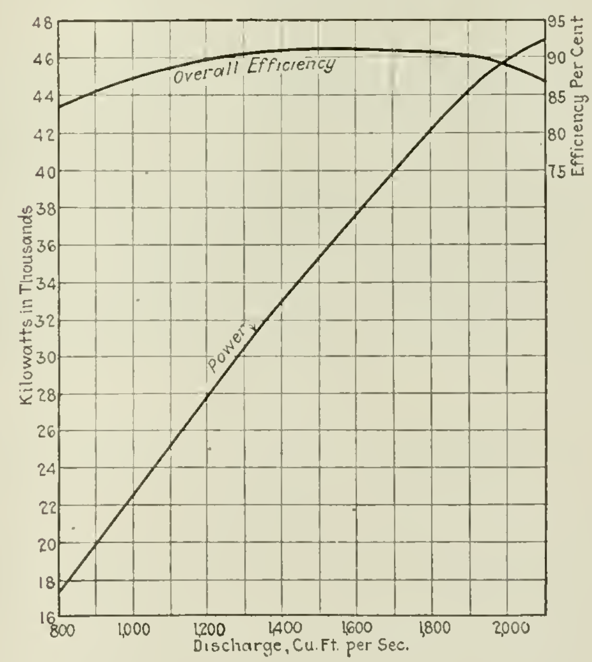

Fig. 5 Overall Efficiency and Power-Discharge Curves of Unit of Fig. 4, Head, 305 ft.

is correspondingly great, it is in the best interests of economy, as well as safety, to operate normally at the point of best efficiency, and to employ the excess capacity of an overgated turbine for emergency purposes only, and not for routine operation. This statement has an added significance, also, when the water supply is artificially stored.

Furthermore it is obvious that as the point of maximum efficiency is also the point of minimum hydraulic loss, the rate of runner deterioration at this point must also be a minimum. From this point on the rate of runner deterioration is an accelerating progression, directly related to the degree of overgate.

The points in favor of gating the super-turbine back to the point of best efficiency are: first, safe and efficient operation, particularly where long pressure conduits are involved; second, economy in the use of water under high heads, where the gross potentiality per second-foot of water is great, and where artificial storage is a factor; and third, on account of runner deterioration, particularly where runner replacement involves a material revenue loss.

The matter of turbine gateage has not, in the past, received the

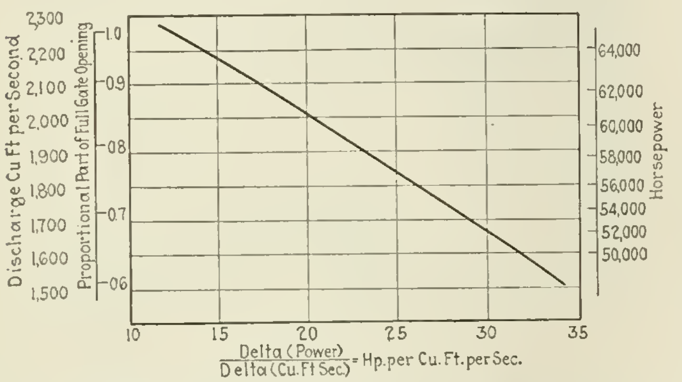

Fig. 6 First Derivative of Power-Discharge Curve of One of the Queenston Turbines, Showing Rate of Gain in Power for Increase in Discharge

attention it deserves at the hands of the purchaser. It does not particularly interest the manufacturer, and must be covered, if at all, by the customer's specifications.

It would also appear that the main factor offsetting the above argument is one of cost and not of engineering: namely, the additional cost, if any, of providing emergency plant capacity in the form of a separately installed unit or units, instead of relying on the overgate capacity of the normal installation.

It may be stated in conclusion that generalizations have probably less weight in hydraulic work than in any other branch of engineering, as nearly every prospective installation is a unique problem in itself, and no class of construction work is less governed by precedent.

Test Methods

The factors entering into a turbine test are forebay and tailwater level measurements, net head measurements, records of gate opening, and measurements of power and flow.

Most of these factors are susceptible of easy and accurate determination by well-established methods, but in the case of flow, the immense quantity of water taken by the modern super-turbine introduces an almost insurmountable problem as regards accurate measurement by ordinary means. It so happens, however, that there has recently been devised a method of flow measurement in closed pressure conduits, which by reason of its accuracy, cheap application, and conformity to an established principle of natural law, entitles it to be classed among the essential advances in the hydraulic art as related to super-turbine practice.

The Gibson Method of Flow Measurement. This method of flow measurement, known as the Gibson process, is based in principle upon Newton's second law of motion, and upon the less generally known theorem of Joukovsky, which is to the effect that when the velocity of flow in a closed pressure conduit is retarded, an oscillatory pressure wave is induced, the intensity and amplitude of which is proportional to the degree of retardation and to the duration of the period over which the retarding influence acts. Briefly, Gibson used the penstock and turbine gates to produce the Joukovsky pressure wave, which he recorded graphically with an apparatus of his own devising, and then reduced the result by the mathematical process of Newton's second law.

The method is therefore almost unique in the field of practical hydraulics in that it involves no empirical constants whatever, and the mathematical accuracy of the result is limited only by a relatively small instrumental and personal error involved in graphically recording and measuring the pressure wave.

The Gibson process has been fully described in the technical press, and it is not the intention here to cover the details of its theory or application. It may not be amiss, however, to describe briefly, the unique and interesting method of obtaining and using the "pressure-time" diagram which forms the basis of computation.

The recording apparatus consists of a mercury U-tube connected to the penstock through a $^1/_4$-in. pipe. The glass leg of this U-tube is connected to a camera box containing a lens focusing on a light-proof cylinder, the latter carrying a sensitized film and revolving at constant speed behind an oscillating seconds pendulum. When gate closure occurs, the mercury column in front of the lens rises and falls with the pressure wave, and the record is printed on the revolving film. At the same time the stem of the seconds pendulum, swinging across the face of the lens, records the time period of gate closure on the film, in the form of a vertical black line.

Fig. 7 illustrates a typical pressure-time diagram thus obtained. The point A represents balanced conditions in the system just previous to gate closure. The distance from A to the vertical line EF represents the full-time period of gate closure. The oscillations to the left of the line EF are due to the mercury column gradually stabilizing by friction, until at the point P static head is registered, with the penstock water column at rest. The vertical distance between the point A and the point P therefore represents, to the scale of the diagram, the recovery of velocity and friction

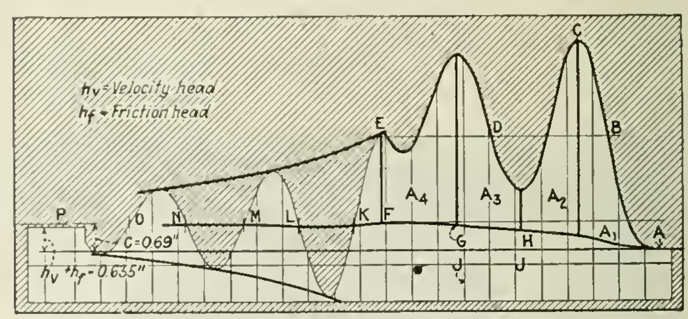

Fig. 7 Typical Pressure-Time Diagram Obtained in Flow Measurement by the Gibson Process

head. The lines J represent the second intervals recorded by the pendulum.

The total area above the base line, and to the point of gate closure at F, represents a total energy absorption containing three separate elements, velocity head, friction head, and the destroyed momentum of the water column. This latter element being the one required for the application of Newton's second law, it follows that the energy absorption due to recovery of velocity and friction head must be segregated.

At the point A it is evident that the full value of velocity and friction head is existent, while it is equally obvious that at F, the point of final gate closure, this energy has been fully recovered. The line $AHGF$, technically known as the "recovery line" divides the total energy area into two parts, the upper part of which, $ABCDEFGH$, represents the value sought, namely, the destroyed momentum of the water column. The area below the recovery line of course represents the sum of the other two elements, friction and velocity head. Intermediate points between A and P on this line are obtainable through the fact that the area generated at the end of any partial period of gate closure is proportional to the amount of flow reduction at that point, and also that the velocity and friction heads still unabsorbed are proportional to the square of the residual flow. The intermediate points C and H

were determined on the basis of these relationships, through the medium of the measured sub-areas A_1, A_2, A_3, and A_4.

A test of one of the Queenston units, with all the other necessary operations in connection with head and gate-opening measurement, etc., was made complete within about four and one-half hours, and included 28 separate runs at various gate openings, an average of ten minutes per run. The unit itself was out of commercial operation for about one hour altogether, showing clearly the facility and cheapness with which the Gibson test can be carried out.

An interesting feature of these tests manifested itself in an apparent inconsistency in some of the finally computed points for the efficiency curve, which varied for equal power outputs. This trouble was due to a discrepancy in the power readings, which were actually correct in themselves within the error limits of laboratory standards. The reason is that under the Gibson process the velocity measured is that existing at the instant the gates begin to move, and if the speed of the unit is perfectly uniform at this instant, the corresponding power reading will be correct for the measured discharge. If, however, at the instant of the flow measurement, the unit is in process of a speed change even so small as to be unnoticed on the frequency meter or tachometer, an error will be introduced in the electrical power measurement which the Gibson process is sufficiently precise to detect.

The flywheel effect of the Queenston generators is 21,000,000 lb-ft.^{2} If, at the instant of a flow determination, the speed of the unit is dropping at even so small a rate as one cycle in ten seconds, there is 570 hp. registered on the wattmeters which the wr^2 of the generator is supplying, but not the water as measured.

Conversely, if the speed of the unit is in process of increase at the rate of one cycle in ten seconds, there is 570 hp. which is not being registered on the wattmeters, but which the water, as measured, is actually supplying, for absorption by the generator wr^2.

This means that for any one value of discharge there may be any number of wattmeter measurements which may possibly be in error in any amount up to 1000 hp. It is possible that this disability may be overcome by devising some simple means of recording the minute speed change of the unit synchronously with the instant of flow measurement, and thus permit a proper correction to be applied to the power readings.

The Salt-Velocity Method of Measuring Flow. The use of the Gibson process is naturally limited to conditions which are properly conducive to the production of the phenomena upon which the theory is based, the first essential being a closed pressure conduit of reasonable length and uniform section. In short conduits of, say, 50 to 60 ft. in length, more especially if they have at the same time a non-uniform section, it becomes necessary to apply correction factors which have a greater relative influence on the ultimate accuracy of the result than is the case with long conduits of uniform section. It so happens, however, that the recently devised Allen "salt-velocity" method of measuring flow is susceptible of application to short as well as long conduits and to non-uniform as well as uniform sections, the accuracy of the final result being dependent, not upon an instantaneous pressure rise, but on the refinement of method and money outlay applied to the injection of a salt solution, the time of passage of which, through a fixed length of conduit, forms the basis of the final computation. Practical applications appear to indicate that it has a useful function and will become a recognized process as related to this branch of hydraulic engineering.

In conclusion, it may be well to call attention to the fact that the definition of a turbine of large capacity, as given in the preamble of this paper, is applicable in particular to the Francis type, as there are now in operation, under heads of less than 70 ft., super-turbines which would come within the definition as regards capacity and revolving weight. These turbines are, however, of the new propeller type and any discussion of this new departure in turbine design would open up a subject far beyond the scope of this paper.

In evidence before the International Joint Commission two years ago the author advocated the propeller-type turbine for the St. Lawrence River Development, and was subjected thereby to severe criticism. However, recent performance, under actual installation conditions, has largely confirmed his views and it is more than likely that the Development, when consummated, as it ultimately must be, will see the propeller-type turbine installed.

Discussion

Written discussions of the paper were submitted by Messrs. R. W. Angus, H. Birchard Taylor, and Lewis F. Moody, extracts from which follow. Professor Angus[1] wrote that much of the paper would apply with equal force to medium- as well as large-sized units, and much of it to low-head as well as to high-head plants. Surges were present in all plants having long closed supply conduits, and their magnitude depended on the friction in the line and on its length and the initial and final velocities in the conduit, as well as on the diameters of the pipe and tank, but was independent of the head on the plant, so that the control of surges was really of more vital importance in low-head than in high-head plants.

The form of draft tube, Professor Angus wrote, was not as important in high-head plants as was generally supposed. In the modern low-head turbine of high specific speed the water entered the top of the draft tube with a high velocity of whirl, and the ordinary bent tube was unable to regain efficiently the energy in the water leaving the turbine. The water in such a tube whirled as it passed around the bend and the discharge conditions were bad. In this case the tube must have a special form, capable of recovering the energy leaving the wheel, and the hydraucone and spreading draft tube appeared well suited to this purpose.

On the higher-head plants wheels of comparatively low specific speed were always used, and it was a relatively easy matter to deliver the water to the top of the draft tube in an axial direction at the load showing highest efficiency, and if this was done the straight tapering tube, or even the quarter-turn, gave very good results. It was true that there would be whirling of the water at all other loads but one, and the spreading tube might show higher efficiencies on these loads than the quarter-turn tube, but as yet there did not seem to be enough evidence available in this connection.

Leakage was a serious matter in high-head plants and, according to the illustration given by the author, was relatively much more objectionable in the high-head, smaller plants than in the larger ones. Water-turbine builders were trying the labyrinth packing which had long been in use on steam turbines and turbine pumps. It was true that in both the latter cases the rings had been used on smaller diameters than on water turbines, and this fact made the use of the labyrinth more problematical in the case of water turbines, although it seemed to offer a good solution of the leakage problem.

In regard to the making of reliable tests, there was serious danger in hurrying the work too much, and it did not seem desirable to shorten the tests unduly. Averages taken over a reasonably long time with steady loads, Professor Angus believed, would obviate the difficulty mentioned by the author, as the latter stated that errors up to nearly 2 per cent were possible.

H. Birchard Taylor[2] wrote that the Queenston project, which had first come to his notice in 1911, had been carried out substantially in accordance with the original program with respect to the unit capacity of the turbines, and that practically every improvement that had been developed in the art of turbine design and construction for high-head turbines had been incorporated in the units there installed.

When units of such large capacities as 60,000 hp. were adopted, the importance of such questions as the attainment and maintenance of high efficiency, the elimination of runner corrosion, the avoidance of dangerous water hammer or vibration, the prevention of permanent injury from wear and tear by the provision of renewable parts, and careful study of operating requirements, became evident. The author had shown the great monetary loss involved in only a few days' shutdown of a unit, and his figures made it clear that an enforced interruption of service would not have to last long to produce a loss exceeding the entire cost of a turbine unit. Any safeguard against such interruption, therefore, would easily justify a large capital outlay.

Still larger units were now being constructed for the Niagara Falls Power Co., namely, of 70,000 hp., and it would appear that

[1] Prof. M. E., Univ. of Toronto, Toronto, Ont., Canada. Mem. A.S.M.E.

[2] Vice-Pres., Wm. Cramp & Sons' Ship & Eng. Bldg. Co., Philadelphia, Pa. Mem. A.S.M.E.

the factors which would put a limit on power capacity in the future would be other than those involved in the construction of the turbine itself; and it was reasonable to believe that units of larger capacity than any yet built, when feeding large systems, would be just as dependable as units of smaller capacity had been in the past when connected to systems of lesser magnitude.

Lewis F. Moody[3] wrote that he believed that any one who read the paper or investigated the manner in which the engineering of the Queenston plant had been carried out would be impressed by the unremitting endeavors of the author and his staff to secure the best possible solution for every element in the plant design, and by their adoption of new solutions for many problems arising whenever a new departure could be demonstrated to have advantages, even if its adoption was entirely contrary to accepted standards. Certain features, such as Mr. Taylor's method of constructing the turbine casing without a separate speed ring, had been worked out for the Queenston plant for the first time. Even in the features which had been previously tried out, however, an additional problem had been introduced at Queenston due merely to the unprecedented size of the turbines.

In his specification for the penstock valve for installations of this magnitude the author enumerated the most vital points which had to be covered. A supplementary feature which should also be considered was that of tightness. If the penstock valve passed any appreciable amount of leakage, it was unfitted for location close to the turbine for the purpose of permitting quick access to the turbine without unwatering the penstock. Another important feature was that the motion of the valve should not require the dragging of an unlubricated surface tangentially over another under a heavy normal pressure caused by the static head. The Johnson valve met both of these additional considerations, as the sealing took place by a motion at a large angle to the sealing surfaces, and only at the time of final closing did a heavy pressure due to the static head force the surfaces against each other, thus effecting extremely tight closure.

In connection with the author's references to the design of spreading draft tube adopted for the last three units at Queenston in which a central core was extended all the way to the runner, Mr. Moody called attention to comparative tests that had recently been carried out for the U. S. War Department at the I. P. Morris laboratory in Philadelphia. The turbine tested was of very much higher specific speed than the units at Queenston and consequently involved a more severe draft-tube problem due to the relatively much greater tangential or whirl component present in the water leaving the runner. A draft tube which successfully met the requirements of this high-specific-speed turbine, however, would be equally applicable to the low-specific-speed turbine, and its ability to regain energy of whirl would be effective in improving over-gate and part-gate performance in a lower-specific-speed installation. The particular form of spreading draft tube showing the highest efficiency in these tests was one in which the central core had been carried to the runner as in the Queenston units. The tests had been undertaken primarily to learn whether it would be possible by a simplification of design or the use of an elbow form of tube to reduce the cost of the power-house substructure sufficiently to balance the loss in efficiency. They had shown that the increase in turbine efficiency secured by using the spreading type of tube was so substantial that its use was fully justified. It might be of interest to mention that this type of tube had been adopted for installation either built or building which aggregated approximately 1,750,000 hp.

With reference to the author's statement that the two 10,000-hp. turbines installed by the Canadian Niagara Power Co. in 1904 were the largest units ever built up to that time, he would say that the first 10,500-hp. turbine at Shawinigan was completed at practically the same time, and that it deserved a special place in this branch of engineering because of its being entirely of American design and because of its many years of successful service.

H. A. S. Howarth,[4] who opened the oral discussion, dealt at some length with the development of the Kingsbury type of thrust bearing and its characteristic features, as well as the influence which the work of Prof. Osborne Reynolds, had exerted on thrust-bearing design. The Michell bearing, which had frequently been described in the English technical press, was of the Kingsbury type and was independently invented by an Australian engineer who acknowledged indebtedness to Professor Reynolds' mathematical treatise.

William White[5] said that he was heartily in accord with what the author had to say in reference to specific speeds. Electrical engineers insisted upon going higher in speeds, which meant a greater liability of pitting. The author was the first representative of the customer that he had heard say that the customer also assumed the liability for some of the changes or damages which necessarily would result in going to these higher speeds.

He appreciated the author's remarks concerning the hydraucone and he wished to pay a tribute to Mr. Moody's work. However, he would call attention to the fact that the hydraucone and the spreading draft tube were one and the same thing, because tests had shown that when the cone was taken out the results were the same. Mr. Moody's work, however, had brought out the fact that the cone steadied the performance of the unit, and its extension up to the hub of the runner might prove a valuable addition.

He appreciated Mr. Moody's reference to the Shawinigan unit, as he had been responsible for its design.

Prof. C. M. Allen,[6] who devised the salt-velocity method of measuring water flow, gave brief particulars regarding it. In this method, which is said to be a very accurate one, a charge of brine is injected under air pressure into the stream flow and its passage between two or more known points is accurately timed. By dividing the volume of the conduit between these points by the time of passage, the rate of flow is obtained. The conductivity of the water varies as its salt content, and the timing of the passage of the charge is effected by means of a stop watch or recording seconds clock and indicating electrical instruments, or by recording electrical instruments.

In his closure the author, replying to Professor Angus, said that it was quite true that surges in low-head installations and draft-tube conditions in low-head installations had not been given much prominence in the paper. The reason was that under low-head conditions these two factors became, in the majority of cases, the major elements of design, and it had been impossible to include an adequate discussion of low-head plants under this particular subhead.

Professor Angus had mentioned the possible interest which might attach to a discussion of the comparative efficiencies obtained on the units at Queenston, using the spreading draft tube as against the elbow type. There was a considerable amount of interesting data available in connection with these comparative tests, but it had not yet reached the stage of coördination and final consideration where it could be profitably discussed.

With regard to the question of error introduced into discharge measurements, it was quite true that in the paper he had given figures that would lead to the inference that error was possible. As a matter of fact, this phenomenon did not occur every time one made a test run for discharge. He had merely mentioned that fact as an interesting feature brought out by a method of discharge measurement that at the present time was sufficiently accurate, and the existence of this error could be more or less counteracted either by multiplying the number of runs for any particular opening or by devising some simple method of keeping track of the minute speed changes of the generator at the time of flow measurement.

Mr. White had spoken of the comparative efficiencies of the hydraucone and the spreading draft tube with the cone, and he thought what he said was quite true in so far as it affected one factor, namely, the overall efficiency. He had been discussing that overall efficiency in so far as it was influenced by draft-tube design, and it was not possibly quite as important as the manifestations which gave bother in the form of vibratory effects. At the time Mr. White made his investigations those vibratory effects had not reached the stage of seriousness which they had at the present time. A decade ago they were simply taken as a matter of course, because they caused no trouble. Under present conditions, due to resonance, etc., they constituted a serious factor in operation.

A Practical Laboratory and Drawing-Room Course in Industrial Engineering at Cornell University

By MYRON A. LEE,[1] ITHACA, N. Y.

The paper shows how the early courses in industrial management have been widened in scope to include the engineering phases of the problems of manufacturing. This has been accomplished by supplementing the lecture courses with a practical laboratory and drawing-room course in which the student has his own problem to work out in the design and operation of a modern industrial plant.

A NUMBER of years ago it became evident that the work of the engineer was broadening in scope. The engineer in practice was increasingly concerned with management problems, and it was deemed advisable to give the engineering student some instruction along the line of industrial management. The first attempt at Cornell was by means of a lecture course which proved very popular and was of unquestioned benefit to the student.

The increasing importance of this study to the engineering student was soon evident and the limitations of a lecture course were realized. It is recognized, for instance, in teaching machine design that a lecture or even a recitation course alone cannot accomplish results that can be attained in the drawing room. If a student actually designs some piece of apparatus such as a triplex pump, for example, he acquires and, what is more important, retains a knowledge of machine design which he could obtain in probably no other way. Moreover the knowledge he obtains is not limited in its application to merely the apparatus he has designed, but to a large extent is fundamental and applies to the whole field. This is particularly true if the drawing-room course is correlated with a carefully prepared and well-presented course of lectures which show the application of the principles of the subject to the general field.

It was felt that these well-recognized principles of teaching would apply equally well to industrial engineering, and that a course in which the student applied the principles of industrial management to definite problems would give him a knowledge of the subject which he would retain and could apply to any problem in that field. After several years of experiment and development, a course has been evolved which it is the object of this paper to describe.

Time Study

One part of the work consists in actual time-study practice. This work has no direct connection with the rest of the course and could be given at any time. As a matter of convenience it is usually undertaken during the early part of the second term. Studies are made by the student of actual operations in the university shops. As it has not been found practicable to have the student make a preliminary study, he is given mimeographed sheets which enumerate the elements of each operation to be studied and the time when each reading is to be taken. Before taking the study he is required to demonstrate that he has practically visualized the sequence of the elements making up the operation and will almost automatically know when to take readings. This requirment is the result of sad experience as it has been found that otherwise the student will be confused and will get no dependable readings for the first few runs. It has also been found that it pays to have the student practice reading the watch before he attempts observations on a workman. The standard time-study watch reading hundredths of a minute is used and a person accustomed to seeing an ordinary watch needs some practice before he can quickly read one of these watches, as he must when using the "continuous" method of observation.

Each student is provided with a stop watch mounted on a board of convenient shape and records his observations on the usual type of time-study log sheet. It is possible usually to have not more than ten men taking observations upon one operator. Several complete operations or cycles are observed so that representative times can be obtained.

After the observations are made the student then determines "reasonable minimum" times for each element, and making the customary allowances for personal needs, usual delays, etc., prepares an instruction card for the operation determining standard time for a given number of parts, and also writes a descriptive report of the study.

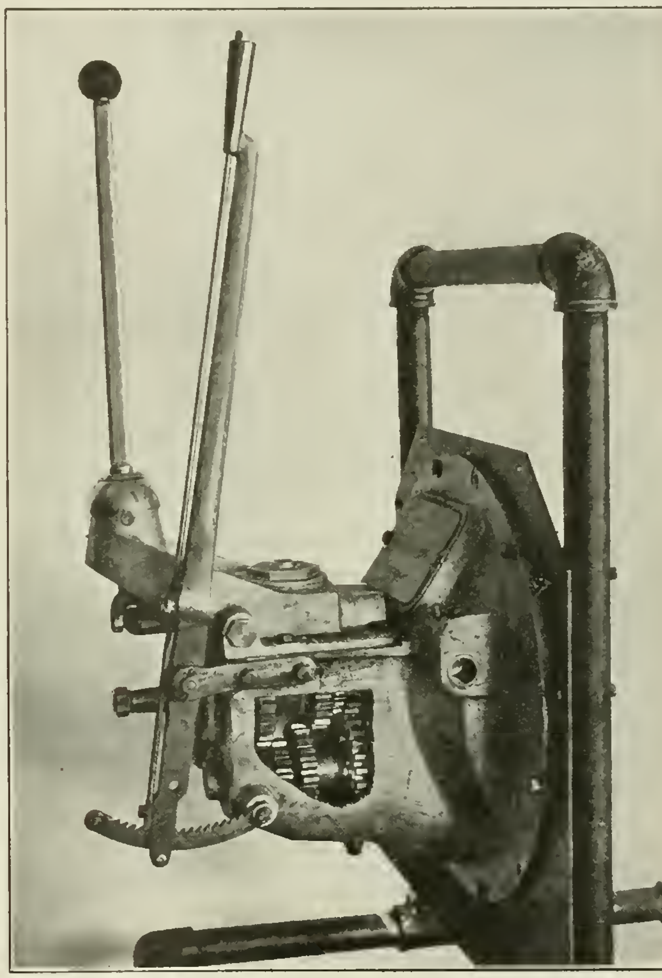

Fig. 1 Automobile Transmission Used as Basis of Student's Mass-Production Problem

Each student makes a time study of operations on perhaps five or six different jobs such as operations on a molding machine, a drop hammer, drills, turret lathes, etc. This work, of course, does not and is not expected to make an experienced time-study man of a student, but it does familiarize him with the taking of a study and stimulates him to a much keener interest in the lectures on the subject which explain the various methods, difficulties, and results of time studies.

A Practical Drawing-Room Course

In the endeavor to develop a satisfactory drawing-room course it soon became evident that specific and definite problems must be used. This was particularly true since the educational problem was one of mass production, a large number of students taking the

Contributed by the Management Division and presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. All papers are subject to revision.

course. As the problems to be taken up were to apply to factories it seemed advisable for each student to have (on paper) a factory to which his problem could apply. Through the courtesy of the Brown-Lipe Company, of Syracuse, blueprints for one of their transmissions and operation sheets for each part were obtained, and each student makes floor plans of a factory to manufacture a definite number of these transmissions. All students can make use of the same data, but since each is designing a plant

Fig. 2 Typical Operation Sheet

of different capacity, each man has a different problem. An automobile transmission was used as the basis of this problem as it was not too complicated and was a mechanism with which practically all students are familiar. Experience has demonstrated it to be a wise choice. One of these transmissions (Fig. 1) was mounted in the drawing room so that all students could acquaint themselves with its design and operation. Each student is supplied with sheets detailing the operations on each part. A typical operation sheet is shown in Fig. 2. Also, as an assistance toward a thorough understanding of the problem, manufacturers' catalogs of all machines used were obtained and made available, each machine number as given on an operation sheet referring to a definite machine. For convenient reference each kind of machine used was given such a number, and data of which the following are typical were supplied for each machine.

Machine No. 1

Double-Spindle Hartness Flat Turret Lathe, 3 in. by 36 in.
Mfd. by Jones & Lamson Machine Co., Springfield, Vt.
Floor Space, 4 ft. by 10 ft.
Rated Horsepower, 7.5.
First Cost, $3800.

While the data by which a student determines the number of machines required in his plant are based on one type of transmission, his plant is laid out as it would be for the manufacture of several types. That is, he does not lay out what would be practically a continuous industry.

The first step in the problem is to determine the number of machines of each kind required. This is accomplished by filling out a chart as shown in Fig. 3. From the operation times as given on the operation sheets the number of hours per month required for each machine, for each part, can be computed, and a summary of vertical columns gives the total number of machine hours per month required of each machine. The shop is assumed to run 210 hours per month. If the machines are assumed to operate on the average 80 per cent of this time, then the average number of hours that a machine will operate per month is 168. Dividing the total of a column by 168 gives the number of machines of that type required. As was previously pointed out, each student is assigned a different number of transmissions per month as the capacity of his shop. For this reason the number of machines determined by each student will vary and in this way each will be working on a different problem.

Having determined the number of machines required, the student draws floor plans for a factory to house the machines. Because it makes a more comprehensive problem, a multi-story type of building is required, constructed in conformity to the requirements of the Industrial Code and Labor Law as to exits, stairways, sanitary conveniences, etc. The machines are located for convenient flow of material and also grouped to assist in proper supervision. The chart shown in Fig. 3 is at this time of considerable value as it shows at a glance where and for what purpose a machine is used.

Organization and Production Control

Having the floor plans and data regarding machines, it is possible for the student to attack a large variety of problems. The first one attempted is to make an organization chart for the management of the shop. The theory of organization has been previously discussed in lectures, and the development of functional (or line and staff) organization, as industries grew too large for line organization, has been explained. In the discussion of organization and organization charts the charts shown in Principles of Industrial Organization, by D. S. Kimball, and charts like those by L. V. Estes which have appeared in *Industrial Management* are very helpful. The student is examined on his knowledge of the duties and functions of each department shown in his chart to make sure he has studied the subject and expended thought upon his work. It is considered far more essential that a student expend thought on his solution of this problem than that he arrive at an ideal solution.

Mechanisms of control and the use of orders and returns are next studied. It is assumed that a customer's order is received calling for some parts which can be shipped from stock and some which have to be manufactured. This originates shipping orders

Fig. 3 Chart Used in Determining the Number of Machines Required of Each Kind

production orders, work orders, material issues, etc. It has been found that the use of charts similar to that of Fig. 4 helps to fix the relation of these various forms in the student's mind.

It is pointed out that a separate work order is issued for each operation on each part or lot of similar parts. The method of handling the issuing of stores and keeping of a balance of stores ledger is explained and the forms usually met with are discussed in detail. The student then devises sample forms such as the following: A requisition, material issue, work order, shipping order, production order, and job time card. He must also be able to trace the path of each one of these forms in its travel through the shop, telling who fills in each item and his authority or reason for doing so; also what information is obtained from each form, by whom, and what uses he makes of it. It has been found that this problem gives the student a very real knowledge of the method of using orders and returns for the control of production; he also

gains a knowledge of good practice in the make up of forms and an opportunity is presented for interesting him in the subject of modern job-time recorders, cost-keeping methods, etc.

Cost Analysis

After several lecturers on the subject of cost finding and demonstration of the fact that accurate costs depend on accurate distribution of expense, the various methods in use for this distribution are explained and the student computes an hourly expense charge by the machine-rate method for each machine in his plant. To determine these rates, the student compiles a chart such as that shown in Fig. 5. Such items as cost of pulleys, shafting, motors, tools, jigs and fixtures, furniture, miscellaneous equipment and supplies, and indirect labor have to be assumed and are given to each student on the basis of the number of transmissions he is to manufacture each month. This problem also presents the opportunity for the student to familiarize himself with the operation of a modern duplex adding machine which he uses for totaling columns, etc., in this problem. During this problem the student also gains a speaking acquaintance with the subject of depreciation, as items of depreciation enter into his computations and he attends a number of lectures dealing with the various phases of this subject. The advantages of a good cost-keeping system are explained, as well as the advantages and also disadvantages of the machine-rate method for distribution of expense.

After studying the subjects of routing, scheduling, and dispatching the student is in a position to appreciate the advantages of the Gantt chart which has been so ably explained by Wallace Clark in his recently published book. Using the standard Gantt chart forms each student makes out man-record charts for several operators assumed to be employed in his plant and covering a period of one month for each. He makes all his own assumptions as to the amount of scheduled work each man does, failure to achieve schedule, etc. Next he makes a machine-record chart for the machines operated by the workmen he has listed in his man-record chart, and the two charts must correctly correspond. Finally he makes a layout chart for these same machines and this chart must correspond in each detail with the other two charts. When a student has demonstrated that he can make out these three charts all correctly correlated, it is fairly certain that he has gained a working knowledge of the use of the Gantt chart.

These are the problems now used in this course. It can be readily seen that many others could be devised. The outstanding advantages of the course are that the student has definite, specific problems to attack which are absolutely general in their application. The knowledge he gains makes a lasting impression, and from the standpoint of instruction his work can be easily and accurately supervised, for while each student's problem differs from that of his neighbor, still they are all based on the same data and the same rules will apply to all.

It might be well to mention the fact that this is a course given to men who are students of mechanical engineering ~~and receive~~ the M.E. degree. All students who are to receive this degree have a common curriculum until the end of the junior year, which includes courses in elementary economics and English. During their junior year they all attend a course of lectures on industrial organization which is elementary in scope. In the senior year those who wish to specialize in industrial engineering take the course outlined in this article together with the lectures which it accompanies and a lecture course in safety and fire protection, and may elect courses in accounting, business law, industrial relations, and related subjects.

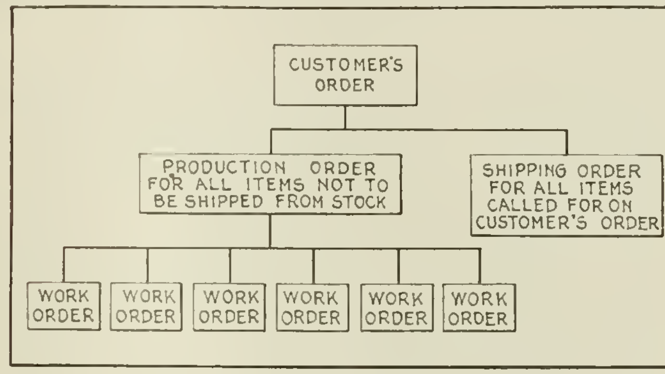

Fig. 4 Chart Showing Disposition of Customer's Order

In teaching this subject the lack of standardization of industrial terminology is an ever-present cross. Even the correct name for the subject itself is a matter of personal taste. Here it is called "Industrial Engineering." Another educator might call an identical course "Industrial Management," "Factory Management" or any of a score of titles. In one plant a certain form is called a "Material Issue," in another the same thing is a "Requisition." The first plant keeps an article in a "Store Room," the second keeps the same article in its "Stock Room." Standardization of nomenclature is certainly a goal worth the effort to achieve, and may the committee appointed for that purpose have all manner of success.

Fig. 5 Type of Chart Used in Determining Machine Rates of the Various Machines in a Plant

Discussion

J. O. Keller[1] submitted a written discussion in which he called attention to the fact that Prof. Hugo Diemer had early recognized

[1] Head, Industrial Engineering Dept., Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

the importance of the propositions set forth in the paper, and as a consequence the course in industrial engineering at Pennsylvania State College, under his able direction, had comprised laboratory courses in time-study work, job routing, factory planning, etc.; and now included such courses in cost accounting, cost analysis, and production control.

His criticism of the course described by the author was that it was largely "cut and dried" and that not enough was left to the initiative of the students, most of his work consisting in the filling in of forms. The course, as he understood it, however, was somewhat limited in regard to time, and to cover so large a field rapidly and effectively some such procedure had probably been found necessary.

George H. Shepard[2] outlined the course in industrial engineering at Purdue University and pointed out that although developed independently, both it and the course at Cornell had evolved along the same lines. In the matter of time study he considered the setting of standard time only one of the objects to be sought. It was of at least equal importance to determine a correct method and to draw up a standard-practice instruction for it. In order that the engineer might be able to do this, it was essential that he should be able to make his own job analysis, and at Purdue they especially avoided giving to the student mimeographed sheets which enumerated the elements of each operation.

In all the work at Purdue emphasis was placed on principles. The characteristic methods of mass production were worse than useless to the jobbing and repair plant, and neither of them employed methods that could be applied to a department store. Yet department stores were beginning to seek industrially educated engineers to serve as the key men of their organizations. Management problems were infinite in their variety, and it was only by doing his own thinking on the basis of general principles that the manager could deal with them.

P. F. Walker,[3] who opened the oral discussion, said that the student training outlined in the paper was identical in many respects with work that was being developed under his supervision at the University of Kansas. It differed most in that in the latter institution an attempt was made to carry the student through the various commercial and business bases of the development of an industry. The points stressed were (1) the market and a sales policy for its development; (2) considerations affecting location of the plant in both general and local aspects; (3) the financial analysis of manufacturing enterprises of various types but with emphasis on machine building, on which the design was to be based. The aim was to plan an industry as to both its commercial and its physical aspects. He agreed with the author as to the value of such courses, for without experience in the actual laying out of plants and in making cost analyses the teaching of plant organization and production control lacked definiteness.

H. Wade Hibbard[4] said that he had three criticisms to offer. The first, which had already been mentioned by others, was on the use of mimeographed sheets which enumerated the elements of each operation to be studied and the time when each reading was to be taken. He believed that a student learned very largely by his mistakes and that everything should not be cut and dried for him. It was the bane of many a large engineering school that so much work of this kind had to be done. His second criticism was as to the use of lantern slides, which gave merely fleeting impressions that were forgotten by the student as soon as they passed off the screen. His third criticism was that the automobile transmission which was used as the basis of the student's mass-production problem was too complicated, and that the principles involved could be better taught by making use of examples of a simpler nature.

J. A. Shepard,[5] speaking from the viewpoint of a manufacturer, commended the cut-and-dried method because, if well devised, it seemed to him to be the most effective way of teaching the best methods to those at the beginning unfamiliar with manufacturing procedure. He stressed the importance of including in such instruction some consideration of the material-handling problems that entered in between the successive processes of production, in order that the student might not fail to provide for material-handling equipment in his building layouts.

F. B. Gilbreth[6] deprecated the use of the cut-and-dried method for the reason that it was wrong to teach students to repeat the mistakes of their predecessors. The time study that had been spoken of was a rule-of-thumb procedure because it determined how long it took to do work but did not determine the method. Time study could be eliminated so far as recording the facts was concerned by using a motion-picture camera for that purpose. Accuracy of time, to his mind, was of secondary importance as compared with accuracy of method. His firm had a very complete collection of films of operations performed by the best demonstration procurable, and these they would be glad to lend to educational institutions for instructional purposes.

John J. Long[7] thought that the cut-and-dried method of teaching could be defended on the ground that it brought to the attention of the untrained student's mind the best practice the instructor knew. Many of the problems of industry were not those of production alone, and he would like to see greater stress placed on the financial and administrative side of industry, particularly with reference to the small shop, for most American shops were those with a personnel of 100 or less.

Dexter S. Kimball[8] said that the thing that was cut-and-dried today might be a totally different thing tomorrow. For many years students at Cornell had been instructed in testing materials in the old way, each one making his own mistakes and repeating those of his predecessors. Then it was decided to make a change and an instructor was accordingly employed who was skilled in the use of the machine and who was able to demonstrate to the students just how a test should be made and how it should be recorded. This had been their practice for a number of years past and, so far as he knew, there were none who wanted to return to the old methods.

The author, in closing, said that he believed any engineer would admit that mass production as it existed today was not essentially a bad thing, and that no one would care to revert to the old handicraft civilization. It was a fact, however, that the problems of mass production were now involved in the instruction of large bodies of students, and he did not believe that the so-called cut-and-dried method was inherently bad. It had been his experience that a student left to himself had an infinite capacity for wandering around and not getting anywhere, and no matter how carefully cut and dried a problem might be, he would make enough of the mistakes that some thought were necessary for him to make in order to succeed as a student.

He was obliged to disagree with Professor Hibbard in regard to the complexity of the basis used in the mass-production problem. An automobile transmission was about the simplest mechanism that could be selected to use in teaching students real manufacturing methods, and in addition it was one with which students were fairly well acquainted. Further, he believed in using lantern slides, for when addressing students he felt it was much easier to make a lasting impression on their minds through the eye rather than through the ear.

He would not attempt to uphold the time-study work of the course in all its features, but it was proper to say that many to whom it had been given in the past had come back and told of the great benefit they had derived from it.

In regard to material handling, no definite laboratory or drawing-room work had been included in the course, largely because of time limitations. However, an endeavor was made to bring out the fact that the layout of a plant was governed largely by the sort of material-handling equipment required in the particular industry for which the plant was to be built.

The Thermal Conductivity of Liquids

Details Regarding Apparatus Employed in a Recent Investigation of the Subject—Difficulties Encountered in Making Tests—Radiation Corrections—Results Obtained and Conclusions Reached

By F. L. KALLAM,[1] LONG BEACH, CAL.

Although the thermal conductivity of liquids has been for a long time a favorite field of research for the physicist, it is still in a very undeveloped and unsatisfactory state. The subject is of profound importance in dealing with problems of heat engineering, and while the present investigation has not progressed far enough to yield definite conclusions, it has nevertheless resulted in the devising of apparatus which is believed to be suitable for obtaining the conductivity of liquids within a reasonable degree of accuracy.

In investigating the conductivity of liquids nothing more than relative values have been obtained, and even the method of arriving at results is often obscure. As early as 1800 Count Rumford showed the low conductivity of water by heating a tube at the middle of its length, boiling the water at the top by convection currents and leaving a chunk of ice at the bottom unmelted.

Despretz in 1838 made a series of experiments with a tin vessel full of hot oil kept at constant temperature floating on the surface of water in a large container, and a series of thermometers one below the other in a containing vessel. In this manner he found that the conductivity of heat in liquids obeys the same laws as in solids, but is much less pronounced. Bottomley in 1881, using a modification of Despretz' method, poured hot water on the top of a mass of water nearly filling a cylindrical wooden tank. Readings were taken from time to time of two thermometers one a little lower than the other, which gave the difference of temperature between the two sides of the intervening stratum, and the quantity of heat conducted in a given time through this stratum was obtained from readings of the temperature of the whole mass of water below on an upright thermometer with an exceedingly long cylindrical bulb extending downward from the center of the stratum in question nearly to the bottom of the vessel. The value for conductivity as determined by this method varied from 5.8 to 6.67 (English units).

Guthrie examined the conductivity of liquids by using two hollow brass cones placed near together, the top of one pointing upward, that of the other downward. The distance separating the bases could be regulated and the liquid to be examined was introduced between them by means of a pipette. The base of the upper cone was kept at a constant temperature by a current of hot water, and the lower cone was converted into an air thermometer by simple methods. By varying the distance between the bases of the cones as well as the liquids introduced between them, and noting depressions of the air thermometer, a measure of the resistance to the passage of heat of different liquids was obtained.

Weber in 1880 used two small copper disks separated by pieces of glass, the space between the disks being filled with liquid; the lower disk was laid on a smooth block of ice whose temperature it rapidly assumed and measurements were made of changes in temperature of the upper disk with a thermoelectrical arrangement. Lees employed the same method with some refinements, but used an ebonite ring to enclose liquid between the disks. On the whole, nothing definitely satisfactory seems to have been developed hitherto in the way of apparatus or experimental methods for the determination of the true conductivities of liquids.

Mathematical Expression for Thermal Conductivity

When convection is eliminated, the formula embodying the coefficient of thermal conductivity may be deduced in the same manner as for solids.

If Q = B.t.u. flowing per square foot per hour

$T_1 - T_2$ = temperature drop in deg. fahr. between two planes cutting the liquid parallel to each other, and perpendicular to the direction of flow

A = area of section through which heat flows, sq. ft.

S = time of flow in hours

L = depth of liquid or perpendicular distance between two planes, in.

k = conductivity of the liquid in B.t.u. per sq. ft. per in. per deg. fahr. per hour

then

$$Q = \frac{k(T_1 - T_2)AS}{L} \quad \text{or } k = \frac{QL}{(T_1 - T_2)AS}.$$

If it is assumed that k is a straight-line function of temperature, the mean conductivity between any two points is the arithmetical mean of the conductivities at these temperatures. But throughout

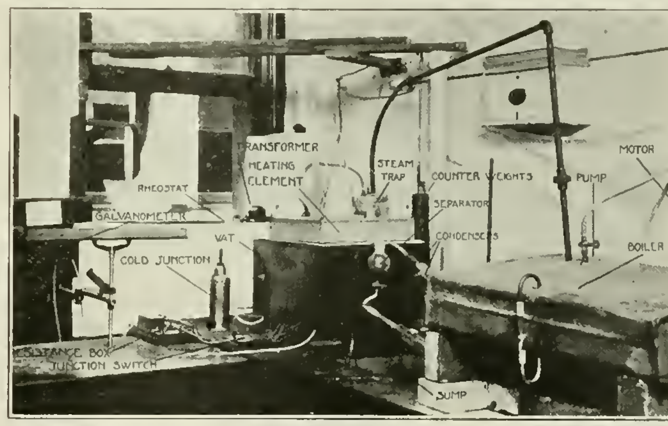

Fig. 1 General View of Apparatus Used by Author in Investigating the Thermal Conductivity of Liquids

this investigation K the mean conductivity is taken as k for the sake of simplicity.

Principles of the Apparatus

In studying thermal conductivity, convection currents must be eliminated. Therefore it is quite certain that the liquid to be tested must be heated at the top.

The material of the container must have a lower conductivity than that of the liquid to be tested or heat will be transmitted through the walls of the vessel faster than through the liquid, and this will lead to convection currents. Hence a material such as wood must be chosen for the container.

The quantity of heat transmitted to the liquid must be known and this would be readily obtainable by supplying the heat from steam at atmospheric pressure and measuring the amount of steam condensed. Hence the use of a steam heater follows. To avoid the complication of radiation losses, the heater must be jacketed with steam at the same pressure and temperature except where it is in contact with the liquid to be tested, so that all the heat released by condensation will pass into this liquid.

Temperatures must be known at different strata instantaneously, and with the strata close together thermometers are eliminated not only on account of lag but because of mechanical difficulties.

The apparatus is based on these principles and the method employed may be briefly described as follows:

The liquid to be tested is placed in a vat, which is itself a poor conductor and which contains thermocouples at known strata.

Heat is supplied to the surface of the liquid by means of a steam-jacketed bath, the vapor being at atmospheric pressure. The amount of heat liberated is determined from the condensate collected. Hence, knowing the vat dimensions, the temperatures at different strata, strata depth, and heat generated, all for the same period of time, the thermal conductivity is readily obtained from the formula

$$K = \frac{QL}{(T - T_2)AS}$$

Description of the Apparatus

The apparatus is illustrated in the views and diagrams of Figs. 1 to 4, inclusive.

Temperature Measurement. Avoiding thermometers of special and complicated construction, thermocouples of copper-constantan were employed, the junctions being welded into the form of a bead. To support these junctions at the proper locations within the vat, the couples were run through a $^1/_8$-in. glass tube, care being exercised to make a good seal between the wire and the glass. A direct-reading galvanometer of the R. W. Paul reflecting type was found to be a simple and effective measuring instrument. The thermocouples were arranged in the center at intervals of approximately 1 in. from top to bottom of the 7 in. depth of the vat. At the point of contact of heater and liquid five couples were used, and the same number at 1 in. lower depth. From this point to the bottom only one couple at each level was used. A seventeenth couple, not fixed as to location, was used to explore temperatures of the container. As it was impossible to place the junctions exactly one inch apart and it was necessary to measure accurately the actual distances, a single cold junction was provided for the seventeen couples and suitable connections were made so that each couple could be put in series with the galvanometer at will.

Calibration was made in place, with the cold junction kept at 32 deg. fahr. and the water in the vat heated by means of two electric heaters. To make the temperature in the vat uniform the water was agitated with a paddle. Throughout the investigation the cold junction was kept at 32 deg. fahr. by the use of cracked ice within a thermos bottle.

The Vat. The vat containing the liquid to be tested is constructed of $1^1/_4$-in. redwood, with a cross-section of exactly one square foot for facility in calculation. Holes are provided for the insertion of thermocouples at vertical intervals of 1 in. The bottom tapers to a drain plug at the center.

Calked joints and waterproof coatings are provided to secure perfect watertightness. A small glass tube is used to see that the water in the vat is always at the proper level. It was thought that the vat was suitably constructed to prevent excessive radiation losses, but it was ultimately found necessary to enclose it in a radiation jacket, in the form of a slightly larger second wooden box so as to provide a dead-air space around the vat proper.

The Heating Element. As shown in the figures, the heating element consists of two parts, the heater or bath proper and a jacket. The heater is exactly 1 ft. square so that it fits snugly into the vat. The entire heater and the surface in contact with the water is of copper, used because of its high conducting power. The heating surface is not exactly flat but is somewhat dished outward, for the purpose of forcing out any air which might otherwise be trapped between the vat and the heater when the latter is first placed in contact with the liquid. The dished bottom also serves as a sump for all steam condensed. A $^1/_8$-in. brass tube having a right-angle turn is so placed within the heater that it dips down to the bottom of the sump. The end of this tube is flared, with four notches cut in its edge, thus affording what might be termed "feet."

29 Pump suction

These are soldered to the dished copper bottom, which leaves four openings in the tube. The latter rises $^1/_4$ in. and then runs parallel to the heater bottom, passing out at the side at the same elevation. Thus, by applying suction at this outer end, the condensate within the heater may be removed. The arrangement of the heater can be studied more closely in the figures. It should be noted that the bottom of the heater is free from the jacket, projecting down into the liquid for good contact. The steam line is divided, part going into the heater and part to the heater jacket. A suitable steam separator is provided at the lowest point in the steam line and as close to the heater as possible. In using the apparatus it is necessary to have the heater and jacket fully heated at the start of the test, hence steam cannot be passed through the heater when it is in contact with the liquid to heat the metal up to working temperature. To facilitate such heating, both the trap and heater are suspended by cords over pulleys and attached to the same counterbalancing weight. Thus they may be readily removed from the test position to a location where they may be heated without affecting the liquid to be tested.

The Condensate Separator. In removing the condensate from the heater there is a possibility of some steam being taken along with it. As the condensate proper is a measure of the heat put into the liquid tested, it must not be contaminated with free steam which has been condensed after leaving the heater. For this purpose a separator is placed as close to the heating jacket as possible. This is nothing but a tee made of glass tubing, with the third leg vertical and connecting directly to a glass chemical separating funnel. The entire tee is covered with magnesia. By means of this tee any steam drawn over passes over the third leg and passes on to the condenser and pump, while the condensate proper, being of greater density than the steam, flows into the third leg of the tee and on to the funnel, where it collects. Suction must not be applied too rapidly or else the condensate will skip the third leg and take the steam route. Before collection in a calibrated vessel the condensate is cooled to prevent possible evaporation due to its high temperature.

Manipulation of the Apparatus

In starting a test the heating element is raised and steam passed through the system. This is continued until both the jacket and bath thermometers indicate 212 deg. fahr. Any steam condensed in the heater must be completely removed, and for this purpose an atomizer was found to give the best results. The vat must be completely filled with liquid, so that when heater is lowered in contact with it, some of the liquid will be forced over the top. This insures good surface contact with the heater. With the heater in contact with the liquid, the test starts. The separator must be instantaneously connected to the heater and the two condensers put into operation. Just prior to placing the heater in contact with the liquid, initial readings on the 17 couples, the two heating-element thermometers, the room-temperature thermometer, and the graduated condensate vessel must be taken.

Difficulties in the Tests

A large number of tests were made but only three are recorded in the report of the investigation, the others being discarded because of such difficulties as inability to maintain constant temperature due to lack of steam, leakage at the entrance of the glass thermocouple, tubes, and short-circuiting of the thermocouples. The vat rapidly deteriorates and at the end of a certain time becomes unfit for use. Blisters are formed on its exterior coating due to water which seeps from the interior. This is a sign that the vat is becoming waterlogged and the temperature of the liquid under test ceases to increase because water flows through the sides of the vat in small streams. Hence in using a wooden container some preparation must be applied to the interior which will prevent the liquid from coming in contact with the wood. No suitable material has yet been found, and the only remedy is to dry out the tank for two weeks when it becomes waterlogged. Intermittent working of the suction pump must be avoided, and other minor difficulties are inescapable.

Radiation Corrections

Even when the vat is jacketed, corrections must be applied to cover radiation losses. To secure these corrections the following procedure is employed: The water in the vat is heated to the boiling point and a calibrating lid is placed in position; this lid is merely a cover of the same material as the vat, through which five thermometers project into the water. Temperatures are taken from time to time, and the temperature of the bath is plotted against time. From this curve the rate of cooling at different temperatures of the vat is obtained, measured in degrees of drop per hour. The readings of the thermocouples are appropriately corrected for this drop when computations are made. The corrections are not absolutely accurate, since in determining radiation losses the temperature of the water in the vat is uniform, whereas in the conductivity tests there is a temperature gradient. The correction is of course always added to the readings of the thermocouples.

Computations

The data obtained in the three final tests are elaborately set forth in the report in tables and curves where temperatures at various depths are plotted against time. It is only after three hours of testing that the temperature difference between strata tends toward uniformity. For this reason the temperatures corresponding to

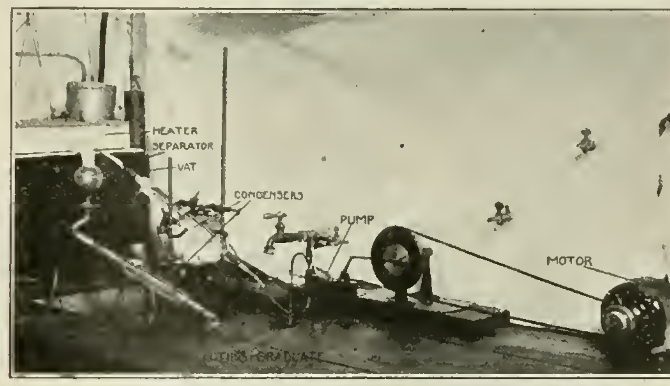

Fig. 4 View of Part of Apparatus with Boiler Removed, Showing Pump and Motor

3, 4, 5, and 6 hours are selected and arranged in a special table (Table 1) after corrections have been made for radiation losses.

From Table 1, temperature is plotted against the depth for con-

stant times as shown in Fig. 5 for the second and third of the three tests accepted by the author. The area under these curves must represent the total heat put into the liquid up to the time in question, since the ordinates represent degrees and the abscissas volumes of water, which can be converted into weight by multiplying by the density corresponding to the average temperature. This obviously gives the heat required to raise a mass of water a certain number of degrees in a given time. Thus the area included between the

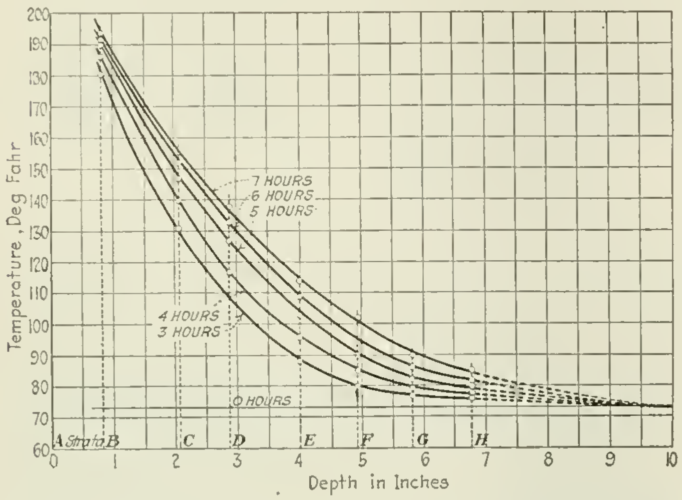

Fig. 5 Total-Heat Curves Relating Temperature, Depth, and Time

(Tests Nos. 2 and 3. Computed for a temperature gradient of $(T_1 - T_2)/L = 17$ to 24.)

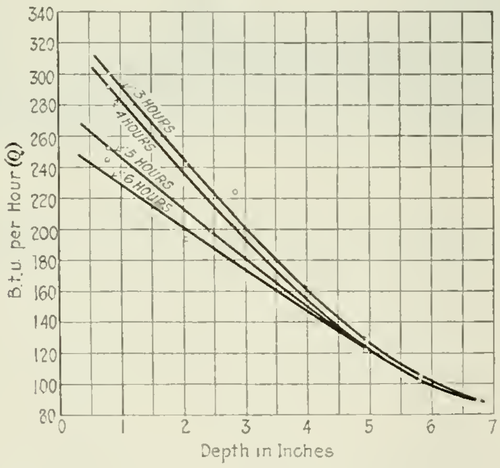

Fig. 6 Heat-Flow Curves Derived from Total-Heat Curves Where $(T_1 = T_2)/L = 27$ to 24

3-hr. and 4-hr. curves is the amount of heat put into the liquid between the third and fourth hours of the test.

In this connection, it will be noticed that the curves of Fig. 5 are extended past their lowest temperature point down to the initial temperature of the water by continuing them smoothly with dotted lines. The author believes that this assumption will yield more nearly correct results than can be obtained by stopping the curves at the lowest temperature reading.

By taking the area between any two time curves starting at any desired depth and planimetering the area for the remaining depths, the heat-transfer rate at the initial depth is found in B.t.u. per hour. This gives Q in the formula direct. Fig. 7 derived in this manner gives the heat-transfer rate at each of the desired strata for the representative tests 2 and 3.

As regards the unit of heat corresponding to a given area in Fig. 5, one inch along the axis of abscissas represents a rise in temperature of 20 deg. fahr. One inch along the axis of ordinates represents 1 in. of depth, which is equivalent to $^1/_{12}$ cu. ft. of water inasmuch as the vat has a surface of 1 sq. ft. From this it follows that 1 sq. in. of area represents 104 B.t.u.

Although some corrections have been made in these curves for radiation losses, a further correction should be made by comparing the rate of heat delivered to the liquid in the vat with the rate of supply from the steam condensed—which may readily be computed from the weight of condensate and the latent heat at the given pressure. The condensate method gives approximately 1.16 times the total heat that the graphical method does and values of conductivity should be multiplied by 1.16 accordingly.

After this work has been performed it is possible to determine the thermal conductivity K from the previously developed expression

$$K = \frac{QL}{(T_1 - T_2)AS}$$

For example, we shall compute K for tests 2 and 3 between strata B and F, the distance between the two being 4.13 in. Also we desire K at the end of 3 hr., at which time T_1 = 180 deg., T_2 = 100 deg., and Q, the rate from the curves of Fig. 6 for 3 hr., is 300

Sectionalization and Remote Control of High-Pressure Steam Lines

By PETER PAYNE DEAN,[1] STAMFORD, CONN.

This paper is intended to bring out need of protection other than that of hand-operated valves for high-pressure steam lines in case of failure of pipe or fittings, and deals with the remote operation of various types of valves by electric motor or steam piston in order to quickly and safely stop escaping steam. It is based on a careful study of valve construction and methods of power operation made by the author during the last few years, and on experience gained with a large number of electrically operated valve installations which he has designed and placed in practically all of the important power-generating stations in the country, and gives particulars regarding the construction of various protective devices, valves, and motor-control systems that are available.

STEAM pressures as high as 350 lb. per sq. in. with 700 deg. fahr. total heat are now frequently encountered, and no doubt 500 lb. will soon be standard practice. Under such pressures every piece of valve, piping, and fitting metal will be subjected to an excessive strain, which, when coupled with high temperature, may produce a result akin to metal fatigue, about which we have very little knowledge and even less experience. Further, no safe standard has been universally adopted for 500-lb. steam fittings, bolts, flanges, expansion loops, etc., but this will very probably come after more exhaustive time tests.

The protection of human life, however, should be the first consideration, and after that, continuity of plant operation and protection of property; and surely all will agree that protection beyond that found in the average plant is necessary. We can only make every attempt to prevent failure by careful design, and then provide, as a matter of safety, the best possible safeguard if it does happen. Those who were present at the tests made at the Essex power station of the Public Service Co., Newark, N. J., on January 28, 1922, and watched the spectacle of high-pressure steam calmly blowing to atmosphere at a velocity of over six miles a minute, do not need to draw much upon their imaginations to visualize the damage that such a discharge would do in a boiler or turbine room.

Location of Master Valves

The master valves should be those nearest the boiler, and either the automatic stop checks or gate valves in the boiler lead. Valves at this point protect the complete piping system and would not be affected by mechanical movement of a broken line, which would possibly throw excessive strain on a gate valve, causing it to jam. Automatic stop-check and boiler-lead gate valves are seldom above 10 in. in diameter and without doubt can be closed in from fifteen to thirty seconds, so that any or all of the boilers may be cut out at will.

Unless all the boilers are isolated there would be a reverse flow from the header back through the break, so that a master valve is also necessary in the boiler lead at the header, which in any event is usually included. Closing both the boiler-lead valve and this last-mentioned valve completely isolates one boiler.

Boiler-lead valves are suggested for three very good reasons:

a They protect the whole system of piping from the superheater and are well located for power operation

b If a bad fracture should occur, it would be almost useless to endeavor to locate it and sectionalize the header to stop the flow, on account of the tremendous volume of condensed steam and consequent confusion

c There is no certainty whatever that header valves above 12 or 14 in. in diameter will close under open-end conditions on account of their construction to withstand such strain.

The principal argument against emergency closing off of the boilers is that the plant would be completely shut down. In the author's opinion, if a bad break occurs its location cannot be determined until almost the entire steam supply is stopped. As soon as the break is located, the sectionalizing valves may be brought into play and the boilers quickly brought back on the line.

Even though large header valves can be closed from a distance, the author nevertheless believes that the quick and safe way is to shut off the boilers in sections until the break is stopped. Incidentally, with any remote-closing scheme the boiler safety valves should be piped to a header and blown to atmosphere, as in the event of a boiler shutdown they would all blow together. Some arrangement also of an auxiliary header should be worked out to supply the boiler-feed pumps, as well as a scheme for shutting down the draft fans. Power-operated header valves of large diameter may be depended upon to stop a very bad fitting blow or gasket leak, so for this reason and also for convenience of operation they should be provided with remote control.

To close an 18-in. high-pressure gate valve requires two men

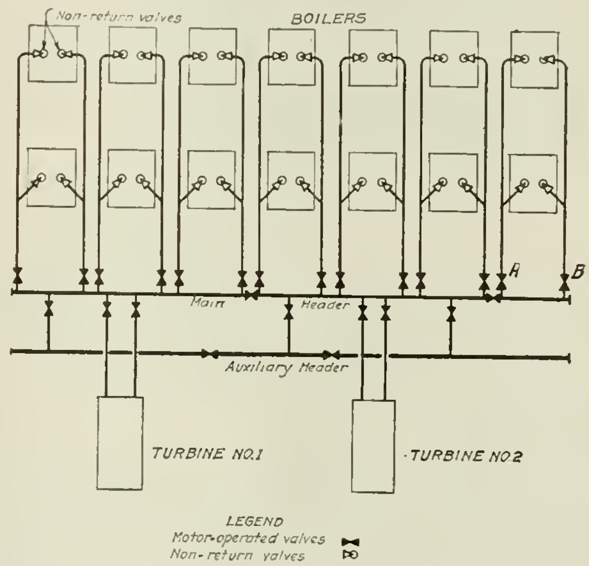

Fig. 1 Boiler and Piping Layout of a Power Station in Which Electricallly Operated Valves are Employed
(Colfax Station, Duquesne Light & Power Co., Pittsburgh, Pa.)

for a period of at least fifteen minutes, including transit to and from the valve, not to mention the physical effort necessary and the danger of penetrating a steam-laden alley with very uncertain conditions under foot. Great care is taken to see that main-line valves are tested for tightness and that they are strong and rugged, presumably for assurance that they will not fail during operation or when an emergency arises. Who knows, however, whether they can be even reached in case of trouble? Therefore, why not turn them into real protective devices by providing remote control? It should not take much of an argument to convince those in charge of expenditures that is worth the money.

Fig. 1 shows a typical existing boiler and piping layout in which electrically operated valves are employed. Complete isolation of one boiler from the line may be made by closing any pair of valves *A*, *B*, either singly or from one switch, but this of course leaves the boiler-lead lines unprotected. Further protection may be accomplished by electrically operating the non-return valves shown and closing them together with valves *A*, *B*, in order to prevent reverse flow from the header.

Fig. 2 shows a similar system wherein the boiler-lead valves may be closed separately and the main and branch-header valves used for sectionalizing.

Contributed by the Power Division and presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

Remote-Control Location

Since any remote-control system must of necessity be electrical, the design and placing of a central switchboard must be carefully thought out. The location should be as near the main means of exit as possible as plant operators in case of trouble will move toward this point. With the open air in view, a man is more apt to regain his composure and presence of mind than when called upon to act hurriedly and then bolt for his life.

Such stations should never be placed in steamproof vaults adjacent to the boiler room and without means of safe exit. They will be useless in emergencies as the operators will not travel in that direction.

The operation of switches to shut the valves should be as simple

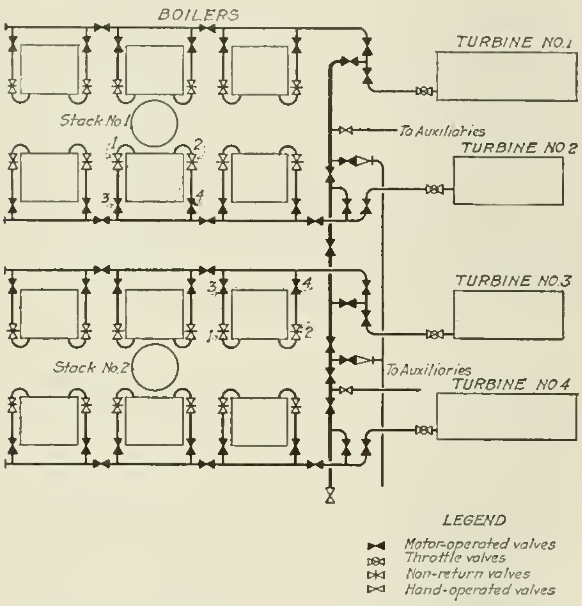

Fig. 2 Boiler and Piping Layout in which the Boiler-Lead Valves May be Closed Separately and the Header Valves Used for Sectionalizing

(Hell Gate Station, United Electric Light & Power Co., New York.)

as possible, preferably by breaking a protective glass window and pushing a button.

Under no consideration is it safe to open master valves from a remote point which may be opened locally, either by hand or electrically. In order to allow the operator to see exactly what he is doing, the face of the valve-control switchboard should be provided with a plainly marked miniature representation of the complete station piping, with push buttons to represent the valves. Red and green indicating lights should be provided to show whether the valves respond and to show the general position of the valves in the complete system.

Types of Master Valves

There are two types of quick-acting valves, the straight triple-duty, and the piston-operated trip valve, both of which are of the globe type. The former is a combination of non-return, stop and "automatic closing on drop of line pressure," performing therefore the three duties. Engineers have not taken kindly to line protection upon drop of pressure; therefore the third duty is operated by an electrically controlled pilot valve admitting steam on top of the closing cylinder. Such a valve and its auxiliary pilot are shown in Fig. 3. This valve depends upon the excess-area piston forcing the disk to its seat against the pressure.

The straight trip valve closes with the pressure and is remotely operated by a solenoid magnetic latch. It is used mostly as an additional emergency turbine stop upon overspeeding, being placed in the turbine lead between the header and throttle trip valve. On account of its somewhat complicated construction, it is hardly suitable for line protection. The triple-duty remotely controlled valve would seem to be the logical type for quick closing, provided that it can be made to close against the extreme velocity which would result with an open-end line blowing to atmosphere and would possibly reach 50,000 ft. per min., depending upon the friction loss in the pipe between the header and the boiler. The action in this case would not be that of a non-return automatic check valve which actually closes due to the reverse flow, but the disk would be forced on to its seat against an extreme velocity in the opposite direction and the action would be somewhat akin to that of stopping a high-pressure nozzle with one's finger. Valves of this description are generally closed by pressure being admitted to the top of the excess-area piston, but test data on closing under extreme velocity conditions do not seem to be available, and until they are, much cannot be said.

A high steam discharge is very apt to carry over slugs of water, and there may be some doubt as to the advisability of instantly closing a valve under this condition. It would seem that a closing time of ten to fifteen seconds would be safer.

Motor-Operated Non Return Valves

Electrical operation of non-return valves was first suggested by the author and has been adopted by many leading engineers. The operation is the same as that required on the triple-duty design, with the exception that the valve stem is driven by a motor provided with reduction gearing, as shown in Fig. 4. Their action under most extreme conditions is positive, provided that the motor control is of the proper design and application. The valves are ideally located with respect to line protection, being directly at the superheater outlet and where vibration due to the whip of a broken boiler lead would not be excessive on account of the valve being securely anchored. They close easily under normal conditions, and for emergency closing should be provided with ball thrust bearings to eliminate the closing friction as much as possible. The control unit should be bolted directly to the yoke and geared to the stem through the yoke nut, which is of the rising-stem type. The travel of the disk is not more than one-quarter of its diameter, so that quick closing is possible. Although ruggedly built this valve will not stand much jamming, and therefore calls for a special type of motor control to prevent it.

There is only one safe point of closing, and that is when the disks and seats are in perfect contact; to effect this the motor drive should have an automatically operated mechanical clutch completely disconnecting the high-speed armature and gears from the motor at the moment of closing, thus eliminating its momentum and allowing the motor armature to freely come to rest. Without this clutch the limit switch must be set to stop the motor before the valve reaches its seat, and a certain amount of drift due to the momentum of the armature and gears must be depended upon to seat the valve.

This drift depends upon the resistance to closing, which distinctly varies with line conditions; for instance, when the valve is closed with balanced pressure and there is no flow in the boiler-lead line, there is no resistance to the disk and the electrical limit must be set to trip just at the point of closing so that the disk can drift into its seat.

Assume, then, an open-end pipe condition with steam blowing to atmosphere during which the disk encounters excessive resistance. The moment the electrical limit opens, the velocity will overcome the momentum and act as a brake, thus causing the motor to stop instantly and before the valve is actually seated.

The non-return or globe valve must seat tightly and has no leeway to travel as has a gate valve. Therefore it should be made to seat tightly under all conditions and without jamming or strain.

Types of Gate Valves

The Essex station tests showed that valves of this description up to 10 in. in diameter may be safely closed under emergency conditions, and from a careful study of their behavior it seems safe to recommend them for line protection up to 12 and 14 in. in diameter. Data on emergency closing of valves of above this size and up to 22 in. are not available and the safest construction would be to machine the guides, provide the yokes with ball bearings, and attach a control unit of extra large capacity. Valves of this size are used generally for line sectionalizing, and no attempt should be made to close quickly. A typical electrically operated boiler-lead valve is shown in Fig. 5.

Table 1 shows the speeds of closing recommended under various

conditions that have been standardized by most of the valve manufacturers.

For emergency closing with an unknown direction of steam flow in the line, there seems to be little choice as to the type of gate-valve construction between the solid-wedge taper seat, the split-wedge taper seat, and the parallel-seat Hopkinson type. A valve of each type was tested at Essex station and examination showed that none of them was excessively affected by the strain.

For steam lines with one direction of flow, such as boiler and turbine leads, the Borsig type is particularly well adapted as the steam flow assists in closing and against a minimum of friction. It has the advantage of minimum pressure drop on account of the straight opening and may be quickly closed by motor operation up to large diameters. The motor-control apparatus need be only of sufficient capacity to open the valve under balanced conditions. This type is used extensively abroad in place of globe valves and a 6-in. Borsig valve that was tested at Essex operated satisfactorily under emergency conditions.

Motor Control

There is hardly a piece of machinery in the power plant that is subjected to such extreme operating conditions as the motor-controlled valve:

a It is usually located in an out-of-the-way gallery and covered with coal dust, and in a temperature ranging between 150 and 165 deg. fahr. which necessitates special heatproof motor-coil insulation

b It is thrown directly across the line without the aid of starting resistance so that the full voltage is impressed upon the windings, and at the same moment the motor may be called upon to exert its maximum mechanical effort in unseating a tightly seated valve

c It must be small and compact, automatically lubricated, and entirely steamproof and waterproof

d Periods of inoperation range from a minimum of one week to, say, three months, during which time plant conditions may be such as to prevent its operation; and it is expected to function perfectly, even though it has not been tested over this extended period

e Steam from a leaky gland may be allowed to blow freely on the control unit for an indefinite period, and to withstand this it must be impregnated

f In case of piping rupture it is more than likely to be enveloped in condensed steam, and just at this time it will be called upon to exert its maximum mechanical effort to close the valve.

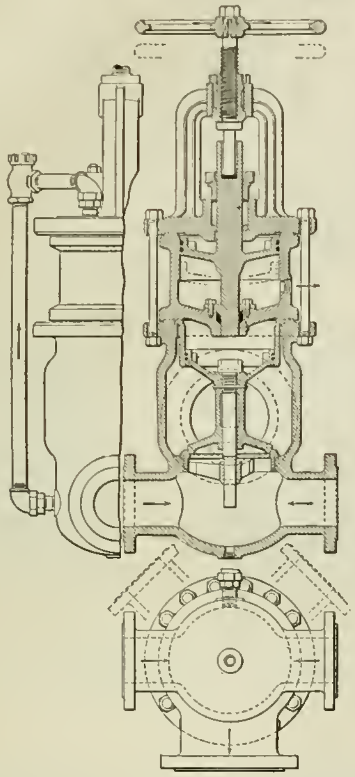

Fig. 3 Cross-Section of an Emergency Piston-Operated Steam Stop Valve

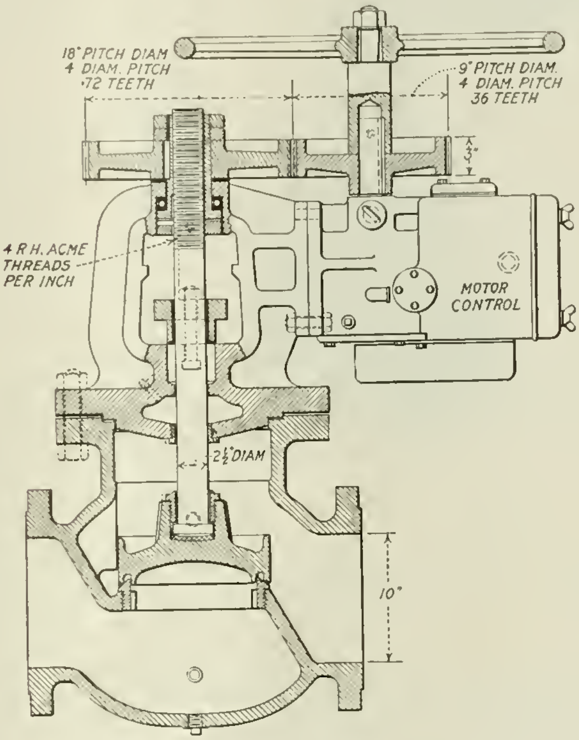

Fig. 4 Cross-Section of an Electrically Operated Globe Valve Provided with Ball Thrust Bearings

The duty on such equipment is extremely severe and without doubt necessitates much special construction. The motor must be of the totally enclosed type and provided with ball bearings of excessive diameter. It should be bolted directly to the reduction-gear casing, leaving no coupling or high-speed shafts and bearings exposed. It should be series wound with such characteristics that it will automatically slow down upon the application of load caused by the valve disk passing into the seat. This is the surest means of protection against cutting of the disk and seat rings.

The reduction gears should be of heat-treated steel, on account of their compactness and the excessive strain that may be applied and should be continually immersed in oil. Any oilless or self-lubricating type of bearing for either the motor or slow-speed shaft should be avoided on account of its inability to withstand excessive heat, long periods of rest, and the accumulation of dust in the bearing.

On account of the excessive drift of the motor armature and gears after tripping, a declutching device should be provided to enable the valve stem to be stopped automatically at a predetermined point without jamming. In the same casing should be provided a self-contained electrical limit which is capable of breaking the main motor current without arcing and so geared that operation of the valve by hand will not throw it out of adjustment.

The casing should be provided with one conduit opening arranged for making a steamproof joint between the internal connections and the line and all internal connections should be of asbestos-covered heatproof cable.

Control of the valves may be effected from either one point or from multiple points by the aid of a totally enclosed dustproof reversible drum switch capable of reversing the armature connections.

The stations should be provided with lamp indication showing the full open and closed positions of the valve at all times. Such a control switch should be provided with a lock, an emergency glass window, and hammer. For multipoint control an interlocking system should be provided so that the first operator to reach a valve will have full control even though other control stations are operated at the same time and in reverse directions.

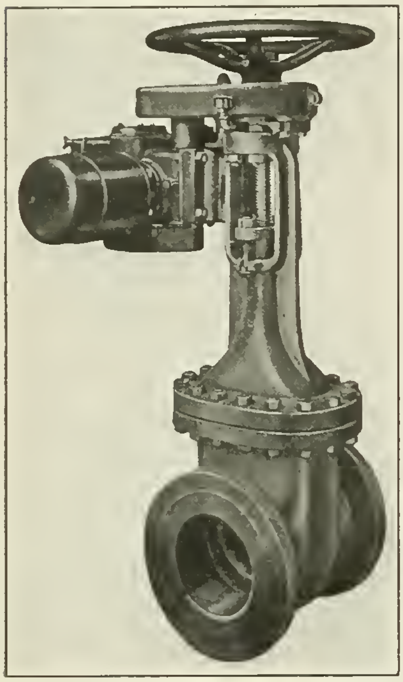

Fig. 5 Typical Electrically Operated Boiler-Lead Valve

In every case both poles of the electrical circuit should be interrupted when the switches are in the "off" position. Single-pole break is dangerous, as a ground may cause the valve to either open or close and produce very serious inconvenience.

Voltage. A valve control system should be connected to the most reliable source of current in the station, which is either the direct current exciter or switch control battery circuit, as it is equal in importance to any piece of auxiliary machinery. The voltage should not exceed 250, firstly because direct-current battery circuits of this voltage are standard, and secondly, because higher voltages would cause an unnecessary strain on the very closely packed windings. Valve motors are thrown directly across the line without resistance and encounter at the same moment their full mechanical strain due to a tightly seated valve.

Control-Station Location. Each valve should be provided with a local control station, mounted at some point from which opening and closing the valve may be observed. Preferably there should be two points of control for each valve, one in the boiler room close to the door leading into the turbine room, and the other at a safe point unlikely to be affected by steam flow. Where a centralized control board is adopted, the second point of control may be mounted in the turbine room, and for the closing of the turbine lead valves the control may be mounted on the turbine gage board.

Conduit and Cable. All conductors should be suitably protected by fuses having a capacity equal to the full-load starting current of the motor, and fuses rather than switches should be provided for disconnection. The cable should be chosen according to the location, and for the operation of high-pressure super-heated steam equipment, cable should have an asbestos heatproof covering.

It is a good plan to end the rigid conduit within 3 ft. or so of the control unit, and from that point use a flexible loop of Greenfield or similar duct. This will allow considerable vibration in the pipe line without affecting the cables, and will further enable the control unit to be freely moved.

Hand Operation. Handwheels should be provided in case of failure of current supply. No declutching device should be installed between the motor and valve which destroys the relative position of valve and motor mechanism. A properly designed and cared-for valve-operating system, especially in a power plant, need never fail, and in case of possible failure at a critical moment the valve may be closed by the handwheel, through the gears and motor, in almost as short a time as when the parts are disconnected. The great danger of a declutching device is that it is very apt to be left disconnected with no means of showing its position at the control station, and that it introduces a non-foolproof feature by providing a piece of mechanism that can be tampered with by any unauthorized person.

If such a device is insisted upon, it should be a self-contained part of the mechanism and operated externally by the aid of a wrench. Further, it must be so arranged that positive indication of its position must be noted on the indicating lights at the control station.

Periodic Tests. Every electrically operated valve should be opened and closed at least once a week, preferably under load conditions if possible, and an examination of the internal parts should be made at least once a month and all records of such tests and examinations kept on file.

The Author's Control System

The Dean control system of valve operation was designed exclusively for the operation of valves, and since it embodies all the

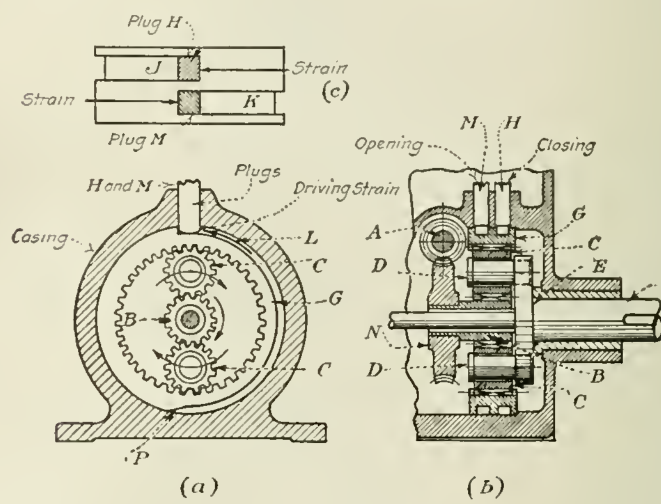

Fig. 6 Mechanism of One Type of the Author's Valve-Control Unit

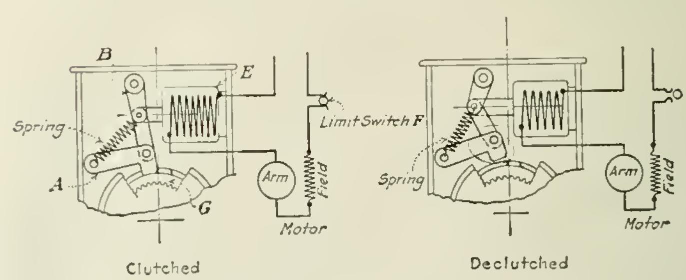

Fig. 7 Sketch Showing Principle of Operation of a Second Type of Valve-Control Unit

features that have been enumerated, only a brief description of its mechanical operation will be given.

The type E unit consists of a driving motor, reduction gears, and limit trip mechanism mounted in a single case. The feet of the unit are provided with four holding-bolt holes of standard dimensions for a given range of valves. Four standard units cover the complete line of valve sizes in use.

The motor is totally enclosed and steamproof, and possesses an extremely high torque. It is connected to a system of combination worm and planetary gearing for the necessary reduction in speed. The motor speed is normally 1600 r.p.m. and that of the slow-speed shaft 40 r.p.m., the gear reduction being 40 to 1.

The motor shaft is coupled to the worm shaft A (see Fig. 6) both running in ball bearings, and the worm wheel N is keyed to a sleeve forming the sun pinion B of a planetary gear. The planet pinions C revolve on large studs D forced into a flange E

forming part of the slow-speed driving shaft *F*, and these pinions mesh into the internal gear *G* forming the outer member of the planetary.

Fig. 6 (*a*) shows the assembly of the planetary gear, the external member or internal gear of which is marked *G*. The center or sun pinion *B* is caused to revolve by the motor, and this pinion turns the planetary pinions *C* and shaft *F* in the direction shown. The outer member or internal gear *G* is free to revolve on a machined surface in the casing, but is restrained from doing so by two plugs *M* and *H* which also pass through the casing in the manner shown.

Fig. 6 (*c*) shows another view of the outside surface of the internal gear *G*, and it will be seen that this surface is provided with two peripheral channels, one extending half-way around in one direction as shown at *J*, and the other in the opposite direction as at *K*. When both plugs *H* and *M* are in, or in the locked position, the internal gear *G* cannot move, therefore with the sun pinion being driven by the motor, the planetary pinions must turn on their own axes and travel around the internal gear, thus also moving the flange *E* and drive shaft *F*.

Referring again to Fig. 6 (*a*), let it be assumed that the valve is closing and the plug *H* is restraining the movement of the internal gear which tends to move in the direction indicated by the arrow *L*. At a predetermined moment when the valve is tightly closed, but not jammed, this plug is quickly withdrawn from the slot by a special cam movement, and since there is no friction now restraining the movement of the internal gear, it is of course free to revolve in the direction shown.

At the precise moment of withdrawing the plug the electrical circuit is interrupted by the limit switch and the drift of the motor coming to rest is taken by the internal gear revolving in its casing. Experiments and practice tend to show that the motor comes to rest after the internal gear has traveled about half a revolution. Should any further drift take place, the plug *M* is automatically moved upward by the moving tapered stop *P* in the groove, which operation does not open the electrical limit.

It will be noted that the plug *M* is still in the other slot. During the opening of the valve the motor will of course be reversed, and the internal gear will have to revolve in the opposite direction before the plug *M* comes in contact with the stop. This provides a hammer blow which is sometimes necessary to open a tightly seated valve, but it is by no means essential as the motor has sufficient torque with which to operate the valve under all conditions.

It is very easily seen that the moment one of the plugs is withdrawn, the slow-speed drive shaft stops instantly and that it can only stop at exactly the same point during every operation, quite irrespective of load or friction. Thus the valve gate is never jammed.

The valve gate is made to seat tightly, under power, and to a predetermined point, drift and overtravel being disregarded as a means of seating the gate.

Tachometer readings show that at the moment after tripping, the motor armature speeds up considerably before the electrical limit contact is broken, which indicates that the load is released prior to the interruption of the circuit, in this way eliminating arcing.

The gearing for speed reduction is encased in a cast-iron housing partly filled with oil, so that the gears are always well lubricated. The limit mechanism is contained in a separate part of the housing and provided with a removable cover.

The type M or magnetically operated improved Dean system as shown in Fig. 7 (*a*), is very similar to the type E design with the exception of an improved limit and method of releasing the restraining plugs. In place of the plugs *H* and *M* as shown in Fig. 6 (*b*), a restraining pawl *A* is provided which is held in the operating position by an energized magnet *E* connected in the main electrical circuit. At the moment the electrical limit switch trips at the end of travel the spring-operated toggle *B* is broken and the restraining pawl *A* instantly releases, allowing the internal gear *G* to freely revolve and take the complete drift of the motor armature. A very noteworthy feature in this design is that the handwheel is always free to operate without the necessity of employing a declutching device.

Discussion

N. E. Funk[1] said that the non-return valve, if motor-operated, provided the simplest scheme of boiler control. However, the practice of placing gate stop valves on the boiler header in addition to the non-return valve on the boiler was almost universal, so that it was better to operate the valve which was most readily controlled when there was any choice.

Since very definite tests had been made on gate valves showing their characteristics in so far as shutting off high-velocity steam was concerned, and since this information was not available on non-return valves, apparently the best engineering judgment would be to operate the gate valves electrically and use them to cut off the boilers in event of trouble.

There was a possibility that considerable trouble would be experienced in shutting a non-return valve against extremely high steam velocities experienced in event of the break of a header. There was considerable unbalance in this type of valve and it was necessary to shut the disk directly against the stream flow of the discharging steam. Mr. Funk believed that any attempt to use the non-return valve in this manner not only complicated the valve, with a tendency to make it less likely to function when it should act as a non-return valve, but also would mean redesigning practically all of them so that they would withstand the tremendous forces encountered when shutting them against a break.

Experience in closing a standard 250-lb. non-return valve against a 400-lb. hydrostatic test on the boiler had shown how difficult it was to make such a valve tight, it being necessary for two men with a long wrench to pull up on the hand wheel to put a heavy strain on the disk to keep the edges from lifting under this pressure and causing the valve to leak.

Trouble of course might be experienced in shutting gate valves by having the wedge plow up the seat and turn up enough metal ahead of it to prevent the gate from closing. The tests made at the Essex plant, however, seemed to indicate that not much fear of this need be experienced.

Until very recently large steam valves had been operated electrically more as a matter of convenience and labor saving than with the idea of shutting off the steam in event of a steam-line break. The old types of controls, however, would not close a valve against any unusually high steam velocity due to insufficient power in their operating mechanisms.

As to steam-pipe sectionalization, Mr. Funk stated that he had heard some very good engineers speak more or less disparagingly of such procedure, indicating that they believed that piping should be so designed that it would be impossible for a break to occur. But even if everything was tested considerably above its working pressure, there was a possibility of rupture from outside causes or from flaws which could not be detected in this manner. In addition, with the industry thinking of higher pressures and temperatures at which there was uncertainity as to what would happen to the metal, the necessity of sectionalizing was even greater.

His company believed thoroughly in remote control of steam valves, and in their new designs were not only arranging to shut off each boiler from a remote point, but also to sectionalize the steam-pipe headers. The remote-control point was located outside of the turbine and boiler rooms so that no matter where a break occured the damaged section might be isolated without a serious or lengthy interruption of operation.

W. S. Morrison[2] said that the New York Edison Co., operating at only 200 lb. pressure, had never experienced any difficulty in valve closing, but to forestall any such troubles as those described in the paper they had provided controls on their 18-in. header valves. When they came to consider the question of higher pressures, however, the subject would be analyzed a great deal closer.

Alfred Iddles[3] said that it seemed to be the general practice to consider the non-return valve purely as a check valve, and that in his opinion it should be confined to this use for the present. Later it might be possible to develop a device that would function successfully as a combined shut-off and non-return valve.

SURVEY OF ENGINEERING PROGRESS

A Review of Attainment in Mechanical Engineering and Related Fields

The Gas Turbine in Theory and Practice

A SERIES of articles discussing the subject broadly. The author considers the problem of gas-turbine development a difficult one but not impossible of accomplishment. It is primarily, in his opinion, a matter of engineering design and selection or development of suitable engineering materials. As regards the field of the gas turbine, he believes that while it will not displace in many cases the present internal-combustion motor, it will, under certain conditions, prove a formidable competitor of the steam turbine. It has, however, a long road to travel before this will really become of serious commercial importance.

As regards the competition between the gas or heavy-oil engine and the gas turbine, the former though economical when it does not exceed a certain power output, becomes unwieldy in very large sizes. The real scope for the internal-combustion turbine will be found in certain cases where, in competition with steam plants, the elimination of the boiler and condensing installations offers peculiar advantages, while in other, such as the utilization of blast-furnace gases, the fact that it can be made to develop large powers on comparatively small dimensions may, even in spite of possibly inferior thermal efficiency, render it a suitable alternative to the large gas engine. Until, however, some well-thought-out design is actually constructed and tested, engineers must rest content with estimates of efficiency instead of proofs, and it remains to be seen whether they are of a sufficiently attractive nature to justify embarkation on the development of a new type of prime mover. Without experimental verification, much further progress in the design of the gas turbine cannot possibly be made.

The main difficulty encountered by designers of gas turbines lies in the usual severe temperature conditions. In the constant-pressure internal-combustion turbine, the application of heat at its maximum is constant; both in it and in the constant-volume type the blading is subject to a constant impinging temperature, although one of reduced intensity, but in both cases the function of the material is to withstand the heat and, as far as possible, not to transmit any of it. It will immediately be realized, therefore, what considerable differences and difficulties are involved in the use of internal-combustion products, whether expanding in a cylinder against a piston or impinging upon a turbine wheel through a nozzle, for the maximum reduction in initial temperature that can efficiently be used in the latter case is only in the region of 1000 deg. fahr., and therefore the temperatures in furnace, combustion chamber, or explosion chamber, and that on the blading can only be separated by about this amount. This very high initial temperature of the working fluid at first involved very considerable mechanical difficulties, even in the intermittent working of the reciprocating oil engine. It has hitherto almost entirely frustrated the solution of the gas-turbine problem, and nearly all, if not all, the serious difficulties encountered arise from this element—the initial temperature. The constructional troubles likely to be created from this cause react on the entire proportions of the design, and in order to obviate them recourse must eventually be had to improving the heat-resisting properties of metal. At present it is necessary either to restrict the initial temperature to such a point that, with the nozzle drop, the impinging temperature—probably the cardinal point in all gas-turbine design— does not cause deterioration of the blading, or else to accept some form of intermittent working, either of which will reduce the amount of positive work obtainable from the cycle or involve a more elaborate machine. The nature of the internal-combustion cycle—to be referred to later at length—completes the chain of difficulties, because, if the turbine operates on the constant-pressure cycle, the proportion of negative work to the available positive then becomes unduly large; while if it operates on the constant-volume cycle, the positive work obtainable can only be developed in a multi-chamber machine which, compared with other forms of prime mover, is unduly large and complicated. Moreover, the real point at issue must always be borne in mind; there is no question at all of evolving an internal-combustion turbine which shall be saliently superior to the present oil engine, just as the steam turbine proved to be to the reciprocating engine; economically this is probably impossible with a non-condensable gas. The real question is whether, in spite of these limitations, and the difficulties which are liable to arise if they are exceeded to any extent, a gas turbine can be produced which will compete with the steam engine and its accessory plant.

Of all the fragmentary work which has already been done on the gas turbine very few designs and even fewer test results have actually been made public. It would appear, however, that efficiencies equal to or even exceeding the best oil-engine practice are probably obtainable in theory, though not within the same cycle limits. They are not in sight today and are unlikely to be for some years, mainly owing to the lack of material suitable for withstanding the very high temperatures which such efficiencies demand.

The original article gives construction data and results of trials of a number of internal-combustion turbines. This part is not suitable for abstracting.

Of the many various types of gas turbine which have been constructed, the majority were designed to work on the constant-pressure cycle; but of those for which any detailed information has been published, three out of the seven were explosion turbines working on a constant-volume cycle, one was an exhaust turbine, and the remaining three, while operating on the constant-pressure superatmospheric cycle, were all mixed-fluid turbines. That is, besides the air and the fuel, steam or water injection was used to reduce the temperature of the mixture. Two of these constant-pressure, mixed-fluid turbines were also tested with air only. No published results are available beyond these air tests for a pure constant-pressure single-fluid machine, nor for any gas turbine working on a subatmospheric cycle, though the latter would probably give results very much superior to any other type. Before going any further into the question, it is necessary to explore the possible efficiencies obtainable when operating the turbine form of engine on an internal-combustion cycle, and the constant-pressure method will be investigated first.

In all heat engines the continuous output of work is effected by some from of mechanism which utilizes the pressure difference in a working substance created by the heat energy supplied. Whichever cycle is adopted, however, the internal-combustion turbine, as is the case in all practical heat engines, consists of the following essential parts:

1 A furnace or combustion chamber in which heat is supplied to the working fluid.

2 A heat sump or cooler into which the working fluid expands after leaving the combustion chamber.

3 Between these, a mechanism which will absorb the available energy of expansion in the fluid as it flows from 1 to 2 and reproduce it in the form of positive work, and

4 A mechanism which may either (*a*) supply the working fluid to the combustion chamber, (*b*) withdraw it from the cooler, or (*c*) combine both functions.

The work for these may be supplied either by the excess positive work or by other means, but in any case forms the negative work of the cycle. Owing to the fact that for the heat flow from furnace to cooler—which in the case of internal-combustion engines using

non-condensable gases must eventually be the atmosphere—and because this rejection usually takes place at a pressure somewhat greater than that of the atmosphere, in the constant-pressure cycle air must be supplied to the furnace under pressure, whereas the constant-volume cycle can, if necessary, be worked without precompression, although a certain small amount is advisable in practice. In lieu, however, of using a purely superatmospheric cycle, either an entirely subatmospheric cycle can be adopted, an exhauster taking the place of the compressor, or a combination of the two may be adopted. Precompression has hitherto always been adopted, the subatmospheric cycle not having been employed, and with the exception of Holzwarth, who uses a very small degree of exhaustion, the exhaust pressure has hitherto been above atmosphere. It was stated above that the constructional difficulties all arose through the element of temperature. The very real difficulty in achieving an efficient design of internal-combustion turbine, which would render it *facile princeps* among prime movers, lies in this matter of compression or exhaustion—that is, in the negative work of the cycle.

It should be clearly emphasized at this stage of the thesis that the broad principles upon which heat energy can be supplied, absorbed, and rejected in their various proportions are perfectly well known, and that no design which fails to comply with them can possible succeed. This is the reason why a good working solution of the internal-combustion-turbine problem depends in no way on some fortuitous or radically novel design on the part of some lucky inventor.

Owing to the initial temperature difficulty, the reaction turbine is unsuitable for the internal-combustion cycle, though it may become feasible eventually for the exhaust and in the case of certain forms of subatmospheric working, but only if very large volumes are involved. Our choice is therefore restricted to either the single-wheel impulse turbine or to a velocity-compounded turbine with two, or possibly three, rows of moving blades, though it is very doubtful if the efficiency of the latter is even nearly adequate. From the cycle limits and the analysis of the working fluid, it is possible to calculate the maximum value of the available energy, and the turbine efficiency is the ratio between the useful work developed in the turbine shaft and the energy available for expansion. Two transformations of energy take place in the turbine: first, from thermal to kinetic energy; secondly, from kinetic energy to useful work. The first loss which occurs lies in the radiation from the combustion chamber, which reduces the amount of energy available for conversion into kinetic work; the second consists in the friction and eddy losses in the nozzle. From this point the author proceeds to a discussion of the various losses.

As regards the stage efficiency of the turbine itself, the author bases his opinion on curves of stage efficiency for various ratios of blade speed to steam speed for different angles of wheel for which data have been published by Lasche and Baumann. From this it would appear that within very narrow limits the respective stage efficiencies do not exceed 0.8 and 0.68. All things considered, the author comes to the conclusion that for gas-turbine work the two-row wheel is practically the only one suitable.

It would therefore appear that the successful operation of a gas-turbine, apart from questions of mechanical construction, depends primarily on: (1) The ratio of positive to negative work in the cycle employed, and (2) the efficiency of compression and expansion, and for the constant-pressure superatmospheric-cycle single-fluid machine it was shown that with a two-row velocity-compounded turbine of 65 per cent efficiency, the ideal brake efficiency, even with an initial pressure of 500 lb. per sq. in. pressure, would not exceed 19.6 if the compression were adiabatic and the compressor had an efficiency of 90 per cent, or 23.2 if the compression were isothermal and the efficiency reached 70 per cent. These brake efficiencies are capable of considerable improvement on the air cycle used, but when dealing with the real working fluid the absolute thermal efficiency is adversely affected by the variation in the specific heat of the substance.

Compared with the internal-combustion piston engine, the gas turbine can never enjoy the vast advantages over the reciprocating type of mechanism which the steam turbine possesses. The same brake thermal efficiency may be obtained by working comparatively inefficiently on a cycle of high absolute efficiency just as well as by working more efficiently on a cycle of lower absolute efficiency. This is precisely what occurs in the case of the steam turbine and the piston engine. With steam, however, enormous expansion ratios are readily obtainable, in fact, a volumetric expansion of 750 to 1 is not out of the question, and the turbine mechanism lends itself very readily indeed to the utilization of small pressure differences and the "toe" of the P-V diagram. It can also utilize much higher superheat than can the engine, for there are no surfaces in contact, as well as vacuums which are entirely beyond the range of constructional possibilities where piston and valve mechanism are involved. Increased thermal and mechanical losses with reciprocating mechanism follow any attempt to go far in the direction of utilizing the energy of expansion at pressures below about 2 lb. abs., though there is still useful energy remaining in the steam. The result is that this engine is restricted to a cycle

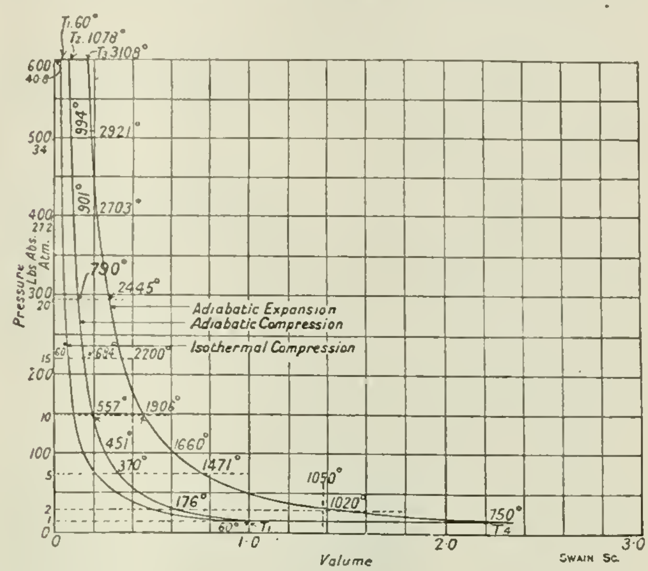

Fig. 1 Pressure-Volume Diagrams for Various Cycles

of much lower efficiency In the internal-combustion piston engine, as shown in Fig. 1, the "toe" of the diagram with atmospheric exhaust only forms a small proportion of the available work, this fraction becoming smaller as the initial pressure increases. But with the products of internal combustion, which are non-condensable gases, the advantages of the turbine over the piston engine, in that it can utilize the "toe" of the diagram, very largely vanish, because the expansion ratio is greatly curtailed by the fact that the gas does not change state, and though use can be made of subatmospheric working, the limits of the internal-combustion P-V diagram cannot be extended in the same manner as they are with steam owing to the condensation which the latter undergoes. We are, in the internal-combustion turbine, as with steam, employing a mechanism of lower intrinsic efficiency with which to extract the available kinetic energy, but whereas in the latter the limits between which we can readily work are so much greater, and consequently so much more energy per pound of working fluid is available, in the former the range of expansion available hardly differs at all in the two cases, and pressure compression ratios in both exceeding 15 offer hardly any advantages with the materials at present at our disposal, as higher compressions involve initial temperatures which become increasingly difficult to handle. The efficiency of a non-condensing steam turbine is notoriously low, and between initial and atmospheric exhaust pressures the piston engine is much superior—is even superior down to, perhaps, 26 in. vacuum. The same applies with internal-combustion gases, and no little misapprehension has often been caused by lack of appreciation of the fact that the turbine per se is inherently less efficient than the reciprocating engine except in the utilization of the subatmospheric range, but that it derives its vastly superior brake thermal efficiency from the fact that it can operate on a cycle of far higher absolute thermal efficiency, and *not* from the fact that its mechanical efficiency or efficiency of energy conversion is better, because it is not so except at very low pressures.

With the limit of velocity-compounded-turbine efficiency on the

low side of 70 per cent there are two directions in which improvement in the efficiency in internal-combustion-turbine installations can be made, viz.: (1) By increasing the air-compressor efficiency, and (2) by an increase in the ratio of positive to negative work in the cycle. The former improves the thermodynamic efficiency of the combination, and therefore the brake thermal efficiency for a given cycle. *The Engineer*, vol. 135, nos. 3514, 3515, 3516, 3517, May 4, 11, 18 and 25, 1923, pp. 466-468, 490-491, 515-517, and 557-559, 7 fig., 12 tables.

Short Abstracts of the Month

AIRCRAFT ENGINEERING

A New British Light-Weight Airplane

The Gnosspelius Light Plane. General description of the airplane designed by Maj. O. T. Gnosspelius and recently tested at the Lympne aerodrome.

The design of the plane is based on aerodynamic tests made with the pendulum apparatus which was developed at the works of Short Brothers. On this pendulum the models are mounted with the wings parallel to the pendulum arm, and the tests are carried out by raising the pendulum to a horizontal position, releasing it from there and noting how far it swings up on the other side of the dead center. This gives an indication of the resistance of the model, while the lateral deflection of the pendulum at its lowest position gives an indication of the lift.

On this pendulum Major Gnosspelius has tested a large number of models, and he has discovered several very interesting, and to some extent inexplicable, things. First of all he tested certain wing sections of which data were already available. He found that reasonably good agreement was obtained. He then tested other wing sections, as, for instance, the R.A.F. 19, which was found by model tests at the National Physical Laboratory to give a very high lift. On the pendulum this high lift was not attained. Now the curious fact about this test is that when tested on the full scale R.A.F. 19 does not give the high lift which wind-tunnel tests on models indicated. The logical conclusion seems to be that the pendulum, in certain circumstances, is in better agreement with full-scale work than is the wind tunnel. A good deal more evidence is necessary before one can definitely say that this is so, but several experiments seem to point that way. If this should prove to be so, the fact may considerably alter present views on aerodynamics, and it even seems possible that the phenomenon commonly known as "scale effect" does not exist, and that the differences between model and full-scale results, as indicated by wind-tunnel tests, may be due to other causes, possibly to the effect of the walls of the wind tunnel.

The Gnosspelius light plane has considerable resemblance to a bird in so far as the shape of the wings, body and tail are concerned. The body, which is of circular cross-section, comes to a point in the nose, and this point is not on the center line but is slightly bent down much as is the head of a bird during flight. The tail plane is long in relation to its span and is of triangular plan form. The ailerons are of considerable size, each being over 12 ft. long and of high aspect ratio.

The wing section employed is of fairly deep camber, although not of great thickness. One result of this is that it would have been almost impossible to obtain sufficient torsional stiffness with the usual two-spar construction. Consequently Major Gnosspelius decided to employ four spars, and so to design his ribs that any deflection of any one spar should be transmitted to the other three. The spars themselves are of the box type, with spruce flanges and three-ply walls. The ribs are of lattice construction, with double flange strips, in between which are passed the ends of the lattice bars, tacked and glued in place. To be quite accurate, it should, perhaps, be said that the ribs are N-girders rather than lattices, as the compression members are vertical.

The plane weighs about 530 lb., which figure includes gasoline or about two hours' flight, and the minimum horsepower required or horizontal flight is in the neighborhood of 3 b.hp.

The machine is fitted with specially light glider instruments such as an air-speed indicator reading from 10 to 80 m.p.h., a revolution indicator, an aneroid, and oil-pressure gages.

In tests during the first flight a height of about 1500 ft. was reached, the machine climbing strongly. The duration of this flight was about 15 min. In the next flight a height of 2500 ft. was reached and the machine remained in the air for approximately half an hour. The maximum horizontal speed attained as shown by the air-speed indicator was about 65 m.p.h. (*Flight*, vol. 15, no. 753/22, May 31, 1923, pp. 292–295 and 291, 8 figs., *d*)

AIR MACHINERY

Explosions in Air Compressors

Explosions in Air Compressors, J. A. Vaughan. Discussion based on official inquiries into sixteen explosions occurring in the pipes of passages through which the gas passed. The author comes to the following conclusions:

a Carbonaceous deposit is the seat of the trouble.

b Leaks in the final stage of compression or discharge are dangerous.

c The most likely time for firing or explosion is when the compressor is unloading.

d One or two fusible plugs do not provide an adequate safeguard against firing, explosion, or the delivery of dangerous air to the mine workings.

e The system of temperature gaging and record requires alteration.

The term "carbonaceous deposit" is used to denote the deposit which is left in the intercooler system, the valve chests, or the discharge passages owing to the cooling and the baffling influences to which the moving compressed air is subjected.

The proximate analyses of the deposits show that the substance, besides being a good gas reservoir, is of a nature liable to spontaneous combustion, while it is probable that the presence of metals in a finely divided state accelerates the oxidizing process, these metals being maintained in an unoxidized condition owing to a protecting film of oil.

There is little doubt that, as is the case with coal, the rate of absorption of oxygen rises with the temperature, so that, seeing that the temperature of the carbonaceous mass is necessarily increased as the oxidation proceeds, the rate of absorption will increase by a sort of compound-interest law, in the absence of any cooling effects.

The discharge pipes and receivers are unlagged and free to radiate heat, while at full load the stream of compressed air (at, say, 300 deg. fahr.) must assist in retarding any tendency of the deposit to heat up to a dangerous degree, unless the deposit is situated in mass, out of the flow, as may be the case in the bottom ends of intercoolers.

As regards the leaky discharge as a source of danger, the author shows by a series of indicator cards the effect of a leak, which, in this case, was intentionally created in the valves or piston of either the first or second stage of a 1440-cu-ft. air compressor. The inspection of the diagrams shows material alterations from normal conditions. Among other things, the fact that in a two-stage compressor leakage in the high-pressure discharge valves or in the piston will always raise the first-stage discharge and intercooler pressures. The temperature of the compressed air in this position will always necessarily be higher.

At full load the effect of the high-pressure discharge-valve leak is to put more work on to the low-pressure side. In this cylinder, with its inlet a little delayed due to the clearance air being of a higher pressure, a full charge of air at atmospheric pressure is compressed to a pressure higher than normal, the actual height reached depending on the size of the leak, which determines the point of the high-pressure stroke at which the inlet valve will open. The capacity of an intercooler of usual proportions will not be sufficient to prevent a rise of temperature on this account. If the leak were sufficiently large the high-pressure piston would merely float in air at receiver pressure, while the whole of the compression would be accomplished in the first-stage cylinder.

In addition, the author presents the curve giving data of tests with a broken valve plate in the second-stage discharge, from which it would appear that:

a Heating undoubtedly does take place if a high-pressure discharge valve leaks.

b The smaller the load, the greater the heating effect under this system of governing.

c The higher the pressure, the greater the heating effect.

There are two causes, interlinked, why leaky discharge valves produce rise of temperature in the receiver air (meaning by this term the compressed air that is in the discharge pipe or receiver—outside the high-pressure cylinder):

a The rate of compression in the low-pressure cylinder is increased, as more work is performed by this cylinder and a higher delivery pressure reached. Therefore the high-pressure intake is at a higher pressure and temperature, and consequently the high-pressure delivery and the receiver air are higher in temperature.

b The air that leaks back into the high-pressure cylinder does not fall appreciably in temperature on reëxpanding, and is by reason of its recompression delivered back to the receiver at an increased temperature.

As regards the danger at the time of unloading, the author advances the point that this time appears to be the most suitable for the proper explosive mixtures to be formed. Further, the dangerous gases being formed at the compressor end of the line should be capable of detection. An alarm device which would call the attention of the engineer to danger in that carbon monoxide or methane were being generated, should prove effective in preventing gassing or explosion. (*The Journal of the South African Institution of Engineers,* vol. 21, no. 9, April, 1923, pp. 171–176, 7 figs., *pA*)

ENGINEERING MATERIALS

Tentative Specification for Gray-Iron Castings. Text of the specifications prepared for submission to the Manchester Conference of the Institution of British Foundrymen in June, 1923.

All gray castings are divided into two classes: important castings, in which test bars shall be cast on when possible; and other castings, in which the bar may be cast separately at the option of the foundryman.

The thicknesses of any casting shall determine the size of the test bar required, namely:

Bar 0.875 in. diam. cast 15 in. long, for all castings where no main cross-section of the metal exceeds $^3/_4$ in. in thickness.

Bar 1.2 in. diam. cast 21 in. long, for all castings where no main cross-section of the metal exceeds 2 in. in thickness.

Bar 2.2 in. diam. cast 21 in. long, for all castings where no main cross-section of the metal is less than 2 in. in thickness.

The specification gives requirements for the transverse test and the tensile test, and provides that where physical tests are specified the amount of any chemical element other than phosphorus shall not be specified, and for phosphorus only its maximum percentage. (*The Foundry Trade Journal*, vol. 27, no. 354, May 31, 1923, p. 449, *p*)

Pearlitic Cast Iron. Pearlitic cast iron is a cast iron having a microstructure consisting mainly of pearlite with deposited graphite. The properties claimed for it are said to be:

1 High transverse and tensile strengths and toughness

2 High resistance to impact stresses

3 Moderate hardness when properly treated

4 Only a slight tendency to the formation of "pipes," and hence the possibility of making complicated castings

5 Great resistance to sliding friction (abrasion)

6 Fine and dense structure, the structure being unaffected by temperature changes.

The process of producing pearlitic cast iron consists essentially in the combination of two media, in the variation of the furnace charge, and in the correct heat treatment of the molds. Correct mixing is intended to give as little stimulus as possible to the formation of graphite. The materials used are carbon, silicon, and low-phosphorus pig iron. High sulphur content does not appear to be detrimental.

When cooled in the ordinary way, an iron of this kind would solidify "white." In order to preserve the desired pearlite-graphite structure a slow rate of cooling is necessary, this being obtained by preheating the mold. The degree of preheating depends of course on the wall thickness of each particular casting.

Theoretically speaking, it would be possible to get, from one and the same charge, and by suitable heat treatment of the mold, every desired cross-sectional area with the same final product (pearlite-graphite structure) when once the rates of cooling for the different cross-sectional areas had been determined. In practice, various cross-sectional areas are grouped together and a special burden or charge selected for each group, assuming the same amount of preheating of the mold. The possibilities of pearlitic cast iron have been discussed by Professor Bauer in a recent issue of *Stahl und Eisen.* The present writer has carried out some tests with the view to determining whether the claims for this new type of cast iron are justified and gives the results in the original article. From these it would appear that pearlitic cast iron has superior strength properties as compared with other kinds of cast iron tested. It would further appear that the casting made by the pearlitic cast-iron process must be practically free from stresses owing to its slower and more uniform cooling, whereas the ordinary types of cast iron show considerable strains due to casting. (*The Foundry Trade Journal*, vol. 27, no 355, June 7, 1923, pp. 454–456, 5 figs., *dp*)

FUELS AND FIRING

The Clyde System of Oil-Fuel Burning

The Clyde Oil-Fuel Burning System. Description of the equipment fitted on the *Fezara*, a geared-turbine steamship of the Khedivial Mail Line.

The outstanding features of the Clyde oil-fuel burning system are a compact and novel design of heater and pump unit, a simple

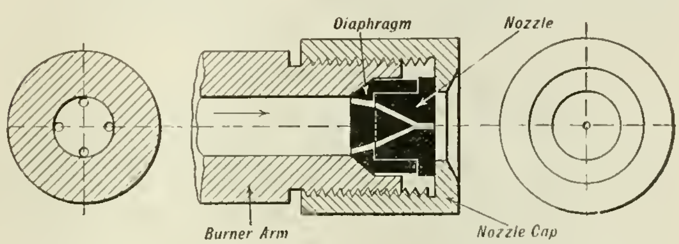

Fig. 1 Arrangement of Atomizer

oil-spraying device, and a special arrangement of furnace front, which, with suitable modification, may be fitted to any type of boiler.

In this system the fuel is drawn from the storage or settling tanks and suction strainer by a pump, which delivers it to a heater in which its temperature and corresponding viscosity are raised to the point necessary for its complete atomization under pressure in the burner, through which it is injected into the furnace in the form of a finely atomized conical spray.

As regards the heater, the flow of the oil being in series through the tubes, the danger of silting up is obviated, for the scouring action set up sweeps the tube spaces clear and prevents any deposit taking place. But, should one tube give out, only a small part of the whole heating surface is rendered inoperative. The main heater body is made of cast iron, and has within it a series of bored holes which are interconnected at their ends by means of machined passages. The arrangement of these passages compels the oil to travel in a sinuous path throughout the entire length of the heater.

The atomizer used with the Clyde pressure-jet system is shown by Fig. 1. The patented spraying nozzle is carried on the lower extremity of an L-shaped arm which is clamped by a quick-release attachment to a fixed bracket on the furnace door. Both the diaphragms and nozzles have been designed for high efficiency. They impart to the oil projected into the furnace the centrifugal force necessary to break it up into a minutely atomized conical spray, in which condition it is in a position to combine intimately with the air required for combustion. The atomizing effect is produced by a series of four oblique holes converging toward a conical projection, and a feature of the design of this part is that the conical projection is completely shrouded, thus protecting the point from injury.

The spraying nozzles are so proportioned as to be capable of

completely atomizing the oil at pressures of 25 lb. per sq. in. and upward. The weight of the oil dealt with and the output of the burner may be varied through a wide range by increasing or decreasing the pressure. When working in conjunction with the air director, the contour of the flame produced may be kept constant throughout the pressure range for the particular size of nozzle which is being used. Should it become necessary to work at pressures either above or below the normal limit, it is only necessary to substitute another size of nozzle corresponding to the requirements of the new pressure. Only the nozzle need be replaced, and the diaphragm remains the same throughout all pressure ranges.

The furnace fronts are described in the original article. As regards the starting-up gear, which is an important element when no steam is available, a special steam boiler fired by a Clyde kerosene-vapor burner is employed, the steam generated in this boiler being used to drive one of the pumping and heating plants.

The original article gives data of the results obtained with the oil-fuel system described and also the steam and air systems which may be used in place of the pressure-jet system.

The Clyde steam-jet system of oil burning is not quite as economical as the pressure-jet system, but is cheaper in first cost. The low-pressure air system is especially applicable to small boilers, galley ranges, central heating, and general furnace work, the oil being atomized by air at a pressure varying from 8 in. to 18 in. water gage. The Clyde high-pressure air burners may be used in cases where intense local heat is required. None of these systems is described in any detail. (*The Engineer*, vol. 135, no. 3519, June 8, 1923, pp. 611–614, 15 figs., *d*)

INTERNAL-COMBUSTION ENGINEERING (See Measuring Apparatus)

MACHINE PARTS AND DESIGN

Avoiding Shock on Intermittent Machine Work

Avoiding Shock on Intermittent Machine Work, Fred Horner. Discussion of methods of overcoming the jerky action when tools are cutting ridges or passing over slots and gaps, and also for preventing backlash in gears.

After describing some of the cruder methods the author mentions types of electric drive which provide control by tappets appropriately situated at the table edge by which the motor speed is increased while the tool is traveling over the empty spaces, and brought to normal cutting speed just before encountering the metal again.

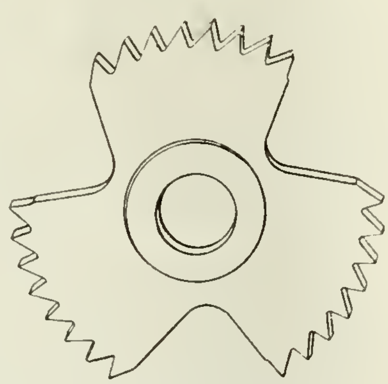

Fig. 2 Relieved Slitting Saw

The same principle is now being applied to the operation of some milling machines, feed increases being arranged to jump the work gaps at high speed.

The general object of such tools is to provide a relief from the strenuous continual action of normal tools, either in the way of dividing the chips into smaller portions, or of that idea combined with greater facility for chip escape. The principle embodied means omission of a succession of similarly shaped cutting edges, and their staggering or modification of lateral position, or the alteration of alternate teeth in such a way that successive chips differ.

The commonest model on the latter plan is the well-known stepped cutter used for gear cutting, which has nicked teeth with staggered grooves, and the cutter with alternate plain and waved teeth. A good many milling or slitting saws and the larger saws used on the regular cold-sawing machines are built with teeth having interrupted action, such as every other tooth a vee, splitting the square or round-nosed cut of the normal teeth. Or alternate teeth are beveled opposite ways, to throw the chips out freely. A somewhat similar incident occurs with the alternate-tooth mills now utilized for cutting deep grooves, the teeth standing to the right and left so that ample space for cutting and coolant is left in front of each tooth.

A novel principle has also been applied to slitting saws (Fig. 2) giving relief from the continuous cut all around and letting coolant get in and chips come out with greater ease. This scavenging action of the open spaces enables deep slots to be rapidly cut without fear of saw breakage. (*Canadian Machinery*, vol. 59, no. 22, May 31, 1923, pp. 17 and 24, 2 figs., *dt*)

Nomenclature of Power-Press Parts. The original article gives two drawings of a power press in which each part is numbered, together with a list of the names for the various parts. The availability of such a list is desirable as various terms are used to identify the same style of press; as, for example, "straight column," "straight-sided," and "straight-sided pillar." Even the machine itself is sometimes called a power press and some times a punch press; in the latter case it may be confused with the machine for punching holes in plates.

The nomenclature reproduced in the article is taken from a catalog issued by the Toledo Machine & Tool Co., Toledo, Ohio. (*Machinery* (N. Y.), vol. 29, no. 10. June, 1923, pp. 813, *p*)

MACHINE TOOLS

A Novel Combination Bench Tool

The Walker Mechanic. Description of a tool which aims at combining the features of a lathe, a drilling machine, and a vise.

The base of the machine comprises a casting which has more

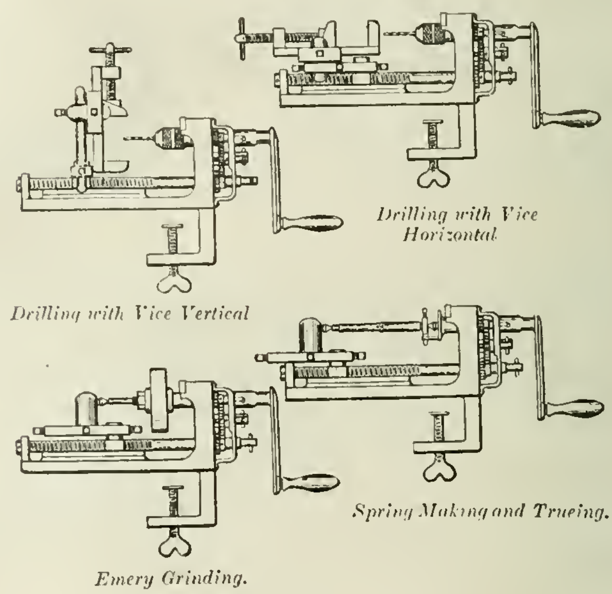

Fig. 3 The Walker Mechanic

or less the form of the front jaw of a parallel-jawed vise. This part, which is clamped on to the bench, is equipped with two short spindles and a long screw that are all geared together. The driving-crank handle can be fixed on any of the three spindles, so that a corresponding number of speeds can be obtained.

The illustrations show how, by means of some comparatively simple adapters, the machine can be employed in several different directions, while a substantial back jaw that is provided can be used in combination with the base and screw to form a powerful vise. The back jaw, incidentally, has a fair-sized anvil face and beak. (*The Practical Engineer*, vol. 67, no. 1894, June 14, 1923, p. 335, 1 fig., *d*)

MARINE ENGINEERING (See Fuels and Firing)

MEASURING APPARATUS

Positive Measurement of Fuel Oil on Motorships. Description of the Bassler meter, which integrates the flow through oil lines with compensation for temperature.

The meter may be calibrated either in "constant-weight gallons"

or in "constant-volume gallons" and in both cases it is, within practical bounds, unaffected by rates of flow, line pressures, viscosities, temperatures, or other variable factors.

In construction this device consists fundamentally of a closed cylinder containing the oil, within which there is a concentric barrel, through which the oil is measured by the ton. The space between the measuring barrel and the outer body is divided into two chambers, one containing the inlet valves to the measuring barrel and the other housing the delivery valves. Thus the flow through the meter is always in one direction.

Piston valves are used to which plunger rods are attached. At a certain point in each stroke the measuring piston makes contact with the plunger rods of the inlet valve and delivery valve at one end of the cylinder and moves them against spring pressure until, at a predetermined point, a trip falls and holds the valves in place. Simultaneously, on the other side of the piston, a trip is released, permitting the pair of valves at the opposite end of the cylinder to assume their defined position under their spring action. It will be readily understood that the valve operation requires the inlet valve on one side of the piston to be open when the inlet valve on the other side is closed, and the delivery valves to be correspondingly taken care of. There is nothing special or intricate in this.

Of importance, and of particular design, are the adjustments, two in number, namely, the thermostatic control and the manual control. The first of these consists of a small metal tube containing a liquid of similar coefficient of expansion as the liquid that is to be metered. It is permanently fixed at one end, with the other end floating and carrying the valve-trip bar. Consequently the temperature changes cause the valves at one end of the meter to open proportionately earlier or later, thus having the effect of increasing or reducing the volume measured by the piston on each stroke. In this way the measurement by weight-gallon is maintained constant. Manual control is virtually a factory adjustment, being made on the valve trip at the other end of the measuring cylinder.

For any definite grade of oil the thermostatic control can be made exact. To take care of the varying grades of oil which a ship may have to purchase as it bunkers at different parts, the engineer should order a series of thermostatic controls to be charged with different liquid at the factory. (*Motorship*, vol. 8, no. 6, June, 1923, pp. 426–427, *d*)

MOTOR-CAR ENGINEERING (See Special Processes)

Eight-in-Line Engine Packard Chassis, J. Edward Schipper. The new Packard chassis incorporates two features novel in American motor-car construction, namely, the eight-in-line engine and four-wheel brakes. The eight-in-line engine has been selected to replace the twin six because of its overlapping power impulses, its inherently good balance with consequent freedom from vibration periods within the range of driving speed, and its relative accessibility.

The engine is $3^3/_8$ in. by 5 in., block cast and of the L-head type, with a compression ratio of 4.51. It was designed to develop 85 hp. at 3000 r.p.m.

The engine parts generally are of the usual type with the exception of the crankshaft. In this the crankpins for cylinders Nos. 3, 4, 5, and 6 lie in one plane at right angles to the common plane of the crankpins for cylinders Nos. 1, 2, 7, and 8, and it is claimed that such an arrangement eliminates excessive vibration. The nine-bearing construction is used to provide a small intervening span between the main bearings giving a rigid support to the crank shaft, in addition to which a vibration damper is fitted to the front end of the crankshaft. (*Automotive Industries*, vol. 48, no. 24, June 14, 1923, pp. 1266–1274, illustrated, *d*)

The New Saturation Problem, Alvan Macauley. The author, who is president of the Packard Motor Car Company, discusses the physical saturation of the country with motor cars. By this he means that the number of motor cars already in existence has become so large as to make driving difficult and unpleasant in many instances.

Already traffic conditions are forcing voluntary limitations on the use of automobiles. Many suburban residents have stopped bringing their cars into the city; many city owners will not use them at all during certain hours; in the shopping and theatrical districts of New York, walking, even in bad weather, is preferred by some to the exasperating experience of trying to get to destination in a taxicab.

Above all, the problems of public safety cannot be dodged. It is not relevant to blame the "jay walker." It is not relevant to flourish statistics showing that fewer people die in automobile accidents than of measles. It is not relevant to prove that politics and the police department are responsible.

Many remedies have been suggested but they will all be merely temporary, as they do not go to the root of the difficulty.

Repetitions of New York's traffic difficulties can be avoided—and must be. The fundamental traffic problem is the problem of the city plan. Traffic crowding, delays, accidents, high taxes for police purposes and relief streets, high costs of deliveries of food—all these problems and many others can be traced in large measure to the planlessness of our cities.

A few municipal authorities and city-planning engineers are studying the unexpected increase of automobile traffic and the provisions which should be made for it. Too few public officials and public bodies realize what is needed. They do not see yet that it is cheaper to plan ahead than to cut new avenues through big buildings or rear bridges many miles long over crowded streets.

It is up to the automobile industry to face this new saturation problem frankly and intelligently, and to do all in its power to help plan and build our cities so that our industry can safely and effectively serve them. (*Automotive Industries*, vol. 48, no. 23, June 7, 1923, pp. 1231, *pA*)

PHYSICS

The Reduction of All Physical Dimensions to Those of Space and Time, Prof. A. P. Mathews. The author believes that ultimately all physical entities of the universe will be expressed in terms of four dimensions—three of space and that of time. With these four dimensions the whole of the physical universe could be expressed in equations of a four-dimensional space with the sole reservation that this would leave out the fifth dimension, namely, psychism, by which the author means that property of matter at present neglected by the physicists which is exhibited in its clearest form in living things and which shows itself in thought and consciousness in such large psychic units as human beings.

From this the author proceeds in an attempt to show how all the physical phenomena of the world may be expressed in dimensions of space and time. He considers for this the dimensions of quantity of electricity, dimensions of magnetism or magnetic flux, and of ethereal constants.

The reduction of physical quantities to space and time is claimed to make clear the nature of energy, which the author expresses as $(E) = \left(\frac{L^5}{T^2}\right) = \left(\frac{L^3}{T} \times L^2 \times \frac{1}{T}\right)$ = magnetic flux $\times$ electric quantity per second.

In other words, all energy of whatever kind, potential or kinetic, is the product of magnetic flux and electric current, or magnetic flux times electric quantity per second, or magnetic flux times electric quantity times a frequency. This magnetic flux may be identified, as is usual, with ether flow (that is, electric quantity times velocity), and electric quantity with ether twist. Hence all energy is in the ether and is nothing else than a certain quantity of twisted ethereal flow or strain.

That potential energy is nothing else than some kind of strain in the ether, the latter being perfectly elastic, is generally supposed. So all the energy of position, whether this be gravitational energy, as in the separation of masses; electrostatic, as in the separation of charges; or chemical, as in the separation of magnetic poles or currents, is nothing else than a strain, twist, or what not in the ether. It is an ethereal phenomenon. It is always and everywhere magnetic flux times electric energy times frequency. Similarly with kinetic energy; for kinetic energy is the expression of inertia and elasticity. Inertia is self-induction. To move an electric charge from rest, or to increase its velocity when in motion, strain in the ether is set up or increased just as in separating unlike charges to make potential energy. The greater the velocity, the greater the mass; i.e., the greater the number of electric charges moved, the greater is this strain. When a moving body or current stops, or is retarded, this strain or energy or deformation is suddenly

released. Consequently all energy, whether kinetic or potential, is ethereal strain. And quantity of energy is quantity of ethereal distortion per second.

Temperature has the dimensions of energy, and is also magnetic flux times electric discharge per second. Temperature is nothing less than the product of magnetism by current.

The author further develops the above ideas by considering the dimensions of a natural physical phenomenon on the basis of an assumption that time is a four-spatial coördinate. If this is so, then mass and energy have the dimensions of volume. On the other hand, if time is kept as a separate entity not to be equated with the length, then energy is more than mass. (*Journal of the Washington Academy of Sciences*, vol. 13, no. 10, May 19, 1923, pp. 195–210, *t*)

POWER-PLANT ENGINEERING

The Yarrow Stationary Water-Tube Boiler

The Yarrow Land-Type Boiler. Description of a Yarrow boiler intended for use in electric power stations, in particular the type installed at the Dunston Power Station of the Newcastle-upon-Tyne Electric Supply Co. The boiler described has been in operation for several months.

Fig. 4 illustrates the general arrangement of the boiler at Dunston, which is of the Yarrow straight-tube type, fitted with a superheater and air heaters, the elements comprising a steam drum 5 ft. in diameter and four water drums. The steam drum and the water drums are connected by $1^3/_4$-in. cold-drawn steel tubes, which are expanded and bell-mouthed at each end by pneumatic power in accordance with the usual practice in this type of boiler. The outside water drums are 30 in. in diameter and are connected to the steam drum by twelve rows of tubes, while the two drums nearer the fire, which are 23 in. in diameter, are joined to the steam drum by four rows of tubes. The total evaporating surface of the boiler is 9100 sq. ft., of which 2135 sq. ft. are provided in the two tube nests on either side of the fire and 6965 sq. ft. in the outer nests.

At each side of the boiler between the two nests of tubes one-half of the superheater is installed, the steam passing first through one and then crossing by a pipe to the other.

The superheater, which has a heating surface of 2000 sq. ft., is composed of a number of U-tubes, $1^1/_8$ in. in diameter, which are expanded and bell-mouthed into a circular drum, access to the tube ends being obtained from inside the drum—which may be entered by a manhole in the usual way. The superheater is of the self-draining type, and is designed so that the steam makes two passages through each part, or four passages in all. The drop in steam pressure through each part under the highest rates of evaporation does not exceed 1 lb. per sq. in.

Features of the boiler are the large combustion space of 1800 cu. ft. and the extent of the evaporating surface which is exposed to the direct radiation of the fire. An examination of the combustion chamber after the boiler had been in commission for some months showed that the tubes had remained quite straight.

The air heaters are placed in the uptake. They are of the tubular type and contain 1504 tubes 8 ft. in length and $2^3/_4$ in. in external diameter, the combined heating surface being 8631 sq. ft. The gases pass through the inside of the tubes, and the air to the grates is heated by passing over the outside of the tubes. The air to the grates is not only heated by passing through the air heater itself, but it also absorbs additional heat during its passage over the boiler casings, both to and from the heater. By this means the boiler casing is used to assist in heating the air and at the same time the radiation losses through the casing are reduced.

In tests the normal output of the boiler is 64,000 lb. of steam from and at 212 deg. fahr. The trials, however, were made from a feed temperature of 80 deg. fahr. to superheated steam of about 720 deg. fahr., which at the working pressure of 215 lb. per sq. in. corresponds to a degree of superheat of about 330 deg. fahr. This feedwater temperature was used on the trials and was fixed to meet certain specified conditions, but in general practice it is considerably higher. An output of 64,000 lb. of water evaporated per hour from and at 212 deg. fahr. corresponds to an evaporation of rather more than 7 lb. of water from and at 212 deg. fahr. per hour per square foot of generating surface. At this rate of evaporation, approximately 30 lb. of coal were burned per square foot of grate area per hour. An analysis of coal was obtained in accordance with recognized methods, and an efficiency on the normal load trial of 86 per cent was obtained, the analysis of the waste gases showing 12.6 per cent of CO_2. During the overload trials the output obtained was approximately 90,000 lb. of water evaporated per hour from and at 212 deg. fahr., and it was shown that the limit of output on this trial was determined by the capacity of the forced-draft fan, which had not been designed for so high an overload demand; otherwise there was no reason why the boiler should not have been worked up to a greater output.

There is one feature in the trials which is particularly interesting, namely, the difference between the draft at the funnel base and that over the grate. At normal load the draft at the funnel base was

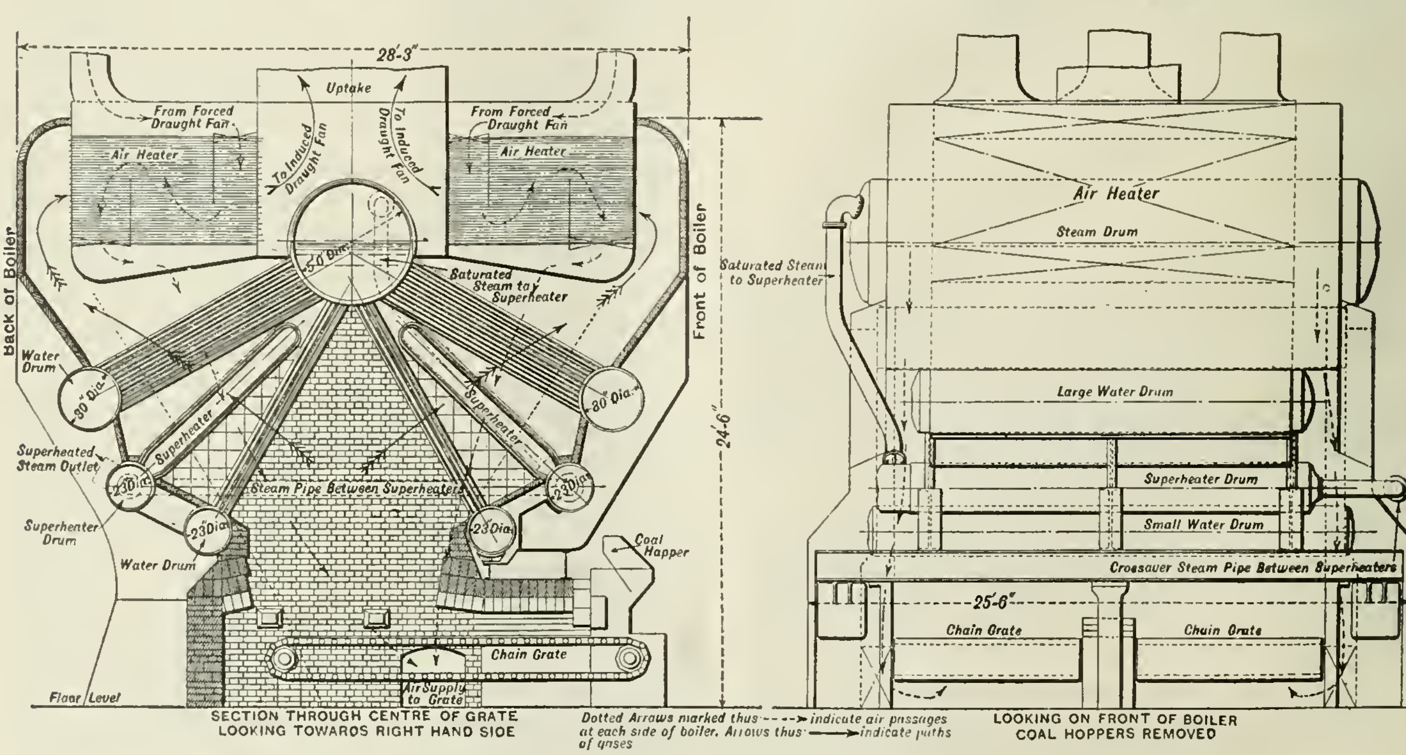

Fig. 4 Yarrow Water-Tube Boiler at the Dunston Electric Power Station

0.32 in. of water, while a similar reading taken over the grate was 0.25 in. This small difference is to be attributed by the large area provided for the passage of the gases from the furnace, through the nests of tubes to the chimney, as well as to the absence of baffles or other restriction. Possibly the absence of bird-nesting experienced with this boiler is to some degree to be accounted for by the slow velocity of the gases through the tubes.

At normal load the temperature of the flue gases was reduced by 220 deg. fahr. by the air heater, while the average temperature of the air passing under the grate was about 300 deg. fahr. So far no injurious effects have been experienced on the grates or the brickwork or any other part of the boiler by air temperatures up to 362 deg. fahr., which is the limit reached during the trials, and it would appear that the grates might have been worked at a still higher temperature without harm.

The Dunston boiler was designed for coal firing, but other boilers illustrated in the original article have been arranged also for oil or powdered fuel. The original article shows also a boiler with superheater on one side, and likewise a boiler arranged with the downtake to economizer. (*The Engineer*, vol. 135, no. 3520, June 15, 1923, pp. 638–640, 7 figs., *dA*)

N.E.L.A. Report on Prime Movers

Report of Prime Movers Committee, National Electric Light Association. Only a few parts of this interesting document can be abstracted owing to lack of space.

Higher Steam Pressures and Temperatures. Considerable progress has been made toward the adoption of higher pressures and temperatures in new central-station plants since last year's report was written. A few plants have been operating with 350 lb. and 600 to 650 deg. fahr. at the boiler for several years, and these conditions have been adopted in additions now being made to existing plants.

One company, after several years' operating experience with 350 lb. at the boiler and 300 lb. at the turbine, is building a new plant using 400 lb. at the boiler. One of the large operating companies is building a plant designed for 400 lb. at the boiler and another a plant for 550 lb. In the latter case the boilers themselves can be operated up to 650 lb. The steam temperature in these later installations ranges between 650 to 750 deg. fahr.

In considering the improvement in economy which can be gained through the use of higher pressures and temperatures, the possibilities in the use of lower vacuum should always be kept in view. The temperature range worked through is of primary importance, and it may be possible under certain conditions to extend this range with a smaller increase in first cost by working at a lower vacuum than by increasing pressure and temperature. In studying this problem the relationship of the yearly load curve to the condensing-water temperature must be considered. The sub-committee on condensing equipment is studying these conditions and expects to discuss the problem in its report.

The high-pressure plants now under construction or about to be constructed represent a considerable advance in American practice. Great credit is due to the engineers and executives who have taken these forward steps in development. In a few years there will be available a considerable quantity of actual operating data on items that are, now, more or less a matter of conjecture. It is felt that in going beyond 400 lb. pressure at present, a field is being entered where little is known about the operating difficulties which may be encountered, and many engineers feel that it would be well not to advance too rapidly until more is known about these difficulties and more actual operating experience is available.

On the other hand, it unquestionably would be an error in judgment to continue installing plants designed for 200 to 250 lb. pressure at the boiler without giving due consideration to the possibilities latent in the use of higher pressures. The successful operation of 300-lb. and 350-lb. plants over a period of years shows unquestionably the wisdom of having gone to a higher pressure than the old standard.

Attention is directed to a paper presented at the 1922 Annual Meeting of The American Society of Mechanical Engineers by Geo. A. Orrok, Mem. A.S.M.E., on The Commercial Economy of High Pressure and High Superheat in the Central Stations. Mr. Orrok's article covers the effect of regeneration as well as the effect of increased temperatures and pressures.

There is quoted in full in the original report an article by L. E. Kemp which appeared in the *Electrician* of June 30, 1922. This article gives an analysis of this problem from the English viewpoint. Certain editorial comments are made on this article and additional curves are given which present Mr. Kemp's conclusions in a rather different manner.

Station Piping. Preliminary investigation of the subject of pressure drop in steam lines was started by the Committee and up to the present time a limited amount of data for specific cases has been made available by the member companies.

It would seem from some of the data submitted that considerable variation in the results obtained will occur unless measurements are made more carefully than has been the case in some instances. This is particularly true in the case of drop through reducing fittings, venturi valves, elbows, tees, and bends. Gage connections at points where direction of flow changes should be so located as to get the average pressure. The crowding of steam toward the outside of turns of all kinds is probably responsible for many discordant results. In the matter of non-return valves, checks, etc., allowance must be made for the pressure required to float the disks. Large drops through valves and fittings are not necessary. Proper design will reduce pressure losses to comparatively small amounts. The extent to which such losses can be reduced is indicated by the following tabulation which gives data for one make of throttle valve.

	Steam flow, lb. per hr.	Pressure, lb.	Temperature, deg. fahr.	Pressure drop, lb.
20-in Schutte & Koerting throttle valve built in 1915...........	425,000	208	541	11.0
	225,000	208	541	3.5
18-in. Schutte & Koerting valve built at a later date..........	320,000	212	525	1.0

The report also contains a discussion of the power-station heat balance, dealing in particular with power-station auxiliaries. This is not suitable for abstracting. Among other things this part of the report contains description of various auxiliaries, together with a brief bibliography. (*National Electric Light Association*, Report presented at the New York Convention, June, 1923, 78 pp., 87 figs., *gd*)

The Kestner Vertical Water-Tube Boiler

The Kestner Boiler. Description of a boiler invented by the French engineer, Paul Kestner, and built in England. It consists essentially (Fig. 5) of an upper steam drum 1, and a lower mud drum 2, which are connected together by straight vertical tubes expanded into accurately machined holes. The tubes are arranged in the form of a repeated letter V and there are only two rows.

The feed arrangement is of particular interest. The feed is delivered into a distributing tray 7, from which it overflows at definite points. It then passes down the small circulating tubes and on striking the deflector tray 8, it has its velocity reduced prior to its return to the steam drum by way of the evaporating tubes 4 and 5.

It is claimed that on account of the feed and circulating arrangements very little scaling takes place inside the boiler even when using comparatively hard water. To provide for expansion the boiler is supported by the upper or steam drum which rests on a steel staging 21, and the lower mud drum is supported by the tubes. The circulation tubes 6, are directly heated by the gases and do not produce steam.

The grate 11 is placed on a level with the mud drum 2, and in front of it; the mud drum being shielded from the hot fuel bed and the hot gases by a firebrick wall 12. Above the grate is an inclined arch 13 which is continued up to the tubes, and firebrick baffles 14 are arranged as an extension of the arch in order to fill up the gaps between the tubes. Complete combustion of the fuel takes place under the refractory brick arch, the hydrocarbons distilled off from the fuel bed by the heat of combustion being ignited and burnt under high temperature conditions before they come into contact with the tube surfaces.

To gain access to the interior of the boiler for inspection and cleaning, it is simply necessary to remove two manhole covers. Access may also be gained to the exterior portions of the tubes through a number of openings 20.

The simplicity of the Kestner boiler enables it to be opened up,

cleaned, and inspected in a very short space of time, and there is therefore a considerable reduction in the cost of labor. The ease with which the tubes can be removed and replaced will be understood from Fig. 5. The firebrick slates shown at 10 in Fig. 5 are removable, and can easily be taken off to enable the tubes to be withdrawn, the new tube being placed in position in the same manner. The length of the tubes in the standard boiler is 23 ft., but where head room is of importance the makers supply another type with shorter tubes.

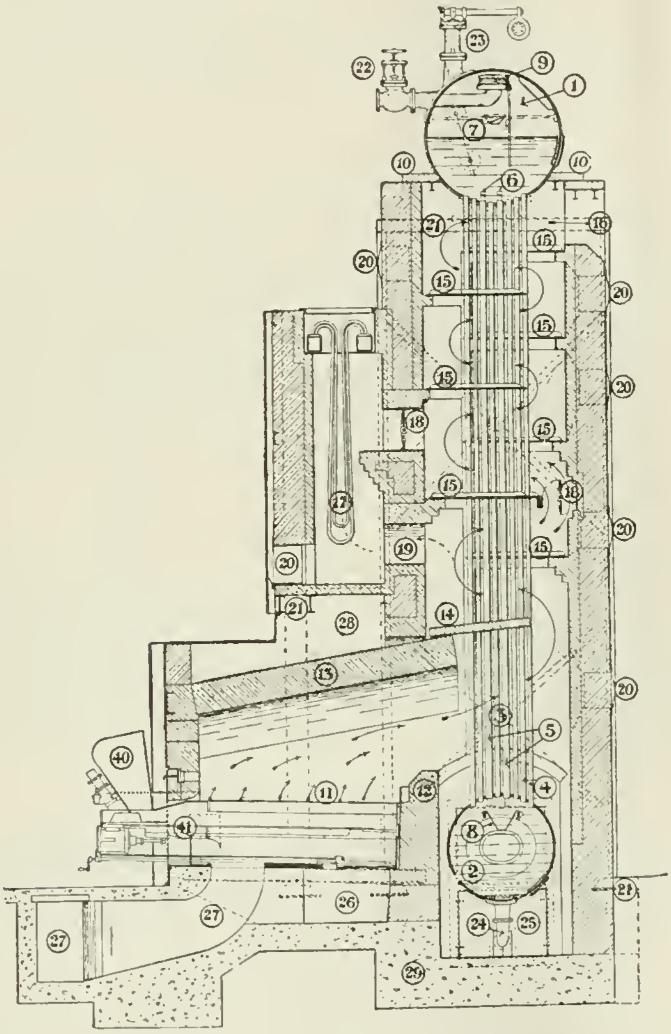

Fig. 5 The Kestner Boiler

For gas firing the Kestner boiler is claimed to be specially suitable, and, where necessary, it can be arranged for use with coal or gas, an extra combustion chamber being provided for the combustion of the latter. It is also suitable for the utilization of waste heat. All the superheater joints are accessible, and any tube expanding or plugging that may be necessary can be carried out outside the boiler setting. Steam can be raised very rapidly, and hogging of the tubes is said to be practically unknown. The boiler is claimed to have a more rapid steam circulation than any other steam generator on the market, thus allowing of a high evaporation per square foot of heating surface and a high rate of combustion of inferior fuels. The hottest gases impinge upon that part of each evaporating tube which only contains water, while the cooler gases make contact with that part of the tube which mainly contains steam. (*The Practical Engineer*, vol. 67, no. 1890, May 17, 1923, pp. 278–279, 4 figs., *d*)

Design Features of New 1200-lb.-Pressure Boilers. Description of an installation designed by the Babcock & Wilcox Co. for the Commonwealth Edison Co. of Chicago for installation at the Calumet Station. In this steam will be furnished at 1200 lb. pressure to an extra-high-pressure turbine which will exhaust at about 300 lb. into the superheater supplying steam to the steam mains feeding the main station turbine. The extra-high-pressure turbo-generator is expected to be of a capacity from 2500 to 3000 kw. The boiler will furnish about 110,000 lb. of steam per hour. The unit is of the inclined-header cross-drum type and comprises a Babcock & Wilcox forced-draft chain-grate stoker 24 ft. wide and 18 ft. 3 in. long, a lower deck of eight-high sections of 2-in. tubes having a setting height of 25 ft. $9^3/_4$ in., a primary and a secondary superheater in an interdeck space 8 ft. $1^1/_4$ in. between decks, an upper deck of seventeen-high sections of 2-in. tubes, two rows of horizontal $3^1/_4$-in. circulating tubes entering a 48-in. cross-drum, and a Babcock & Wilcox steel contraflow economizer. The lower deck is not baffled; the upper deck has a vertical baffle causing the gases to make two passes. The complete unit is about 28 ft. wide, $36^1/_2$ ft. deep, including the economizer, and 45 ft. high above the floor. The heating surfaces have not yet been definitely fixed, but they will be approximately as follows: Boiler, 15,750 sq. ft.; primary superheater, 2120 sq. ft.; secondary superheater, 3300 sq. ft.; economizer, 9230 sq. ft.

One marked difference in the construction of this boiler is in the cross-drum. This drum is a forged steel cylinder, 48-in. diameter with 4-in. walls made up by rolling on a mandrel and swaging the ends.

Drum heads are integral, each with a manhole closed by a 12- by 16-in. manhole fitting. In order that the holes for connecting the circulating tubes to the drum may leave the largest practicable ligaments between circumferential rows of holes, an unusual arrangement of connections has been adopted. At the top of each uptake header two horizontal circulators are connected, but the circulators from each alternate header are bent downward and sidewise so that they are connected to the drum in the same circumferential row as the circulators without such bends. This makes the distance between these circumferential rows about 16 in. In the same way the downtake nipples are not straight but bent so that the two downtake headers are connected to each of those circumferential rows of holes in the drum.

Connections to the drum comprise four 3-in. nozzles for safety valves, a 3-in. nozzle for the saturated steam connection to the lower header of the primary superheater, and two 3-in. nozzles for connections to a feed pipe extending the length of the drum below the water line. (*Power Plant Engineering*, vol. 27, no. 12, June 15, 1923, pp. 637–638, 1 fig., *dA*)

A New Boiler-Feeding Device

The Auto-Thermal Boiler Feed. Description of a novel type of boiler-feed device having the following cycle of operations. All available condensation from steam traps brought by pipes *A*, Fig. 6, together with the necessary make-up feed by the pipe *B* is run into the upper of the two vessels *C*, which is provided with a vapor outlet

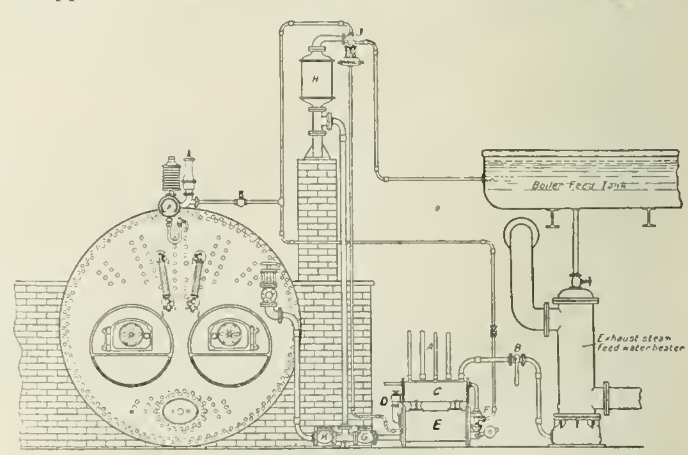

Fig. 6 Auto-Thermal Boiler Feed

and is simply a collector. From this collector the water runs by gravity through the connecting pipe *D*, which is provided with a stop valve and non-return valve, into the lower vessel *E*. An internal float rising with the water line operates the steam valve *F*, which at the psychological moment admits live steam to the vessel, discharges the water through the non-return valve *G*, and lifts it up into the vessel *H* (the feeder) above the boiler. An equilibrium

pipe connects the inside of the lifter with the underside of a diaphragm *J*, by means of which the rise and fall of pressure in the lifter *E*, in performing its functions, is utilized to operate the valves which exhaust or admit live steam to the feeder *H* at the proper time. The mechanism is so arranged that when the lifter is discharging under pressure the diaphragm valve is lifted, exhausting the feeder *H* in order to receive the water. On the lifter exhausting when empty, the valve *J* returns to its normal position and steam of full boiler pressure is admitted to the top of the feeder *H*, whence the pressure being equal to that in the boiler, the water gravitates to the boiler by way of the non-return valve *K*: meanwhile, the water is again filling up the lifter *E* and the cycle is repeated.

The perfect working of the appliance is mainly due to the effective way in which the exhausting or admission of steam to the feeder *H* is absolutely controlled by the lifter *E*. Naturally the reliability of the apparatus is also dependent upon the main steam valve *F*. The valve, which is moved by the steam pressure itself, is in turn controlled by a small subsidiary balanced valve. Hence the float is only called up to exert the small effort required to move the balanced valve, the rest of the work being performed by the steam pressure. (*The Iron and Coal Trades Review*, vol. 106, no. 2881, May 18, 1923, p. 747, *d*)

RAILROAD ENGINEERING

Pilliod-Sleeve-Valve Performance on the Monon Railroad. Date from an initial report on the performance of a Monon Mikado-type locomotive equipped with Pilliod valves.

This valve arrangement comprises a pair of sleeves, each actuated from a different source, which, combined with a piston moving within these sleeves, enables the exhaust and steam admission to the cylinders to be independently controlled. The valve provides for a 95 per cent release at all points of cut-off, thus eliminating excessive compression in the cylinders.

A number of indicator cards taken from the locomotive in regular operation are reproduced in the original article. These in comparison with a card taken on another locomotive of the same class under similar conditions show clearly that at the same point of cut-off the locomotive with Pilliod sleeve valves develops a higher mean effective pressure than the locomotive with ordinary valves. Consequently the Pilliod sleeve valve, in effect, enables the locomotive to develop the same tractive effort as the plain-valve locomotive with a shorter cut-off. In other words, the Pilliod sleeve valves should enable a locomotive to perform the same amount of work with less steam, used more expansively, than a locomotive equipped with an ordinary type of piston or slide valve.

The basis for economy in the use of Pilliod sleeve valves includes of course, other factors that can be more fully appreciated from a study of the thermodynamic theories involved. The theory evolved by Carnot shows that efficiency depends upon the range of temperature in the engine cylinder, and this ideal diagram shows complete expansion and compression of steam. The efficiency of the actual engine can approach this ideal but never equal it. This is due to the fact that in the use of steam in a metal cylinder practical difficulties prevent a realization of the ideal. It is apparent that after the steam is in the cylinder there is but one way to get maximum efficiency, and that is by making its terminal temperature a minimum. This indicates that release should be carried out as near the end of the stroke as possible. With the ordinary locomotive valve release does occur near the end of the stroke when there is a long cut-off but when the reverse lever is moved toward the center, thus shortening the cut-off; the release is also removed further from the end of the stroke, thus increasing compression. In the usual locomotive valve, when the engine is "cutting off" at 25 per cent of the stroke, the release has dropped back to 60 per cent, giving only 60/25 or 2.4 expansions, when under ideal conditions there should be 100/25 or 4 expansions. In this condition, compression occurs at about 40 per cent of the stroke. (*Railway Review*, vol. 72, no. 24, June 16, 1923, pp. 988–992, illustrated, *d*)

REFRIGERATION

The Compression Refrigeration Cycle, W. H. Motz. In the abstract of this article from *Refrigerating Engineering*, vol. 9, no. 9, March, 1923, which appeared on page 366 of the June issue of Mechanical Engineering, it was stated that the amount of ammonia evaporated per minute per ton of refrigeration has been taken for standard conditions as 0.442 lb. It should have read 0.422 lb., as 0.442 lb. of ammonia per ton of refrigeration per minute would not be required unless the condensing temperature was exceedingly high or the evaporation temperature was exceedingly low.

SPECIAL PROCESSES

Making Welded Pressed-Steel Automobile Wheels. Description of a process developed by the Stanley Steel Welded Wheel Corporation, Boston, Mass.

Essentially each wheel consists of a spider made up of two flanges welded together and containing eight spokes welded into pockets formed by depressions in the two flange members. Two of these spiders are butt-welded at the hub portions of adjacent flanges, so that the spokes of one spider will alternate with the spokes of the other. This unit is then assembled into the outer rims, which in their turn are provided with pockets into which the spokes are welded in the final assembling.

The actual presswork is of the usual character and it is the welding that is of particular interest. An automatic machine for spot-welding the wheels is described in the original article. The upper electrode holder is held in a frame that pivots to exert pressure on the weld, this pressure being automatically controlled by cam action. The shaft, by means of which the pressure is transmitted, carries a heavy coil spring and a hand wheel for setting the pressure. The spring is capable of transmitting 600 lb. pressure, and the arrangement for adjusting it is such that foot pressure is not required on the control. The entire cycle of operations in making a spot weld includes depressing the electrode, holding it down under pressure for a given time, switching on the current, breaking the current, and finally releasing the pressure.

After the spokes have been spot-welded through the flanges, two spiders, one outer and one inner, are butt-welded on a special machine.

Pressed-steel automobile wheels are said to weigh about the same as wood-spoked wheels, but they are much stronger. It is also claimed that they increase the life of the tire, which is believed to be due to the fact that the pressed-steel wheel possesses greater heat conductivity and as a result the temperature of the tire is reduced. (*Machinery* (N. Y.), vol. 29, no. 10, June, 1923, pp. 757–760, 8 figs., *d*)

TESTING AND MEASUREMENT

Acoustic Method of Finding Elastic Limit of Metals. According to experiments conducted by the physics department of Lehigh University, Bethlehem, Pa., it is believed that stretching a metal until it squeaks and listening for the squeak with a microphone will give a test showing how much strain that the metal can stand when used in a place of stress, such as a bridge girder or railroad rail. Those conducting the experiments point out that the tests may result in a novel and quick method for determining the elastic limit of metals. Forgings could be tested rapidly before they are put in use.

Several metals have been used in the tests. While the investigators listened through a sensitive microphone similar to the dictaphone for the faintest sound, the metal was subjected to a gradually increasing pull until it broke. It was found that squeaking, rasping sounds were produced after the pull had reached a certain definite value, and this value was different for the various metals used. The tests indicated that the sounds were not produced until the elastic limit of the material had been reached. The work will be continued. (*Iron Trade*, vol. 72, no. 23, June 7, 1923, p. 1671, *e*)

CLASSIFICATION OF ARTICLES

Articles of especial merit are rated *A* by the reviewer. Opinions expressed are those of the reviewer, not of the Society.

Standard Screw Threads for Bolts, Machine Screws, Nuts, and Commercially Tapped Holes

First Report of Sectional Committee on the Standardization and Unification of Screw Threads

THE long-looked-for report of the Sectional Committee on the Standardization and Unification of Screw Threads is now before the Councils of the Society of Automotive Engineers and The American Society of Mechanical Engineers. Upon approval and adoption by these boards it will be submitted by them to the American Engineering Standards Committee for formal adoption as an American Standard.

This Sectional Committee was organized under the Procedure of the A.E.S.C. in the fall of 1920, the S.A.E. and the A.S.M.E. acting as Joint Sponsors. The Committee's instructions called for a complete review of the Progress Report of the National Screw Thread Commission, which was then being printed. In April, 1921, the members of the Committee began their detailed study of the report and on June 9, 1921, they met for the formal organization of the Committee and the election of officers. Luther D. Burlingame was elected Chairman, Ralph E. Flanders, Vice-Chairman, and Clifford B. LePage, Secretary. Realizing the difficulty of a committee of 25 functioning efficiently in the preparation of a report of this kind, a Working Committee of seven members of the Sectional Committee was immediately appointed. This Working Committee consisted of Ellwood Burdsall, Chairman, Paul W. Abbott, Earle Buckingham, George S. Case, Ralph E. Flanders, George E. Hammann, and Will R. Porter.

After a very careful study of the N.S.T.C. report and numerous meetings, the Working Committee issued its first report to the members of the Sectional Committee in February, 1922. Since that date four additional revised drafts of this report have been prepared and carefully considered by the Sectional Committee. As the report neared its final form the Sectional Committee delegated Messrs. Flanders, Buckingham, Case, and Wells as a special committee to discuss with the National Screw Thread Commission the slight modifications which the Sectional Committee desired to make. The resulting discussions in the meetings of the Commission led to the adoption of modifications in the report which were mutually satisfactory.

Purpose of Present Report

During its early discussion of the report of the Working Committee the Sectional Committee definitely limited the field to be covered by its first report to Screw Threads for Bolts, Machine Screws, Nuts, and Commercially Tapped Holes. A number of considerations prompted this action. In the first place it was desired to put in the hands of American industry promptly one of the tools which it greatly needs, viz., a manual of improved screw-thread practice. In the second place it found that standards for pipe threads, fire-hose coupling threads, and small hose threads had either been passed through the A.E.S.C. procedure or were on the way by other means, so consideration of them was omitted. But one part of the Commission's report therefore remains to be accounted for. This is Section VI, entitled Gages, and Appendix 6, Gages and Methods of Test. By a vote of the Sectional Committee it was decided not to recommend any one particular system of gages or for gaging screw threads but to prepare and issue as a second report a general discussion on this subject in which certain fundamentals only will be laid down.

Critical Comment

The first report of the Sectional Committee on the Standardization and Unification of Screw Threads is merely a selection from and a rearrangement of the material which was originally

[1] Basic diameter.

[2] Dimensions given are figured to intersection of the worn tool arc with a centerline through crest and root. Minimum flat at root equals $1/8 \times p$.

[3] The tolerances specified for pitch diameter are cumulative and include all errors of lead and angle.

published in the Progress Report of the National Screw Thread Commission. Several "paper" changes have been made by the Committee but these did not alter materially the product itself. Any threaded product which meets the specifications laid down by the Progress Report of the National Screw Thread Commission will also meet the specifications of the Sectional Committee's report.

This report does not present a new set of standards for screw threads but rather an extension of existing standards by specifying limiting dimensions for the various sizes and pitches of threads already in common use. It also gives official sanction to certain processes such as oversize drill sizes which have long been established by common use. Altogether it is an attempt to codify the best current practice on screw-thread production. How well this attempt has succeeded can be best learned by its general use in industry.

The Committee's decision to limit the field covered by its first report to threaded parts for holding purposes, such as bolts, nuts, machine screws, and commercially tapped holes, seems to be well founded. When the standard practice codified by this report has had a fair tryout by the American screw-thread industry, given an opportunity for revision or correction if necessary, a long advance will have been made toward the further establishment of standards for threading tools and screw threads for special purposes. Among the latter are included studs, fine threads of large diameter and short engagement, for instance, those which are used for cap nuts on machine tool collars, hub and radiator caps, etc. The Sectional Committee fully realized that the screw-thread field is so broad as to make it impossible to cover the entire field in its first report. Furthermore the experience which it is hoped to gain by the use of its first proposals will be of great value in working out satisfactory standards for other applications.

Since it is impossible for us to reproduce in Mechanical Engineering the complete report of the Sectional Committee, we are printing several sections of this report, including four tables to indicate the complete and altogether satisfactory way in which this Committee now presents the results of its two years' study. The report is now being edited for publication in pamphlet form and it is expected that these pamphlets will be ready for general distribution by August 15. Those desiring copies should apply to The American Society of Mechanical Engineers.

II Form of Thread

The form of thread profile as specified herein, and known previously as the United States Standard or Sellers' Profile, is adopted and shall hereafter be known as the American (National) Form of Thread.

1 Where Used. The American (National) Form of Thread Profile shall be used wherever possible for screw-thread work.

2 Specifications. The basic angle of thread between the sides of the thread measured in an axial plane shall be 60 degrees. The line bisecting this 60 degree angle shall be perpendicular to the axis of the screw thread.

The basic width of flat at the root and crest of the thread form is found as follows:

$$F = \tfrac{1}{8} \times p \text{ or } 0.125 \times p$$

The basic depth of the thread form is found as follows:

$$h = 0.649519 \times p = \frac{0.649519}{n}$$

where p = pitch in inches

n = number of threads per inch.

3 Clearance in Nut at Minor Diameter. A clearance shall be provided at the minor diameter of the nut by removing the thread form at the crest by an amount between one-sixth and one-fourth of the basic thread depth.

4 Clearance in Nut at Major Diameter. A clearance at the major diameter of the nut shall be provided by decreasing the depth of the truncation triangle any desired amount down to one-third of its theoretical value.

[1] Basic diameter.

[2] Dimensions given are allowable only with tap having theoretically sharp corners. Threaded hole must not reject correct basic "Go" gage by interference with rounded roots due to worn tap. Minimum flat at root equals $\frac{1}{24} \times p$.

[3] The tolerances specified for pitch diameter are cumulative and include all errors of load and angle.

III Thread Series Adopted

Two thread series are adopted,—a coarse and a fine. The Coarse-Thread Series is the present "United States Standard" supplemented in the sizes below one-fourth inch by the standard established by The American Society of Mechanical Engineers (A.S.M.E.) in 1907. The Fine-Thread Series ($^1/_4$ inch to $1^1/_2$ inches inclusive) is in accordance with the present "Regular Screw-Thread Series of the S.A.E: Standard for Screw-Threads" established by The Society of Automotive Engineers (S.A.E.) in 1911, supplemented in sizes below one-fourth inch by the Fine-Thread Series established by The American Society of Mechanical Engineers (A.S.M.E.).

These two series are specified in Table 1.

IV Classification of Fits

1 Description

There are established herein for general use four distinct classes of screw-thread fits as specified in the following brief outline. The examples given under each class of fit are for the purpose of illustration only.

Loose Fit (*Class 1*) Recommended as a commercial standard for tapped holes in the numbered sizes only. May be used with screws of other classes to obtain quality of fit desired. (See Appendix C.)

Free Fit (*Class 2*) Includes the great bulk of screw-thread work of ordinary quality of finished and semi-finished bolts and nuts, etc. (Called "Medium Fit Regular" in the N.S.T.C. "Progress Report.")

Medium Fit (*Class 3*) Includes the better grade of interchangeable screw-thread work, uch ass automobile bolts and nuts (Called "Medium Fit Special" in N.S.T.C. "Progress Report").

Close Fit (*Class 4*) Includes screw-thread work requiring a fine snug fit, somewhat closer than the medium fit, such as high grade aircraft parts, etc. In this class of fit selective assembly of parts may be required. It is not considered practicable as a commercial standard for tapped holes of the numbered sizes.

2 A Second Method of Obtaining Medium Fit (Class 3)

A detailed examination of the tolerances given in Tables 3, 4 and 5 will indicate that the same quality of fit as given by Medium Fit screws and threaded holes can be obtained by using screws to Close Fit tolerances in holes made to Free Fit tolerances, or vice versa. The general adoption of this practice will reduce the variety of taps, gages, threaded parts, etc., required to be carried in stock. However, the combination of Free and Close Fits should be used in place of Medium Fit only when the substitution is understood and agreed to by all parties concerned.

4 General Specifications

The following general specifications will apply to all classes of fits specified in the body of the report. For special specifications applying to the Loose Fit class see Appendix C.

(*a*) *Uniform Minimum Nut.* The pitch diameter of the minimum threaded hole or nut corresponds to the basic size, variations being permitted above the basic size. The major and minor diameters of the minimum nut are also uniform for all classes of fit.

(*b*) *Uniform Tap Drill Sizes.* The maximum and minimum minor diameters and the consequent minor diameter tolerances are the same for all nuts of a given size for all classes of fit. This permits uniform tap drill sizes for all classes of fit.

(*c*) *Uniform Major and Minor Diameter of Screws.* The maximum and minimum major and minor diameters are the same for all screws of a given size for all classes of fit herein tabulated.

(*d*) *Length of Engagement.* The tolerances herein determined are based on a length of engagement not to exceed the nominal diameter of the thread. Where greater lengths of engagement are required a corresponding increase in the accuracy of lead and thread form is necessary, which may be obtained by the provision of selection of more accurate threading tools, and the use of longer "Go" gages.

(*e*) *Rounded Root Forms.* The crest clearances allowed are such as to permit rounded root forms in both nut and screw. These may be formed either by tools purposely rounded or rounded as a result of wear in use. For the limits of this permissible rounding see Pages 28 and 29, Par. 6 and Par. 7.

Roller Chains and Sprockets

Report of the Joint Committee Which is Composed of Representatives of the S.A.E., the A.G.M.A., and the A.S.M.E.

The organization of a roller-chain committee was approved by the Council of The American Society of Mechanical Engineers at the Spring Meeting of the Society in 1917. The Committee was accordingly organized at Indianapolis, Ind., September 14, 1917. Its second meeting and all subsequent meetings have been held in conjunction with the Roller Chain Division of the Society of Automotive Engineers. At a later date the Sprocket Committee of the American Gear Manufacturers Association was invited to coöperate in the standardization work of the Joint Committee. The Committee will welcome suggestions for corrections or additions to this report. These should be addressed to the Secretary, Geo. M. Bartlett, in care of the Society, 29 W. 39th St., N. Y. City.

Recommendations of the Committee, relating to the standardization of chains and sprockets which have been approved by the Council of the A.S.M.E. and published in the September, 1921, issue of Mechanical Engineering, are as follows:

1 Series of Pitches
2 Roller Diameters
3 Pin Diameters
4 Thickness of Side Plates
5 Widths of Narrow and Wide Series
6 Heavy, Medium, and Light Series
7 Names of Chain Parts
8 Tolerance for Chain Length
9 Measuring Load
10 Test Load
11 Uniform System of Numbering Chains
12 Thickness and Chamfer of Sprocket Teeth
13 Standard Tooth Form
14 Range of Teeth for Each Cutter
15 Number of Teeth on Which to Base Each Cutter
16 Sprocket-Cutter Outlines
17 Outside Diameters for Sprockets
18 Thickness of Cutters.

New Recommendations

The following proposed standards have been approved at meetings of the Joint Roller Chain Committee and are now before the Council of The American Society of Mechanical Engineers for approval and adoption.

19 The *thickness of center plates* for double, triple, and quadruple chains shall be equal to two thicknesses of the regular inside plates as used in the single standard chain.

20 The *minimum breaking strength* of standard chains, when used for publication, shall be $105{,}000 \times (\text{Pin Diam.})^2 - 700$ lb.

21 The following note is to be attached to the formula for minimum breaking strengths.

Note: These are the loads at which the chains may break or become permanently stretched. The actual *working* loads may range from $^1/_6$th to $^1/_{50}$th of the ultimate strength, depending upon the speed, teeth in wheels, conditions of lubrication, and pulsations arising from either power or load end. Chains should not be selected on the basis of breaking strengths.

22 Revise the *standard measuring load* from "1 per cent of the *average* breaking strength" to 1.25 per cent of the *minimum* breaking strength. Reason: The minimum breaking strength is given by a formula—the average breaking strength is not.

23 Revise the *standard test load* from "$^1/_3$ of the *average* breaking strength" to 40 per cent of the *minimum* breaking strength. Reason: same as for 22.

24 Revise the standard nomenclature with respect to the terms "assembled pins," "pin link," and "connecting link" to agree with that given below under the heading Roller-Chain Nomenclature.

25 Four *types of sprocket cutters* to be recognized, namely:

Space Cutters, of which five will be required to cut from 7 teeth up for any given roller diameter. The ranges to be respectively 7–8 teeth, 9–11 teeth, 12–17 teeth, 18–34 teeth, 35 teeth and over. The use of less than 7 teeth is discouraged, but when necessary single-purpose cutters of this type are to be used.

Straddle Cutters, of which two will be required to cut from 7 teeth up for any given pitch and roller diameter. Cutter B is recommended for 17 teeth and under (or for more than 17 teeth if a low pressure angle is desired). Cutter A is recommended for 18 teeth

and over (or for less than 18 teeth if a large pressure angle is desired and the arc of contact between chain and sprocket is fairly large).

Hobs, of which only one will be required to cut any number of teeth for a given pitch and roller diameter.

Fellows Cutters, for use on the Fellows gear shaper, of which only one will be required to cut any number of teeth for a given pitch and roller diameter.

26 All *cutters to be marked* giving pitch, roller diameter, and range of teeth to be cut.

27 *Sprocket Cutter Bores* (recommended practice) to be approximately:

$$0.7\sqrt{\text{Width of cutter} + \text{roller diam.}} + 0.7\,P$$

where P is the pitch. See Table 8.

28 *Minimum Outside Diameters of Space Cutters* for 35 teeth and over (recommended practice) to be approximately:

$$1.2\,(\text{Bore} + \text{roller diam.} + 0.7\,P) + 1\text{ in.}$$

See Table 1.

29 Minimum outside diameters of space cutters for less than 35 teeth (recommended practice) to be as per Table 1.

30 *Minimum Outside Diameters of Straddle Cutters* (recommended practice) to be same as for space cutters for 35 teeth and over. See Table 4.

31 *Size of Keyways* in cutters to be in accordance with present prevailing cutter-arbor practice as given in Table 8.

32 *Number of Cutting Teeth in Sprocket Cutters* to be left to the individual cutter makers.

33 The *standard tooth form for block and twin-roller chains* shall follow the same essential specifications as for standard roller chains with the same angle of bend.

34 Recommended *widths of cutters* as per Table 8.

35 Recommended *designations* for the four principal types of sprockets are as follows:

- Type A—plain plate
- Type B—single hub
- Type C—double hub
- Type D—detachable hub

36 *Revised Sprocket-Tooth Form.* The Joint Committee now submits herewith a proposed modification of the standard sprocket-tooth form as passed upon by the Technical Sub-Committee, and approved at the meeting of the Joint Committee held in New York, January 8, 1923.

In the original design very careful consideration was given to the working arcs of the teeth. The exact height of the tooth was set in an empirical manner, as it was not an important operating element. Subsequent developments have indicated that the long tooth restricted the range of teeth that could be covered by a given cutter, whereas it seemed desirable to increase this range for certain special cases. This was accomplished by shortening the tooth and giving greater clearance between the roller and the point of the tooth.

Also the probability of an increased use of hobs and Fellows cutters for generating the teeth has increased the desirability of modifying the angle of tooth gap for larger numbers of teeth so as to conform more closely to the generating process and at the same time to produce a desired increase in pressure angle for the larger sprockets.

Roller-Chain Nomenclature

Roller Link. An inside link consisting of two inside plates, two bushings, and two rollers.

Pin Link. An outside link consisting of two pin-link plates assembled with two pins.

Inside Plate. One of the plates forming the tension members of a roller link.

Pin-Link Plate. One of the plates forming the tension members of a pin link.

Pin. A stud articulating within a bushing of an inside link and secured at its ends by the pin-link plates.

Bushing. A cylindrical bearing in which the pin turns.

Roller. A ring or thimble which turns over a bushing.

Assembled Pins. Two pins assembled with *one* pin-link plate.

Connecting Link. A pin link with one side plate detachable.

Connecting-Link Plate. The detachable pin-link plate belonging to a connecting link.

Offset Link. A link consisting of two offset side plates assembled with a bushing and roller at one end and an offset-link pin at the other.

Offset-Link Pin. A pin used in offset links.

Design of Standard Sprocket Tooth

P = pitch; D = nominal roller diameter; T = number of teeth

$$D' = 1.005D + 0.003\text{ in.};\quad A = 35^\circ + \frac{60}{T};\quad A' = 35^\circ - \frac{120}{T};$$

$$B = 18^\circ - \frac{56}{T};$$

$$ac = 0.8D;\quad M = 0.8D\cos\left(35^\circ + \frac{60}{T}\right);$$

$$N = 0.8D\sin\left(35^\circ + \frac{60}{T}\right)$$

$$J = 0.8D\sin\left(35^\circ - \frac{120}{T}\right);\quad K = 0.8D\cos\left(35^\circ - \frac{T}{120}\right)$$

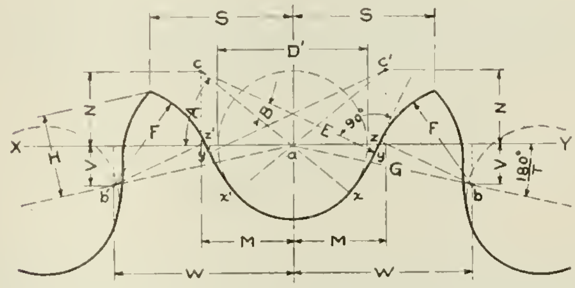

Fig. 1 Tooth Form

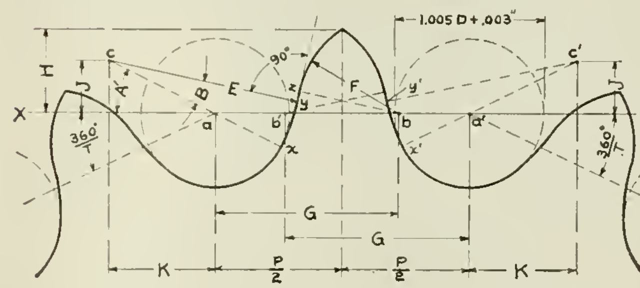

Fig. 2 Tooth Form

$$E = 1.3025D + 0.0015\text{ in.}$$

$$\text{Chord } xy = (2.605D + 0.003)\sin\left(9^\circ - \frac{28}{T}\right)$$

$$yz = D\left[1.24\sin\left(17^\circ - \frac{64}{T}\right) - 0.8\sin\left(18^\circ - \frac{56}{T}\right)\right]$$

$$G = 1.24D;\quad W = 1.24D\cos\frac{180}{T};\quad V = 1.24D\sin\frac{180}{T}$$

$$F = D\left[0.8\cos\left(18^\circ - \frac{56}{T}\right) + 1.24\cos\left(17^\circ - \frac{64}{T}\right) - 1.3025\right] - 0.0015\text{ in.}$$

$$H = \sqrt{F^2 - \left(1.24D - \frac{P}{2}\right)^2}.$$ When $1.24D$ is less than $\frac{P}{2}$, then $H = F$

$$S = \frac{P}{2}\cos\frac{180}{T} + H\sin\frac{180}{T}$$

Outside diameter of sprocket when tooth is pointed

$$= P\cot\frac{180}{T} + 2H$$

Minimum outside diameter of blank $= P\left(0.6 + \cot\frac{180}{T}\right)$

The pressure angle for a new chain is $xab = 35^\circ - \frac{120}{T}$

The minimum pressure angle is $xab - B = 17^\circ - \frac{64}{T}$

The average pressure angle is $26^\circ - \frac{92}{T}$

Standard "Space" Cutters for Sprocket Teeth

Space cutters are made for the following ranges of teeth: 7–8; 9–11; 12–17; 18–34; 35 and over. The lowest number of teeth in any group is designated by n, and the highest by N.

The cutters are based upon an intermediate number of teeth, T, equal to $2Nn \div (N + n)$; but the topping curve zs is based upon N teeth. The values of T for the several cutters are 7.47; 9.9; 14.07; 23.54; and 56.

Space cutters designed for a given roller diameter D will cut sprockets of any pitch.

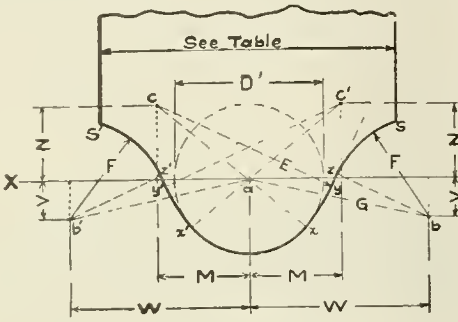

Fig. 3 Space Cutter

Construction. Referring to Fig. 3, draw XY. With a as center and a radius ax equal to $\frac{1}{2} D'$ draw the circular arc for the seating curve xx' (Table 2). Locate c and c' from dimensions M and N (Table 1). With c and c' as centers describe the arcs yx and $x'y'$. Draw yz perpendicular to cy. Locate b from dimensions W and V, draw bz parallel to cy, and with radius bz, equal to F (Table 1), draw the topping curve zs. The line yz is a common tangent to the two circular arcs xy and zs.

Supplementary Data. Tables 1, 2, and 3 give all necessary data for the construction of standard space cutters. Supplementary formulas used in their calculation are given below.

The angle Yab is $180°/T$ when the cutter is made for T teeth only; but it has values as given in Table 3 for cutters covering a range of teeth as here designed. Accordingly the following formulas are special for cutters covering the standard ranges of teeth:

TABLE 1 DATA FOR LAYING OUT CUTTER OUTLINES

Range of teeth	M	N	W	V	F	Chord xy	yz
7–8	$0.585D$	$0.5457D$	$1.1327D$	$0.504D$	$0.7104D - 0.0015''$	$0.2384D + 0.0003''$	$0.039D$

TABLE 3 CHECKS

Teeth	E	G	$b-c$ $b'-c'$	$b-c'$ $b'-c$	Angle Yab
7–8	$1.3025D + 0.0015$	$1.24D$	$2.0133D$	$1.1841D$	24°
9–11	$1.3025D + 0.0015$	$1.24D$	$2.0014D$	$1.0847D$	18°10′
12–17	$1.3025D + 0.0015$	$1.24D$	$1.9852D$	$0.9682D$	12°
18–34	$1.3025D + 0.0015$	$1.24D$	$1.9621D$	$0.8465D$	5°
35 up	$1.3025D + 0.0015$	$1.24D$	$1.9445D$	$0.7576D$	0°

$W = 1.24D \cos Ya\,b$; $V = 1.24D \sin Yab$

$$bc' = b'c = \sqrt{(W - M)^2 + (V + N)^2}$$

$$yz = D\left[1.24 \sin\left(17° + \frac{116}{T} - Yab\right) - 0.8 \sin\left(18° - \frac{56}{T}\right)\right]$$

$$F = D\left[0.8 \cos\left(18° - \frac{56}{T}\right) + 1.24 \cos\left(17° + \frac{116}{T} - Yab\right) - 1.3025\right] - 0.0015 \text{ in.}$$

$$cb = c'b' = \sqrt{(E + F)^2 + yz^2}$$

Width of cutter $= 1.02P\left(0.6 + \cot\frac{180}{n}\right)\sin\frac{180}{n}$ to the next higher 32nd inch. Where the same roller diameter is commonly used with chains of two different pitches it is recommended that stock cutters be made wide enough to cut sprockets for both chains.

Design of Standard Straddle Cutters

Only two cutters of this type are required to cover the entire range of teeth.

P = pitch; D = roller diameter; T = number of teeth on which cutter is based.

Construction. Draw XY and the two seating-curve circles as shown in Fig. 4, making radius $ax = 0.5025D + 0.0015$ in.

Locate c and c' from the dimensions K and J as given in Table 4. Locate b and b'. Draw cax and $c'a'x'$ and with centers c and c' draw the "working curves" xy and $x'y'$. Draw yz and $y'z'$ perpendicular to cy and $c'y'$, respectively. Draw bz and $b'z'$ parallel to cy and $c'y'$, respectively. With b and b' as centers and radius equal to bz, strike the arcs of the "topping curves." The dimensions given in Table 4 may be calculated from the formulas given in connection with Fig. 2.

TABLE 4 DATA FOR LAYING OUT STRADDLE-CUTTER OUTLINES

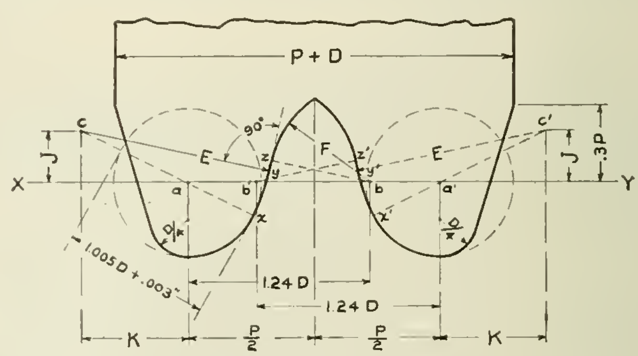

Fig. 4 Straddle Cutter

$$\text{The maximum pressure angle is } xab = 35° - \frac{120}{T}$$

$$\text{The minimum pressure angle is } xab - acy = 17° - \frac{64}{T}$$

$$\text{The average pressure angle is } 26° - \frac{92}{T}$$

Standard Sprocket-Tooth Form for Block Chains

L = pitch of blocks; e = pitch of side plates; P = nominal pitch of chain $= L + e$; D = diameter of round end of block; T = number of teeth.

$$L' = L + 0.005D + 0.003 \text{ in.};\ A = 35° + \frac{120}{T};\ B = 18° - \frac{28}{T}$$

$$ac = 0.8P;\ M = 0.8D \cos\left(35° + \frac{120}{T}\right);$$

$$N = 0.8D \sin\left(35° + \frac{120}{T}\right)$$

$$E = 1.3025D + 0.0015 \text{ in.}$$

$$\text{Chord } xy = 2.6D \sin\left(9° - \frac{14}{T}\right)$$

$$yz = D\left[1.24 \sin\left(17° - \frac{32}{T}\right) - 0.8 \sin\left(18° - \frac{28}{T}\right)\right]$$

$$G = 1.24D;\; W = 1.24D \cos\frac{180}{T};\; V = 1.24D \sin\frac{180}{T}$$

$$F = D\left[0.8 \cos\left(18° - \frac{28}{T}\right) + 1.24 \cos\left(17° - \frac{32}{T}\right) - 1.3\right]$$

$$H = \sqrt{F^2 - \left(1.24D - \frac{P - L'}{2}\right)^2}, \text{ very nearly,}$$

$$S = H \sin\frac{180}{T} + \frac{P - L'}{2}\cos\frac{180}{T} + \frac{L'}{2}, \text{ very nearly.}$$

Outside diameter of sprocket when tooth is pointed =

$$2H + \frac{L' + (P - L')\cos\dfrac{180}{T}}{\sin\dfrac{180}{T}}, \text{ very nearly.}$$

$$\text{Minimum outside diameter of blank} = 0.6e + \frac{L + e\cos\dfrac{180}{T}}{\sin\dfrac{180}{T}}$$

The pressure angle for a new chain is $xab = 35° - \dfrac{60}{T}$

The minimum pressure angle is $xab - B = 17° - \dfrac{32}{T}$

The average pressure angle is $26° - \dfrac{46}{T}$

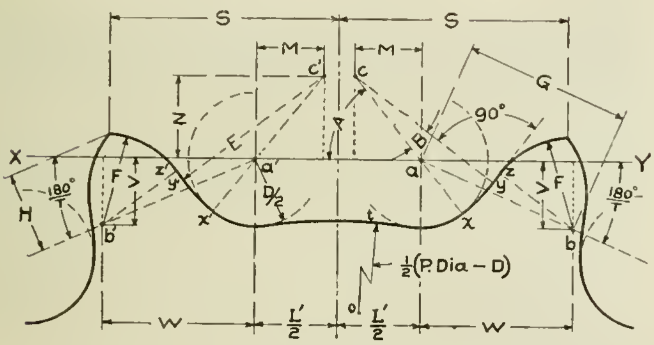

Fig. 5 Tooth Form for Block Chains

Standard Cutters for Block-Chain Sprockets

Sprocket cutters for block and twin-roller chains are made for the same ranges of teeth as for roller-chain sprockets and are based upon the same number of teeth.

Construction. Referring to Fig. 6, draw XY. Locate a and a' making L' = pitch of block + $0.005D$ + 0.003 in., and with these points as centers (radius = $\frac{1}{2}D$) draw the circular arcs for the seating curves. With radius ot, equal to one-half the bottom diameter of the largest sprocket to be cut, draw an arc tangent to the two seating curves. Locate c and c' from dimensions M and N (Table 5). With c and c' as centers describe the arcs xy and $x'y'$. Draw yz and $y'z'$ perpendicular to cy and $c'y'$, respectively.

* Cutter will fill all requirements for chains as made in the United States at the present time.

ENGINEERING RESEARCH

A Department Conducted by the Research Committee of the A.S.M.E.

Résumé of the Month

A—Research Results

The purpose of this section of Engineering Research is to give the origin of research information which has been completed, to give a résumé of research results with formulas or curves where such may be readily given, and to report results of non-extensive researches which in the opinion of the investigators do not warrant a paper.

Aeronautics A2-23. Aeronautic Instruments. This paper describes in detail various aeronautic instruments and will be useful to those interested in the general aspects of the aeronautic-instrument art. It was prepared by F. L. Hunt and is known as Bureau of Standards Technologic Paper No. 237. For a copy address Superintendent of Documents, Washington, D. C.; price, 20 cents.

Building Materials A2-23. Loading Test of a Hollow-Tile and Reinforced-Concrete Floors. The Arlington Building, Washington, D. C. was originally intended for a hotel with a live load of 75 lb. per sq. ft. On account of the purchase by the Government for other uses, the construction was strengthened in view of possible loads on floor panels of 100 lb. per sq. ft. The width of the panels of this building varied from about 11 to 15 ft. and the ratio of length to width varied from 1 to 2.

A 1 : 2 : 4 gravel concrete was used; that in the columns and beam stems was very "sloppy;" in the slabs it was somewhat drier. Tests on the cylindrical specimens and the difficulty of chipping the slabs in the preparation for the test showed the concrete to be of good quality. The age of the specimens was about two and one-half months. Round and square smooth bars and square corrugated bars were used for reinforcement. The tiles used in the floors appeared to be of medium-burned grade, except some of the 4-inch tiles, which apparently were hard-burned. The columns consist of a steel H-section surrounded by a thick casing of concrete, the total column being 16 in. square. Vertical rods for reinforcement were placed at each corner and held in place by square ties made of 1/4-in. round rods placed 12 in. on centers and 2 in. from the surface of the concrete, which were designed to prevent spalling in case of fire.

This type of construction was new in many respects and the structure is considerably lighter than recommended by the final report (1916) of the Joint Committee on Concrete and Reinforced Concrete or allowed by most building codes. The primary purpose of the test was, therefore, to find how much live load could actually be placed on individual panels before serious stresses were developed. It was desired by all concerned in this test to secure as much information as possible on the action of the hollow-tile slabs and incidentally also on the framework when subjected to load.

The tests herein described are among the first to be made on this type of construction, which is a framework of light-weight structural-steel members used as reinforcement for the concrete columns and beams, supporting two-way reinforced concrete and terra-cotta, hollow-tile floor panels.

The authors of this Bureau of Standards Technologic Paper No. 236 are Messrs. L. J. Larson and S. N. Petrenko. The paper includes a bibliography of 29 items describing similar field tests of floors in reinforced-concrete buildings. Address Superintendent of Documents, Washington, D. C. Price, 15 cents.

Fuels A5-23. Combustion of Powdered Coal. This paper contains a review of some tests conducted by the U. S. Bureau of Mines and the Combustion Engineering Corporation on boilers fired with powdered coal, which show that coal when powdered may be burned with greater thermal efficiency for steam raising than when burned in any other way. It was presented before the section of Gas and Fuel Chemistry at the 64th meeting of the American Chemical Society, Pittsburgh, Pa. by Henry Kreisinger, Research Engineer, Combustion Engineering Corporation, and John Blizard, Fuel Engineer of the U. S. Bureau of Mines. Address H. Foster Bain, Director, U. S. Bureau of Mines, Washington, D. C. requesting copy of Serial No. 2470.

Lubricants A2-23. Physical and Chemical Properties of Lubricating Oils Made from California Crudes. This is the second of a series of reports on a survey of petroleum products manufactured on the Pacific Coast from California crude oils. California crudes differ in many characteristics from the petroleum produced in other parts of the United States, and the claim has been made that some of the present Federal Specifications for petroleum products tend to discriminate against California products. The purposes of the present survey are to determine what particular specification requirements California petroleum products characteristically fail to meet, how widely the products deviate from these requirements, and if possible to show whether the fault lies with the specifications or the products, or along what lines investigation to determine the question should proceed. The first report of the series gave the physical and chemical properties of gasoline and mineral spirits made from California crudes.

Data on the physical and chemical properties of the samples tested are given in tables, each of which is preceded by the classification and specifications for the particular class of oil considered. Following each table brief notes show wherein samples deviate from specification requirements.

Most of the oils meet the specification requirements as regards flash point, viscosity, pour point; corrosion and reaction tests, except for deviations which for the most part are of minor importance.

Those desiring full information concerning these tests should address the authors, Messrs. E. C. Lane and N. F. LeJeune at the Bureau of Mines, Washington, D. C., requesting a copy of Serial No. 2482.

Mining A1-23. Monel Metal a Material for Flame Safety Lamp Gauzes. This pamphlet known as Serial No. 2468 of the Bureau of Mines was prepared by Messrs. A. B. Hooker and R. A. Kearns.

Monel metal, the natural alloy of nickel and copper, is practically noncorrodible. Its melting point is approximately the same as that of steel. From time to time it has been suggested that this alloy might be a better gauze material than steel, and the investigation showed that it is a very satisfactory material for the purpose.

Monel-metal gauzes maintained their shape and stiffness under the greatest heat to which they were subjected in gaseous mixtures equally as well as steel gauzes did; this together with the fact they do not corrode perceptibly in humid atmospheres should assure a much longer life for Monel-metal gauzes. For copies address H. Foster Bain, Director, U. S. Bureau of Mines, Washington, D. C.

Non-Ferrous Metals A5-23. Monel-Metal a Material for Flame Safety Lamp Gauzes. See *Mining A1-23.*

Properties of Engineering Materials A1-23. Loading Test of a Hollow-Tile and Reinforced-Concrete Floors. See *Building Materials A2-23.*

Refrigeration A2-23. New Mollier Chart for Ammonia. In reference "Refrigeration A2-23" (July issue of Mechanical Engineering) the publication of Tables of Thermodynamic Properties of Ammonia was announced. These data are now available in the form of a Mollier chart.

Pressures and volumes can easily be read on this chart with an accuracy of 1 per cent and heat content to within 0.5 B.t.u. It may be used as a complete substitute for the tables in calculations which do not require the highest degree of accuracy and such computations can be carried out by this means with much greater speed than is possible from data presented in tabular form.

It is known as Bureau of Standards Miscellaneous Publication No. 52, and can be obtained from the Superintendent of Documents, Washington, D. C., at 5 cents per copy.

Safety Devices A1-23. Monel Metal a Material for Flame Safety Lamp Gauzes. See *Mining A1-23.*

B—Research in Progress

The purpose of this section of Engineering Research is to bring together those who are working on the same problem for coöperation or conference, to prevent unnecessary duplication of work, and to inform the profession of the investigators who are engaged upon research problems. The addresses of these investigators are given for the purpose of correspondence.

Automotive Vehicles and Equipment B1-23. Growth of Cast-Iron Pistons. See *Iron and Steel B2-23.*

Building Materials B2-23. Colorless Waterproofing Materials for Stone. Investigations are now under way at the Bureau of Standards covering the action of frost on building stone and on the value of colorless waterproofing materials with which to protect the surface of stone structures. During the last month the series of exposure tests on such materials, having for its object the determination of the relative durability of these treatments under weather conditions, has been supplemented by a series of tests to determine the efficiency of the different waterproofing materials in preventing decay of the stone.

Crystallization tests are being made on waterproofed specimens of stone to secure a comparison between treated and untreated specimens. Waterproofed specimens have also been exposed to the weather and will be tested after a considerable period of exposure.

Electrolysis B1-23. Efects of Impurities in Storage-Battery Electrolytes. The importance of obtaining information concerning the action of impurities in storage-battery electrolytes arises from the detrimental effects which many of them produce on the operating characteristics and life of the storage battery. Such information is necessary as a basis for the preparation of specifications covering sulphuric acid for use in batteries. In the present investigation the effects of small

amounts of iron, manganese, platinum, and copper have been determined. It was found that the presence of 1 part in 10,000,000 of platinum in the electrolyte increases the local action at the negative plates 50 per cent; the effect of copper is much less, while the effect of iron is of unusual interest because of its accelerating action at the negative plates. Manganese deposits upon the positive plates in the form of manganese dioxide which covers the active material, closes the pores, and causes a large amount of charging current to be wasted as gas. Work is being extended which will include the effect of other impurities.

Hardness B1-23. Study of Quenching Media. The object of a new investigation started by the Bureau of Standards during the past month is to obtain more complete information than is now available on the cooling properties of the ordinary quenching liquids used in the heat treatment of steel. It is also hoped that some information bearing on the subject of dimensional changes, occurring during the hardening of steel, will also be obtained. A few preliminary experiments have been carried out in quenching nickel cylinders in water with very satisfactory results. As the preliminary work is now practically completed, it is hoped that considerable progress will be made on the main investigation during the next few weeks.

Iron and Steel B2-23. Growth of Cast-Iron Pistons. This research has been conducted with special reference to the growth of the cast iron used in automobile pistons. While it has been known for years that pistons can be grown a very small amount, this investigation has shown that this amount can be made many times greater under the proper treatment, and as such developed to the point where it can be used as a certain and practical repair process.

Further work remains to be done on this subject which may be done very profitably: (1) The determination of the variation of the constituents in the material with the number of treatments, the temperature used, etc. (2) The variation of the strength under the same conditions. (3) The more complete control of warp. (4) The extent, the location and magnitude of internal strains. (5) The variation of hardness of the pistons before and after different heat treatment. This investigation has been conducted by A. R. Nottingham, State College of Washington, Pullman, Washington.

Mining B1-23. Non-Destructive Testing of Wire Rope. See *Properties of Engineering Materials B1-23.*

Non-Ferrous Metals B3-23. Scratch Hardness of Copper. The results obtained in cold rolling very pure, electrolytic, unmelted copper and also ordinary commercial copper indicate clearly that the early stages of the deformation of the metal harden it very rapidly. The maximum degree of hardness is soon reached, however, and a reversal occurs, the metal becoming very appreciably softer as the deformation process is continued, so that the metal in its final condition after cold rolling is completed, is softer as measured by the scratch hardness method than in its initial state. These results are confirmed by tests made on the same material by the micro-Brinell method. Annealing cold-rolled sheets at a low temperature (100 deg. cent.) softens the material appreciably, but the general form of the hardness deformation curve is not affected.

After annealing at a higher temperature all specimens showed the same hardness, thus indicating that thinness of the rolled material does not affect materially the results of the scratch hardness test. This is an important point and suggests the use of this method of hardness testing on such specimens as are too thin to permit the determination of hardness by other more familiar methods. The results which were obtained with pure iron and with an iron-carbon alloy (low-carbon) were of the same general character as those obtained with copper and thus helped to confirm the conclusions which had been tentatively reached.

This work which is being carried on by the Bureau of Standards will be extended to a few other metals to determine whether this behavior is peculiar to copper or more general in its nature.

Properties of Engineering Materials B1-23. Non-Destructive Testing of Wire Rope. An investigation of the possibilities of using non-destructive methods for testing wire rope with special reference to hoisting rope is about to be undertaken by the Bureau of Standards. Present methods of inspection are unsatisfactory and do not unfailingly tell when it is necessary to remove the rope from service. The object of this investigation is to develop, if possible, some method by which an actual test can be made to determine the conditions of the rope with respect to its deterioration in service, without destroying it. An advisory committee is being organized which will be composed of representatives of the principal interests connected with the manufacture, use, and testing of wire rope.

Steel—Its Treatment and Products B2-23. Heat Treatment and Properties of Magnet Steels. The Metallurgical and Electrical Divisions of the Bureau of Standards in coöperation, are beginning an investigation to determine the effects of various heat treatments upon the characteristic properties of the steels now used commercially or suggested for use in the manufacture of permanent magnets. During the past month about 10 samples were hardened, and it is hoped that they will soon be ready for the first magnetic tests.

Safety Devices B1-23. Non-Destructive Testing of Wire Rope. See *Properties of Engineering Materials B1-23.*

A.S.M.E. Boiler Code Committee Work

The Boiler Code Committee meets monthly for the purpose of considering communications relative to the Boiler Code. Any one desiring information as to the application of the Code is requested to communicate with the Secretary of the Committee, Mr. C. W. Obert, 29 West 39th St., New York, N. Y.

The procedure of the Committee in handling the cases is as follows: All inquiries must be in written form before they are accepted for consideration. Copies are sent by the Secretary of the Committee to all of the members of the Committee. The interpretation, in the form of a reply is then prepared by the Committee and passed upon at a regular meeting of the Committee. This interpretation is later submitted to the Council of the Society, for approval, after which it is issued to the inquirer and simultaneously published in Mechanical Engineering.

Below are given the interpretations of the Committee in Cases Nos. 414, 416 and 418, as formulated at the meeting of April 26, 1923, and Cases Nos. 419 and 420 as formulated at the meeting of May 31, 1923, and approved by the Council. In accordance with the Committee's practice, the names of inquirers have been omitted.

Case No. 414

Inquiry: Is it permissible, in the case of the flue of an internally-fired boiler which is corrugated for about half of its length and the remainder plain, to calculate the thickness of the plain portion in accordance with Par. 239, assuming that the length of the plain portion is the distance from the center line of the rivets in the head to the beginning of the corrugations?

Reply: It is the opinion of the Committee that in the calculation of the thickness of the plain portion of such a furnace, Par. 239*b* should be used, taking for the length the distance from the face of the flange to the center of the first definite corrugation, and the thickness thus obtained shall be uniform throughout the entire length of the flue.

Case No. 416

(In the hands of the Committee)

Case No. 418

Inquiry: Is it permissible under the requirements of the Heating Boiler Section of the Code, to attach the safety valve to the pipe-header outlet connection of a type of cast-iron sectional heating boiler with sections designed too narrow to admit of a separate opening on any one of them for the safety valve?

Reply: If the design of the boiler is such that it is not possible to form the safety-valve openings directly on the boiler sections, it is the opinion of the Committee that the sections should be connected at two or more points to a manifold or header which will serve as a steam drum, and that it will be permissible to mount the safety valve on this manifold or header.

Case No. 419

(In the hands of the Committee)

Case No. 420

Inquiry: Is it permissible, under the requirements of the Boiler Code, to drive up a blister or blisters on a tube or tubes of a water-tube boiler and reinforce them by depositing metal over the same by the autogenous process; or later when other blisters appear above or below the first reinforcement to again use the same process, increasing the length of the reinforcement; also to weld tubes lengthwise by the same process regardless of minimum or maximum length of weld for any thickness of tube and for any pressure without removing the tube from boiler or annealing the welding?

Reply: It is the opinion of the Committee that such reinforcement or welding of blisters or other defects in the tubes of water-tube boilers would be analogous to the welding of cracks in shell plates subject to tensile strain which is prohibited under the Recommendations for Repairs by Welding in the Appendix of the 1918 Edition of the Code, page 127, third paragraph.

MECHANICAL ENGINEERING

A Monthly Journal Containing a Review of Progress and attainments in Mechanical Engineering and Related Fields, The Engineering Index (of current engineering literature), together with a Summary of the Activities, Papers and Proceedings of

The American Society of Mechanical Engineers

Contributions of interest to the profession are solicited. Communications should be addressed to the Editor.

An American Screw-Thread Series

Luther D. Burlingame

It might be assumed because we have the long-established U. S. Standard for Screw Threads, and for small diameters the more recently adopted A.S.M.E. Standard, also the S.A.E. Standard for fine threads, that all the requirements for American Screw-Thread Standardization have been met. The problem of interchangeability, however, is only partly solved by the establishment of the general form of thread, and of the relation of pitch to diameter. That this is so is shown by the wide variation in screw and nut products now on the market, also of taps and dies. In spite of the degree of standardization so far attained, the screw-thread product of one manufacturer often will not interchange with that of another, because each of them is working within his own range of limits and tolerances.

The requirements of the Navy will illustrate the need of further steps in standardization. The importance of naval vessels' being able to secure from a wide variety of sources necessary supplies involving questions of screw threads is apparent, and yet at the present time interchangeability in such products cannot be assured even when they are manufactured ostensibly according to the same system.

It is to remedy this condition that further efforts at standardization have been undertaken.

As far back as 1912 the A.S.M.E. appointed a Committee on Limits and Tolerances in Screw-Thread Fits. This Committee after a number of years' work rendered a report which will be found in the A.S.M.E. Transactions, Vol. 42, page 1053, and which laid the foundation for further progress.

Members of this original Committee, recognizing that the whole screw-thread problem was too great to solve at a single effort and with limited support, took steps to secure Government coöperation, and through their influence a commission was appointed by the U. S. Government to make a thorough study of the whole matter.

The able and thorough work of this commission resulted in the publication in 1921 of the Progress Report of the National Screw Thread Commission, covering coarse and fine systems of screw threads for general use, pipe threads, hose-coupling threads, and also gaging systems, such as to insure the products' coming within the required tolerances for the classes of work for which each was intended.

This report was officially brought to the attention of the two engineering societies having the most vital interest in its findings, and they (the S.A.E. and the A.S.M.E.) were made sponsors, under the procedure of the A.E.S.C., for the purpose of reviewing the Report of the Commission.

The work of the joint committee appointed under this authorization has been done with the special purpose of adapting the report of the commission to the practical and everyday uses of industry. For that reason its work has been largely a "boiling down" and rearranging process, and the suggesting of such modifications as would make the original report more workable.

Two years of effort, including painstaking committee and subcommittee work and conferences with the National Screw-Thread Commission, have resulted in bringing about full agreement with the commission regarding suggested changes, and the Joint Committee now presents its first Report, several sections of which will be found on page 498 of this issue of Mechanical Engineering.

The question of gaging has not been made a part of this first Report but will take the form of a later one, the subject being treated so as to lay down general principles rather than to recommend the adoption of a particular plan of gaging, as it is felt that the primary purpose is to establish the requirements of interchangeability for the product and leave to each manufacturer the determining of methods to bring it within those requirements.

While the standard here submitted represents distinctly an American standard and is the outgrowth of American practice, there is still a hope on the part of the committee that it will prove a steppingstone toward uniformity with British standards. This possibility has been in the minds of both the commission and the joint committee, resulting in incorporating in the Report such features as would most nearly accord with and aid in interchangeability with the Whitworth Standard. Study has also been given to the question as to what mutual concessions might be practicable so as to eventually bring the two systems of the English-speaking world into uniformity.

The "ice was broken" at the time of the National Screw-Thread Commission's visit to England, in 1919, when the question of the desirability and practicability of unifying the two systems was frankly discussed. The fact that they are so nearly alike as to be in most cases capable of "emergency interchangeability" gives hope for eventually bringing them together.

At the recent Montreal Meeting of the A.S.M.E. a further conference was held between the members of the joint committee and the Canadian Engineering Standards Association, and through the good offices of the latter the matter is now being further discussed with the British Engineering Standards Association in London.

If such conferences should result in bringing about uniformity in screw-thread products throughout the English-speaking world it would be a great achievement and one worthy of mutual concessions for its attainment.

Pending such further negotiations and the final approval of the sponsor bodies it is thought best to make this report now available for use.

Luther D. Burlingame.[1]

Formulas for Computing Economies of Labor-Saving Equipment

The publication of the report of the Formula Committee, of the A.S.M.E. Materials Handling Division, which was presented at the Spring Meeting of the Society held in Montreal, Canada, May 28–31, 1923, has been deferred to a later issue of Mechanical Engineering.

[1] Indus. Supt. Brown and Sharpe Mfg., Co., Providence, R. I. Chairman of Sectional Committee on Standardization and Unification of Screw Threads.

John R. Freeman Recommended for A.S.M.E. Medal for 1923

THE A.S.M.E. Committee on Awards and Prizes has recommended to the Council that the Society Medal for some notable invention or striking improvement in connection with the industries be awarded[1] for the year 1923 to Past-President John R. Freeman for his eminent service to engineering and manufacturing by his meritorious work in fire prevention and the preservation of property. The following is a brief statement of his activities in the development of the system of rules and inspection under the Factory Mutual Insurance Companies, which have saved the industries millions of dollars.

Mr. Freeman became associated with the Factory Mutual Insurance Companies in 1886 when they were small and their membership was confined mainly to New England factories. Immunity from loss was dependent mainly upon careful management and oversight rather than upon appliances for extinguishing fire. One of his earliest activities was the conducting of a series of experiments on fire streams, during which the friction loss of water flowing through various kinds of hose was determined and the most efficient shape for nozzles developed. The results of these tests, made at Lawrence in 1888, were later tabulated and published as the Fire Stream Tables. These tables are the standard used by all engineers having to do with the flow of water through nozzles or hydrants.

Harris and Ewing

John R. Freeman

Next Mr. Freeman made a study of reciprocating duplex pumps and developed the designs for the Underwriters' steam fire pump. Later on the details of rotary fire pumps were improved and standardized.

The automatic sprinkler was being developed in the latter '80's and early '90's, but there was no uniformity in the practice of spacing heads or arranging pipes. In 1892 Mr. Freeman conducted an elaborate series of experiments on sprinklers to determine the effective area of water distribution, and also a series of tests on the flow of water through pipes. Much valuable information was obtained on the friction loss in all sizes of pipes from $^3/_4$ in. to 8 in., together with the fittings, which was used as the basis for the present regulations for sprinkler spacing and supplies.

About the same time Mr. Freeman became interested in the improvement of construction of mills and worked out many of the details of the so-called New England mill-construction type of buildings. The construction of storehouses was studied and many typical structures were devised and adopted by the members. Some of the earliest buildings with the saw-tooth type of roof construction were designed in accordance with his views.

The first comprehensive set of electrical rules was compiled under Mr. Freeman's direction.

Mr. Freeman was placed in charge of the inspection department of the companies in January, 1890, and reorganized it along more efficient lines. He arranged for regular inspection service, systematic surveys and plans of risks, a laboratory for testing and research, and a division for adjustments and appraisals, as well as experts in special lines, such as mill construction, electricity, and chemistry. Tests were made on meters to determine the friction loss and a full flow meter designed that would be fairly accurate yet was free from the danger of becoming obstructed. Dry-pipe valves were developed in order to have automatic protective equipments in cold rooms. "Germ-proof" check valves were designed to prevent possibly polluted water being forced back into public mains.

In the early days of his connection with the inspection department there were a number of losses due to closed valves. All valves were underground; some turned to the right to open, others turned to the left, and there was no certainty as to the condition of the valve unless water was flowing. Mr. Freeman devised the so-called indicator post valve with its extension stem and target above ground to show clearly the condition of the valve. He was also responsible for the development the outside screw-and-yoke type of valve for inside piping.

All of the various features of the construction and protection of factories were studied intensively under Mr. Freeman's direction, and many safeguards were devised which proved a benefit not only to the manufacturers but also to the merchants and the public in general.

W. M. McFarland, *Chairman,*
Committee on Awards and Prizes.

[1] Appendices to the Rules: In no case will this award be made until the invention or improvement shall have been fully described in Mechanical Engineering for a period of thirty days.

A.S.M.E. Council Urges Prompt Trial of Indicted Engineers

AT a meeting of the Council of the A.S.M.E. held in Montreal, May 29, 1923, the following resolutions were passed in reference to the Department of Justice cantonment indictments and suits.

Whereas, the Council of The American Society of Mechanical Engineers, having an organization of approximately 16,000 members, has been shocked by the indictment of certain of the prominent members of the engineering profession on charges of conspiracy amounting to treason in time of war, and by the bringing of civil suits for many millions of dollars against some of the most reputable contracting organizations in the country, some members of which are honored members of the engineering profession, for alleged fraud in connection with the construction of the cantonments; and

Whereas, in the documents under which these actions were brought, it is stated that the findings of the Presidents of three National Engineering Societies and other members of the Committee appointed to pass on the contract adopted by the Emergency Construction Committee were not the result of investigation but of unconsidered substantiation of the actions of the Emergency Construction Committee; and

Whereas, in the text of the documents those indicted and those sued are repeatedly accused of delaying the Government's program of construction for the cantonments, while those who are well informed know that this work was done at an extraordinary speed; and

Whereas, wide publicity was given to those suits at the time they were brought, but now the officials of the Department of Justice are showing a disposition to delay in trying those actions; and

Whereas, the Constitution of the United States guarantees to every accused citizen a speedy trial.

Therefore, be it Resolved: That the Department of Justice, having challenged the integrity and honesty of purpose of prominent men in the engineering profession through these actions, the Council of this Society urge the prompt trial of these charges. Also that it is the duty of every member of this Society to demand through every avenue available that these charges be promptly tried.

And be it Further Resolved: That copies of this resolution be sent to the President of the United States and the Attorney General, and be printed in Mechanical Engineering.

The actions in question were begun in November, December, and January. Indictments were secured against seven former Government administrative officials and agents as follows: Benedict Crowell, Cleveland, former Assistant Secretary of War; W. A. Starrett, New York, contractor; M. C. Tuttle, Boston, contractor; C. W. Lundoff, Cleveland, contractor; C. Foster, Major in the Engineer Corps during the war, engineer in construction business; J. H. MacGibbons, Chicago, representative of a bonding company; and J. A. Means, New York, contractor. These men, members of the Emergency Construction Committee during the war, are accused of frauds in contracts for erection of cantonments, port terminals, warehouses, and fortifications.

The firms against which suits on similar charges, totalling fifteen million dollars, were brought include many members of the engineering profession.

Similar resolutions were adopted by the Associated General Contractors of America, at their Annual Meeting, Feb. 2, 1923.

Objects and Methods of the F.A.E.S. Committee on Coal Storage

THE FEDERATED AMERICAN ENGINEERING SOCIETIES has undertaken the study of coal storage for certain distinct reasons. The main one is that in the extended and somewhat involved discussion on this subject, participated in by several Federal bureaus and Congressional committees, there has arisen a real need for an unbiased report on what is being done and what might be done in the storage of coal for the nation at large. The engineer is by nature the man who can meet this test. What we desire to secure are the facts pertaining to this important question.

In fulfilling this object the first step is to assemble the results of all investigations which have been made. A great deal of scientific work has been done, the reports on which are scattered through public reports. These are to be compiled so that the final report will contain authoritative statements as to the conditions under which coal may be stored. It is believed that such a compilation will serve a distinct purpose. We are fortunate in having on the committee Mr. S. W. Parr, professor of industrial chemistry at the University of Illinois, one of the leading authorities on the chemistry of coal.

One of the immediate functions of this committee is that of securing information for the use of the United States Coal Commission. This means that this work is closely associated with that of the Coal Commission and the Federal fuel distributor in the Department of Commerce. Information will be made available showing the coal requirements of various important industrial districts and of important groups of industries.

Closely associated with the phase of the work last mentioned, is the need expressed by the War Department for information on the fuel requirements of various manufacturing concerns which might supply munitions in case of war emergency. While this is incidental to the main work of the committee, it is expected that information of value may be derived.

It is evident to all that the leading motive prompting the investigation is that of determining the conditions under which storage might affect production in bituminous coal mining fields. For several reasons it is desirable that coal mining operations be stimulated in the Spring and Summer in order to cut down the intensity of demand upon the mines during the Fall and Winter season. The bituminous mines are operating only part time during warm weather, while the rush of orders at other seasons of the year necessitate the maintenance of a force of miners and of producing equipment capable of a peak-load production higher than is necessary. A primary object is to reduce this peak load, and create a more uniform demand throughout the year.

While it is not within the scope of the engineering investigation to initiate the measures to bring about a change, it is distinctly the purpose to furnish the information on which such efforts might be initiated by the proper parties.

It might be said that, in addition to the analysis of conditions under which coal may be stored, one of the most important portions of the work will be to determine the actual cost of storage. In order that industries and Governmental agencies may decide whether storage may be undertaken, it is necessary to know just what it costs.

It is not to be expected, of course, that coal will be stored unless users realize a financial advantage from doing it. To secure this information the combined experiences of all of the concerns which have stored coal are being sought. When such data have been accumulated, and conditions at the more notable coal storage plants have been studied, it is intended to develop typical statements as to the possibilities and suggestions for the best methods which might be employed in storage.

These in brief are the primary objects and methods which will guide the coal storage committee in its work. The support and coöperation of all engineers in the consummation of this work are most earnestly requested.

P. F. Walker.[1]

[1] Dean of Engineering, University of Kansas; Field Executive, F.A.E.S. Committee on Coal Storage.

Southern Appalachian Power Conference Holds Annual Meeting

THE second meeting of the Southern Appalachian Water Power Conference, established in June, 1922, was held at Asheville, N. C., June 25–27, 1923. The adoption of the report of the Executive Committee on the future policy, work, and influence of the Conference was the outstanding event of the meeting. This report proposes the establishment of three bureaus to assist in carrying out the policy of the Conference, which is the "wise and beneficial development, utilization, and conservation of the great water powers, forests, and other natural resources of the Southern Appalachian states."

The bureaus which the plan contemplates are (1) a Bureau of Public Relations, "to effect a more harmonious relation between public utilities, public service regulatory bodies, and the general public;" (2) a Bureau of Industrial Development to "collect, collate, and disseminate accurate and reliable information regarding power and other factors in industrial expansion;" and (3) a Bureau of Research to "compile and digest technical data of value to hydraulic engineers, industrial chemists, and other professional men having to do with the utilization of the Natural resources of the South."

Resolutions were adopted urging the restoration of the original Congressional appropriation of \$2,000,000 for the purchase of forest lands on the headwaters of streams, the increase of the appropriation for coöperation with the states in forest-fire prevention to at least \$1,000,000 a year, and the extension of river navigation wherever possible by the building of navigation-power dams. J. H. Wills, Atlanta, Ga., was elected president for the coming year, and the name of the organization was changed to the Southern Appalachian Power Conference. Interesting papers on power development methods used in surveying a large river system, possible use of large crude-oil engine units for stand-by power plants, etc., were presented.

Federal Power Commission Reports on Distribution of License Fees for 1922

THE FEDERAL POWER COMMISSION announces that it has complete collection of the fees due the Government from operations during 1922 under licenses for water-power development, and has deposited the total of \$29,519.23 in the Treasury for distribution and credit as follows:

To the general fund of the Treasury	\$12,825.21
To the indefinite appropriation (under administration of the War Department): Maintenance and operation of dams and other improvements of navigable waters	12,386.41
To the Reclamation Fund	1,755.21
To Indian funds	1,236.00
To Payments to states under the Federal water-power act, special funds	1,316.40
Total	\$29,519.23

The Commission's receipts from this source during 1921 were \$8,963.57. For 1923 they are expected to be \$60,000. Its operating expenses, exclusive of salaries of assigned personnel, for the years 1921–1923 will not exceed \$107,000, as now estimated. It is expected that within five years from the date of approval of the act (June 10, 1920) the charges collected will have offset all expenses, direct and indirect, in its administration.

Coffin Foundation Makes First Award

THE Southern California Edison Company, Los Angeles, has been selected from eighteen electric light and power companies which submitted records for consideration, as the one which has made the most distinguished contribution to the development of electric light and power for the convenience of the public and the benefit of the industry during the past year. The award, consisting of a gold medal and one thousand dollars, was presented to John B. Miller, president of the company, by Frank W. Smith, chairman of the prize committee of the Charles A. Coffin Foundation, during a meeting of the public policy committee of the National Electric Light Association on June 7, 1923.

Captain Robert Woolston Hunt

LESS than a month after receiving the high honor of the Washington Award "for his pioneer work in the development of the steel industry in the United States and for a life devoted to the advancement of the engineering profession," Captain Robert Woolston Hunt died at his home in Chicago on July 11, 1923.

Captain Hunt was born December 9, 1838, in Fallsington, Bucks County, Pa. His father, Dr. Robert A. Hunt, died when he was only sixteen years of age, and in 1857 the family moved to Pottsville, Pa., where Robert spent several years in the iron rolling mill of John Burnish & Co., acquiring a practical knowledge of puddling, heating, rolling, and other details of the iron-rail business. Later he took a course in analytical inorganic chemistry in a laboratory in Philadelphia, upon the completion of which he entered the employ of the Cambria Iron Works at Johnstown, Pa. The first analytical laboratory maintained in America by an iron and steel company was established under his direction in 1860 for the Cambria Works.

In the Spring of 1861, as night foreman of the Elmira rolling mill, Elmira, N. Y., Captain Hunt assisted in the organization of the working force and the starting of that industry. In the Fall of that year he entered the U. S. Army, and was stationed at Harrisburg. In 1862 he was put in command of Camp Curtin, at Harrisburg, with the rank of captain. The next year he served the state of Pennsylvania as mustering officer, and in 1864 assisted in recruiting Lambert's Independent Mounted Company of Pennsylvania Volunteers.

After the close of the war Captain Hunt returned to the employ of the Cambria Iron Company and was sent to the experimental Bessemer works at Wyandotte, Mich., owned jointly by the Cambria Company and the Kelly Pneumatic Process Company. The Kelly plant had in 1864 produced from pig iron remelted in a reverberatory the first pneumatic steel made in America, and Captain Hunt, while in charge of the works there, introduced the use of a cupola for remelting. In 1866 he returned to Johnstown, where he had charge of the hammering and rolling of steel and superintended the rolling of the first steel rails made in America on a commercial order, produced for the Pennsylvania Railroad from ingots cast by the Pennsylvania Steel Company's plant at Steelton, Pa. The behavior of these ingots led to the successful introduction of blooming by rolling instead of hammering.

The Bessemer plant of the Cambria Company, finished in 1871, was designed and built by John Fritz, chief engineer of the company, with the assistance of A. L. Holley and Captain Hunt. It embodies several new features, such as the continuous running of the cupola, and a new system of bottom casting. Captain Hunt was in charge of these works from the time of their completion until August, 1873, when he resigned to become superintendent of the Bessemer Works of John A. Griswold & Co., at Troy, N. Y. These works were enlarged and remodelled, and the name of the company changed, first to the Albany & Rensselaer Steel & Iron Co., and later to the Troy Iron & Steel Co. Captain Hunt remained in charge until 1888, and during these years he supervised the erection of three large blast furnaces, and made many grades of Bessemer steel not previously produced in America, notably soft steel for drop forgings. He was also a pioneer in the production of steel for gun barrels, carriage axles, drills, and springs. He took out several patents on steel and iron metallurgical processes and machinery, and the Hunt-Jones-Suppes rail-mill feed tables developed during this period, were used later under licenses by the majority of the rail mills in the United States.

In 1888 Captain Hunt resigned his position at Troy and went to Chicago, where he established the firm of Robert W. Hunt & Co., consulting engineers, an organization which now has offices and laboratories in many cities.

Scientific and engineering ability and strict integrity characterize the business enterprise which bears his name, and one of the sources of great satisfaction to Captain Hunt as he approached the end of his long life was that he had been able to place this organization upon a basis which will enable those who were his supporters and assistants to continue the work indefinitely.

The Washington Award is one of many tributes to the work of Captain Hunt. In 1912 he was awarded the John Fritz Medal, "for his contributions to the early development of the Bessemer Process," and in 1920 the Hunt Medal "for meritorius contributions to the art of making steel." He was for many years a trustee of the Rensselaer Polytechnic Institute, which in 1916 conferred upon him the honorary degree of Doctor of Engineering. While residing in Troy he was elected for four successive terms Commander of John A. Griswold Post, No. 338, G.A.R.

In the development of the engineering societies he has played an important part. He was president of the A.I.M.E. in 1883 and again in 1906; president of the A.S.M.E. in 1891; president of the Western Society of Engineers in 1893; president of the American Society for Testing Materials in 1912; and American Vice-President of the International Association for Testing Materials in 1914. He belonged also to the A.S.C.E., the Institution of Civil Engineers, the Institution of Mechanical Engineers, the Canadian Society of Civil Engineers, and the British Iron and Steel Institute. Captain Hunt was secretary of the Committee on Standard Rail

ROBERT W. HUNT

Sections appointed by the A.S.C.E., the final report of which was made in 1893, and of the Special Committee on Rail Sections, appointed in 1892, which reported finally in 1910. The sections recommended by this committee were generally adopted by the railways of America.

His services as an officer and on committees of these societies, as well as his contributions to their proceedings, and lectures before educational and scientific bodies, have been of inestimable value. He was an honorary member of the A.I.M.E., A.S.M.E., American Society for Testing Materials, and Western Society of Engineers.

Captain Hunt was a member also of many athletic and social clubs, and in them, as in all his contacts with his fellow men, had many friends. He placed high value upon these friendships, saying in one of his last public addresses, at the time of the presentation of the Washington Award, "If ever a man has lived who has been blest with the friendship of his fellowmen, it has been myself. Never in my long life have I experienced a moment that, for any reason, I could say I was without friends."

Engineering and Industrial Standardization

Secretary Hoover Advocates Uniform Specifications in Making Government Purchases[1]

I HAVE, with the approval of the state governors, called this conference upon "Specifications" for purchase of supplies by our national and local governments and public institutions. This bald statement of purpose might appear to the uninitiated as a question of little importance. As a matter of fact in its ramifications it means hundreds of millions of dollars to the taxpayer and much more to the private consumer and to the manufacturer. It is an important link in the whole great chain of elimination of waste in our industrial and commercial fabric.

Specifications are the formulated, definite, and complete statements of what the buyer requires of the seller. They must be an accurate representation of the chemical and physical characteristics of the article or material required—and they must be adapted to the best practice of production and distribution.

The first step in formulation, therefore, is the determination of these chemical or physical characteristics and this brings us to the entire field of standardization of commodities; that is, the determination of qualities, of grades, of purposes and performance. Scientific standards, of course, are of old origin; Emerson defined a standard as "That which is established by investigation or authority to be reasonably attainable maximum of desirability." Their formulation requires the services of chemists, physicists, engineers and something that has been often neglected, the added experience of the manufacturer, the producer and the user. There is no economy to be obtained.

Standardization insures quantity production and hence lower production cost; smaller investment of capital and, therefore, the release of capital for other industrial purposes and developments.

Specifications and standards are a changing requirement, for there is steady progress in the arts and invention; and requirements, therefore, must be subject to periodic review.

Being aware from war experience of the great faultiness of specifications used in Federal purchases, I undertook early in this administration that the Department of Commerce should review these specifications. Subsequently, with the establishment of the Bureau of the Budget, an interdepartmental committee was created for the better development of this work, at the suggestion and under the leadership of the Department of Commerce. Each of the specifications are being taken in hand and the chemical and physical requirements of each article in question are being exhaustively examined in the laboratories of the Bureau of Standards. Beyond this, however, after we have arrived at definite scientific background, the manufacturers in each branch are being brought into consultation to make sure that the industrial and commercial setting of a given specification is right from the point of view of the practical producer. By so doing we have found that a great many specifications for large purchases were loosely drawn, so that the various manufacturers making bids were offering really entirely different grades and qualities, and that, therefore, a mere monetary difference in price did not denominate relative merits because of the lack of precision in specifications. Moreover, we have found that other specifications were drawn purely from the point of view of the personal vision of some official, and as drawn required special manufacture, when well-known articles, already standardized, necessarily bid a price that would warrant special production and consequent interruption of ordinary business.

Now, all these reorganized specifications are enabling the Government to buy on much better terms and at savings to the taxpayer. This conference, therefore, has been called with the thought that the Federal government—with its great laboratories and with its large experience in the standardization of purchases, in the formulation of the sequent specifications, and in the development of methods of testing—could be of service to the purchasing agencies of states, municipalities, and public institutions.

Especially in research work and in the elaboration of methods of testing can the Federal Government and its laboratories be of value to purchasing agencies and industry generally. Research is a necessary component of standardization and the formulation of specifications.

This whole question is proving to be of vastly greater importance than even the savings on public purchases might imply. Industry itself has long struggled to establish standards and to secure their acceptance as a method of simplifying the process of manufacture and raising the ethics of production. Furthermore, where standards and specifications are successfully developed by the Government through the methods we have undertaken, they are receiving wide voluntary acceptance and adoption among public consumers. I need only to point to the case of cement, where practically the whole output of the country is now produced and distributed on the basis of Federal standards and tests—it being sufficient in the purchase of cement simply to state "Federal specifications."

Now I do not wish to give the impression that specifications must be newly discovered in order to be proper and advantageous. Our engineering and professional societies, especially the American Society for Testing Materials and the American Engineering Standards Committee, have long been engaged in the preparation and standardization of certain types of specifications; our university laboratories, our great industrial laboratories, the engineers in our large industries, have for years been developing specifications in a great multitude of materials. Many of these specifications have lain dormant for lack of use by the consumer in his demands upon the producer. Others of them have not had applied to them the test of commercial experience in production. It is our purpose to adopt whatever is good, to put it under review as to its practical application, and, as we have done hitherto, to call in the expert manufacturer and producer for his coöperation and advice.

There are a great many directions in which this problem of waste elimination and increased efficiency extends. It extends even into such problems as an ample transportation system. But a very large opportunity for the elimination of waste and the increase of efficiency lies in the field that I have been describing to you today. It is a field of much larger dimensions, in hundreds of millions and billions of dollars, than will be believed by any except men of professional experience; it is proposed to seek your cooperation in this field, not only for the purpose of decreasing the cost of supplies in public purchases, but also in the influence that the consumer can exert in coöperation with the producer to minimize the costs of production and distribution.

I could formulate these propositions into terms of reducing the cost of living, or I could formulate them into terms of raising standards of living. Whichever economic phrase we may adopt, they both lead to the same end—and that is the increased comfort and happiness of our people.

Items of Interest in the Standardization Field

Telephone Group Organized. At a recent meeting of the U. S. Independent Telephone Association it voted to take membership in the A.E.S.C. with one representative. This Association with the American Telephone and Telegraph Company will therefore constitute the Telephone Group.

N. A. of P. A. Discuss Standardization. Dr. P. G. Agnew, Secretary of the A.E.S.C., told the National Association of Purchasing Agents at their annual convention in Cleveland that the purchasing agents of state and municipal government departments are spending approximately $700,000,000 yearly for supplies, materials of construction, and other products. During his address he pointed out how much of this amount becomes a direct waste, then told of what his committee is doing to eliminate a part of this waste.

Methods of Analysis of Paint Pigments. Many of the controversies growing out of differences in methods of analyzing paint pigments should be eliminated by the universal use of the method for routine analysis of white pigments, yellow, orange, red and brown pigments, containing iron and manganese, and of dry red lead, which have just been approved as Tentative American Standards by the

[1] Abstract of address delivered at a Conference of State Purchasing Agents, Washington, D. C., May 26, 1923.

American Engineering Standards Committee. The approved methods provide a basis for the analysis of paint pigments, which has always been a complicated and often a controversial problem. The specifications for these methods of analysis were presented for A.E.S.C. approval by the American Society for Testing Materials under whose auspices the specifications were developed, and the A.S.T.M. has been designated as sponsor for these specifications.

Sponsors for Road Material. The American Engineering Standards Committee announces the appointment of the following four organizations as joint sponsors for the specifications of the Method of Test for Penetration of Bituminous Materials submitted by the American Society for Testing Materials: American Association of State Highway Officials, American Society for Municipal Improvements, American Society for Testing Materials, and the Bureau of Public Roads. This is only one of several standardization projects involving road materials now before the American Engineering Standards Committee,, the others covering the toughness of rock, the distillation of bituminous materials, and specifications for concrete.

Paper-Stock Sheet Sizes. One of the net results of a broadly representative conference which met in Washington on June 19 was the final adoption by the manufacturers' and users' organizations of the following four standard sheet sizes for book-paper sizes:

25 in. by 38 in.	38 in. by 50 in.
26 in. by 29 in.	29 in. by 52 in.
32 in. by 44 in.	44 in. by 64 in.
35 in. by $45^1/_2$ in.	

This conference also agreed that the standard method of determining the basic weight or "substance" of a given sheet of paper shall be on a ream 25 in. by 40 in. of 500 or 1000 sheets for all paper.

Aeronautical Safety Code. The Sectional Committee which is developing the American Aeronautical Safety Code held a meeting recently at the Bureau of Standards. At this meeting the committee adopted reports of two sub-committees consisting of rules for balloons, airships, landing fields, seaplane stations, and airways. These parts of the code are now available for general use and application.

Steel Bridge Standards. The American Railway Engineering Association has submitted its General Specifications for Steel Railway Bridges and its Specifications for Movable Railway Bridges for approval by the American Engineering Standards Committee as American Standards.

Protection Against Lightning. The Sectional Committee on Protection Against Lightning organized jointly by the Bureau of Standards and the American Institute of Electrical Engineers, has been active in the preparation of a tentative standard for the protection of buildings and other property against lightning. A joint meeting of Group I of the Sectional Committee in charge of the work, together with the National Fire Protection Association's Committee on the same subject, was recently held in Chicago. Copies of the tentative standard have also been circulated generally for comment by those interested, and the final draft is now being worked out.

Roller Chains and Sprockets

(*Continued from page 503*)

las are special for cutters covering the standard ranges of teeth·

$$W = 1.24D \cos Yab;\quad V = 1.24D \sin Yab$$

$$yz = D\left[1.24 \sin\left(17° + \frac{148}{T} - Yab\right) - 0.8 \sin\left(18° - \frac{28}{T}\right)\right]$$

$$F = D\left[0.8 \cos\left(18° - \frac{28}{T}\right) + 1.24 \cos\left(17° + \frac{148}{T} - Yab\right) - 1.3\right]$$

$$cb = c'b' = \sqrt{(E + F)^2 + yz^2}$$

Width of cutter $= Q = 1.02 \sin (180°/n) \times$ outside diameter of the smallest sprocket in the range to be cut, to the next higher 32nd inch.

Thermal Conductivity of Liquids

(*Continued from page 482*)

B.t.u. per hr. This rate is taken at the surface B or 0.81 in. below the heater. Hence

$$K = \frac{300 \times 4.13}{(180 - 80) \times 1 \times 3} = 4.13.$$

Correcting for losses as explained above, K becomes $4.13 \times 1.16 = 4.79$ B.t.u. per sq. ft. per degree difference in temperature per inch per hour.

The computed values of K are given in Table 2. In this table the 1.16 correction has not been applied. It should be noted that, partly owing to reasons of time, computed results are tabulated only for temperature gradients $(T_1 - T_2)/L$ having values between 17 to 24, although the gradient values varied between 4 and 43.

For purposes of comparison, the available data upon the conductivity of water and their variation with temperatures were collected and plotted as in Fig. 7. This material was in c.g.s. units and was converted into the English system by multiplying by 2.90×10^3. The names of the authorities are given, and it can be seen that there is a wide variation in the results. The curve drawn through these points was made upon the popular assumption that K varies directly as the temperature.

As can be seen from Fig. 7, the conductivity as determined from these tests falls below the assumed curve based on results of previous investigations. It was unfortunate that the average temperature was not low enough to give a better chance of checking. The only close check is for 110–115 deg. Here Lees obtained 3.5 while the value in the author's test was 3.65. Lees' data contradict those of other authorities, K decreasing with an increase in temperature in his results.

Discussion of Results

In carrying out the work there were a number of sources of error that were not eliminated. For instance, the results should be multiplied by 1.16 to correct for heat losses, assuming the condensate method of measuring the heat input to be correct. There is uncertainty as to just what takes place between the heater and the liquid surface. The thermocouples indicate a condition of turbulence, which would lead to the belief that the surface contact was not good. If this were so, considerable heat would be lost in penetrating the pocketed air space. With good surface contact, another factor might enter into the problem. With the top water layers at higher temperatures than the bottom ones, imperfect or unequal expansion would take place. This would tend to increase the pressure within the liquid and might be a source of convection currents. Also, with continuous heating, the temperature of the bottom layers could not be brought to the temperature of the top layers, and this is an indication that heat was leaving through the bottom of the vat or that the water-logged vat became finally a better conductor than the vat.

Notwithstanding these sources of error, a number of tentative conclusions may be drawn. On the whole, the conductivity seems to vary inversely with the temperature, and in Fig. 8, with curves drawn the various points, two curious things are noticeable, the conductivities for the same temperature gradient $(T_1 - T_2)/L$ lie upon a straight line, and the conductivities themselves vary greatly for the same temperatures. Thus at 130 deg. fahr., K is found to be 1.5 and also 4.15. Experimental error may be responsible for this peculiar phenomenon, but in the opinion of the author K depends upon the temperature gradient and not upon the average temperature.

The foregoing conclusions are purely tentative, and the author believes that the subject must be investigated more carefully and with better-constructed apparatus. A container of bakelite might be used. Some means should be available for keeping $(T_1 - T_2)/L$ constant. The source of heat should be of greater intensity than that afforded by steam, so that a greater quantity could be supplied in a given time. Control of the surface contact would be an advantage. Means of measuring the heat passing each section, if one could be devised, would settle the great difficulty of obtaining the flow rate. Lastly, a more sensitive and more accurate means of measuring temperatures would be desirable.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Exigencies of publication make it necessary to put the main body of The Engineering Index (p. 107-EI of the advertising section) into type considerably in advance of the date of issue of "Mechanical Engineering." To bring this service more nearly up to date is the purpose of this supplementary page of items covering the more important articles appearing in journals received up to the third day prior to going to press.

AUTOMOBILE ENGINES

Combustion Chambers. Combustion Chamber Design. Automotive Industries, vol. 48, no. 26, June 28, 1923, pp. 1406–1412, 16 figs. Mechanical drawings showing recent developments.

Manifolding. Correct Manifolding a Basic Problem of Vertical Eight, P. M. Heldt. Automotive Industries, vol. 48, no. 25, June 21, 1923, pp. 1328–1330, 7 figs. Carefully worked-out design required to give uniform distribution of gases; firing order closely interrelated; single exhaust manifold may be utilized if of sufficient size.

AUTOMOBILES

Brakes. Renault Adopts Front Wheel Brake for Six Cylinder Models. Automotive Industries, vol. 48, no. 25, June 21, 1923, pp. 1334–1335, 2 figs. Servo mechanism, consisting of friction clutch and equalizer, is mounted back of gear box and driven at low speed by worm and worm-gear combination from tail shaft; high pressure obtained.

Sekine. Novel Design of Chassis and Body Shown in Sekine Car. Automotive Industries, vol. 48, no. 25, June 21, 1923, pp. 1322–1326, 9 figs. Unusual power-plant arrangement; driving at left rear wheel; light, unsprung weight; and simple, sectional-body construction, are features of new vehicle by American engineer for Japanese company.

BOILER FURNACES

Oil-Burning. Boiler-Plant Operation with Fuel Oil, Kingsley L. Martin. Power Plant Eng., vol. 27, no. 13, July 1, 1923, pp. 664–667, 2 figs. Features of fuel-oil burning in its relation to installation, operation and maintenance.

BOILER OPERATION

Heat-Balance Calculation. Graphic Method for Computing Heat Balance, F. A. Sborkey. Blast Furnace & Steel Plant, vol. 11, no. 6, June 1923, pp. 348–354, 7 figs. Convenient way to eliminate errors resulting from use of formulas when computations of boiler-room data are required.

CLUTCHES

Automobile. Recent Clutch Designs. Automotive Industries, vol. 48, no. 26, June 28, 1923, pp. 1392–1397, 14 figs. Mechanical drawings showing recent developments in clutches.

COAL HANDLING

Dock Loading Equipment. Flexible Coal-Loading Dock Equipment. Iron Age, vol. 111, no. 26, June 28, 1923, pp. 1851–1854, 7 figs. War-Department plant near Mobile, Ala., has new design of apparatus to avoid frequent moving of ship along wharf; largely automatic and easily handled.

COST ACCOUNTING

Burden Distribution. The Bugbear of Burden Distribution, G. Charter Harrison. Management & Administration (Management Eng. & Administration Combined), vol. 6, no. 1, July 1923, pp. 49–54, 2 figs. Plan to eliminate its work and worry.

COUPLINGS

Flexible. Flexible Couplings for Steel Mills and Other Drives, John J. Serrell. Assn. Iron & Steel Elec. Engrs., vol. 5, no. 6, June 1923, pp. 177–187 and (discussion), pp. 188–230, 34 pp. How to overcome excessive pulsating overload and excessive misalignment, due to operating accident or abuse. Discussion includes papers by Gustave Fast, P. C. Day, J. H. Albrecht, W. Trinks, R. W. Davis, W. E. Trumpler and L. H. Keim.

CUTTING TOOLS

Multi-Cutting. Multi-Cutting Tool Arrangements, Joseph Horner. Engineering, vol. 115, nos. 2977, 2978, 2980, 2983, 2988, 2990, 2996 and 2998, Jan 19, 26, Feb. 9, Mar. 2, Apr. 6, 20, June 1 and 15, 1923, pp. 63–64, 96–98, 163–165 and 176, 259–261, 419–421, 482–485, 673–675 and 731–734, 174 figs. partly on supp. plates. Jan. 19: Standardization of tool angles; old and later tool shapes compared; roughing and finishing, double-edged, stellite, form-turning and form-profile tools. Jan. 26: Tools used in lathes; examples of multi-cutting. Feb. 9: Tool setting in common and turret lathe; tool holders; turret work. Mar. 2: Multiple-spindle machines. Apr. 6: Drilling and boring; spade cutters. Apr. 20: Vertical boring and turning mill; combination features. June 1: Milling cutters; multiple arrangements; interlocking. June 15: Work on plano-miller; Ingersoll machines; examples of work.

DIESEL ENGINES

Acro. New Diesel Engine May Be Practical for Automotive Use. Automotive Industries, vol. 48, no. 25, June 21, 1923, pp. 1336–1337, 2 figs. Describes recent development invented by Franz Lang, of Germany; compression pressure about 200 lb. per sq. in.; practically instantaneous ignition of fuel charge gives flexible operation; novel injection-valve design; low-grade hydrocarbon oils may be used.

FLOW OF FLUIDS

Electric Flow Meter. The Hyperbo-Electric Flow Meter. Power, vol. 57, no. 26, June 26, 1923, pp. 1024–1025, 3 figs. Meter for measuring pressure variations; readings are guaranteed to be within 2 per cent of actual flow, between 15 and 100 per cent of meter rating, and within 4 per cent of actual flow from 5 to 15 per cent of rating, allowing pressure variations of 20 per cent above or below rating and any temperature or specific-gravity variations.

GEARS

Grinder for. Gear Grinding. Automotive Engr., vol. 13, no. 177, June 1923, pp. 170–171, 3 figs. New machine made by Lees-Bradner Co., Cleveland, O., for finishing hardened gears.

Tooth Forms. Tooth-Forms of Green, Burnished, Hardened and Ground Gears, K. L. Herrmann. Am. Mach., vol. 58, no. 26, June 28, 1923, pp. 933–936 and vol. 59, no. 1, July 5, 1923, pp. 5–9, 15 figs. June 28: Instruments for checking tooth forms and spacing; plotting curves; errors due to inaccurate machines and to hardening. July 5: Changes due to repeated hardening; grinding teeth of spiral bevel gears more important than teeth of spur gears; hobbing machines.

HACKSAWS

Speed of Blades. Requirements in Cutting off Metal, M. E. Erskine. Machy. (N. Y.), vol. 29, no. 11, July 1923, pp. 863–864. Consideration of speed at which blade should travel to secure best results; pressure on blade while cutting; effect of design of hacksaw machine, savings effected by correct means for cutting off metals.

INDUSTRIAL MANAGEMENT

Methods and Principles. The Methods and Principles of Frank B. Gilbreth, Inc. Am. Mach., vol. 59, no. 1, July 5, 1923, pp. 25–27, 2 figs. Route sheet to keep track of materials and parts; instruction sheet; duties of foreman and inspector in keeping production stream flowing smoothly.

INTERNAL-COMBUSTION ENGINES

Suction and Compression Temperatures. Notes on the Estimation of Suction and Compression Temperatures in Internal Combustion Engines, W. Morgan. Automobile Engr., vol. 13, no. 177, June 1923, pp. 189–191, 3 figs. Measurement of volumetric efficiency; charge pressure after closing of inlet valve; estimation of exhaust-gas temperature; measurement of compression pressure.

LABOR

Collective Bargaining. Industrial Government Through Collective Agreements in Germany, Emil Frankel. Management & Administration (Management Eng. & Administration), vol. 6, no. 1, July 1923, pp. 39–42. Origin of collective bargaining in Germany; legal standing and basic principles; extension of territorial validity; subjects covered by agreements; hours, vacations, and contract terminations; attitude of employers and workers; future outlook.

LOCOMOTIVES

Coaling Stations for. New Coaling Station Mixes Fuel Automatically. Ry. Age, vol. 74, no. 29, June 23, 1923, pp. 1533–1534, 5 figs. Accurate proportioning of anthracite and bituminous accomplished with simple equipment at Delaware & Hudson coaling station near Plattsburg, N. Y.

OIL ENGINES

Cold-Starting. A Cold-Starting Oil Engine. Engineer, vol. 135, no. 3521, June 22, 1923, p. 666, 4 figs. 2-stroke, solid-injection type brought out by Petters, Ltd. Yeovil.

German Marine. German Oil-Engines for Merchant Ships, Walter Mentz. Motorship, vol. 8, nos. 5 and 7, May and July 1923, pp. 363–368 and 503–506, 27 figs. Observations on building of oil engines for merchant ships, based on journey by author to all large German works where they are built, including M. A. N.; Blohm & Voss; Deutsche Werke in Kiel; Deutz; Waggon- u. Maschinenbau A. G. Görlitz; Krupp Germania Shipyard; Mannheimer Motorenwerke; Sulzer; Vulkan Works in Hamburg; and Weser Corp. in Bremen.

PRESSURE VESSELS

Welded. An Investigation of Welded Pressure Vessels. Am. Welding Soc.—Jl., vol. 2, no. 5, May 1923, pp. 11–162, 120 figs. Report of Pressure vessel Committee of Am. Bur. of Welding. Recommendation to A.S.M.E. Boiler Code Committe; comments on construction; design; hydrostatic hammer test; insurance; physical quality of materials; chemical requirements of plate; welding wire; tests of welded specimens; marking and stamping; Bureau of Standards report.

PRESSWORK

Pressed Steel vs. Castings. Replacing Castings with Stampings. Machy. (N. Y.), vol. 29, no. 11, July 1923, pp. 873–875, 6 figs. Substitutions of pressed metal to replace thin cast shells made by Worcester Pressed Steel Co., Worcester, Mass.; advantages, among which is increase in strength with reduction in weight.

PULVERIZED COAL

Burning Systems. Various Systems of Burning Pulverized Coal, C. F. Herington. Blast Furnace & Steel Plant, vol. 11, no. 6, June 1923, pp. 345–347, 2 figs. Comparison between bin, air-distribution and unit systems; estimated costs for different types of installations.

PUMPS

Suction. Pump Suction, F. H. Smith. Blast Furnace & Steel Plant, vol. 11, no. 6, June 1923, pp. 322–327 and 330, 5 figs. With special reference to pumps for by-product plants for handling various substances, such as water, ammonia liquor, tar wash-oil, etc.

PRODUCER GAS

Open-Hearth Furnaces. The Production and Utilization of Producer Gas for Heating Open Hearth Furnaces, M. G. Husson. Blast Furnace & Steel Plant, vol. 11, nos. 5 and 6, May and June 1923, pp. 264–268 and 328–330, 3 figs. Translated from Revue de l'Industrie Minérale.

RAILWAY REPAIR SHOPS

Locomotive. New Burlington Locomotive Shop at Denver, A. H. Ostberg. Ry. Age, vol. 74, no. 29, June 23, 1923, pp. 1647–1649. $2,500,000 project will employ 750 men, and turn out 200 classified and 50 running repairs a year.

Mallet Locomotives. New Mallet Shop Has Interesting Features. Ry. Age, vol. 74, no. 29, June 23, 1923, pp. 1511–1513, 5 figs. West. Maryland completes modern unit at Port Covington, Md., for repair of heavy power.

ROLLING MILLS

Speed Control. Speed Control of Latest Mills at Gary, Gilbert L. Lacher. Iron Age, vol. 111, no. 26, June 28, 1923, pp. 1832–1834, 4 figs. Two new strip mills have adjustable-speed motor drive; presents novel method of handling coil stock from mill to warehouse; typifies material-handling equipment.

STANDARDIZATION

Economic Hindrances to. Economic Hindrances to Standardization, Walter J. Matherly. Am. Mach., vol. 58, no. 26, June 28, 1923, pp. 937–939. Fundamental problem of economic change; analysis of hindrances to such a change; conservative policy of manufacturers regarding changes in methods of production.

STEAM-ELECTRIC PLANTS

Indiana Electric Corpn. Wabash River Station of the Indiana Electric Corporation, Frank S. Clark, Power, vol. 57, no. 26, June 26, 1923, pp. 1008–1013, 3 figs. First section of 100,000-kw. plant being constructed close to coal fields; outstanding features are 350 lb. steam pressure, high boilers, stage bleeding, house turbine for emergency only, evaporators and special provision for 31-ft. rise and fall of river.

Kansas City, Mo. Northeast Station, Kansas City, Mo., Adds 30,000 Kilowatts, Thomas Wilson. Power, vol. 58, no. 1, July 3, 1923, pp. 2–7, 5 figs. Boilers of latest design supplying steam at temperature of 650 deg. fahr., are equipped with forced-draft chain grates and high-pressure counterflow economizers, and provision has been made for plate-type air preheaters.

Power Costs. Analyzing Power Costs in Small Plants. L. V. H. Armstrong. Elec. World, vol. 81, no. 26, June 30, 1923, pp. 1512–1516, 16 figs. Investigation of various factors involved; use of turbine and oil engines in typical installations; influence of load factors on selection of prime mover. (Abstract.) Paper presented before Atlanta Section, Am. Soc. Mech. Engrs.

STEAM TURBINES

Mixed-Pressure. Calumet & Hecla Large Mixed Pressure Turbines. Power, vol. 58, no. 1, July 3, 1923, pp. 10–12, 3 figs. 2-cylinder, mixed-pressure turbines utilizing exhaust steam from number of copper stamp heads, with supplementary supply of live steam first passing through high-pressure cylinder.

STEEL CASTINGS

Heavy-Type Generator. Casting Heavy-Type Generator Castings. Iron Trade Rev., vol. 73, no. 1, July 5, 1923, pp. 42–43, 2 figs. Method of casting part of rotor of 87,000-hp. unit being built at Schenectady works of Geo. Elec. Co. Casting is 21 ft. in diam. when finished, and 10 of them are required in construction of single generator.

STRUCTURAL STEEL

Yield Point. Experiments on the Yield Point of Steel under Transverse Tests, Alexander B. W. Kennedy. Engineering, vol. 115, no. 2998, June 15, 1923, pp. 736–738, 1 fig. Results of series of experiments on quality of steel familiar in gun construction.

Entered as second-class matter at the Post Office at Easton, Pa., under the Act of March 3, 1879.
Acceptance for mailing at special rate of postage provided for in section 1103, Act of October 3, 1917, authorized on January 17, 1921.

Contributors to This Issue

The National Advisory Committee for Aeronautics, the results of whose work is told in this issue in Making America Independent in the Air, is composed of twelve members nominated by the President and serving without salary To all practical purposes the Committee has charge of all the research work in aeronautics in this country of a general character, and in addition considers all aeronautical inventions submitted to the Navy. It has a laboratory of its own at Langley Memorial Field and arrangements for carrying on experimental and research work at the Bureau of Standards and the engineering departments of several universities and technical schools. The Committee issues a series of bulletins on various subjects of research and voluminous yearly accounts of the work done. It also maintains agents in several countries of Europe, who report to America the aeronautical progress abroad. Unless the matters of research are ear-marked especially confidential by the U. S. authorities, all completed research is published.

FREDERICK W. COWIE

* * * * *

Frederick W. Cowie is the author of the paper on The Port of Montreal, and very fittingly too, for he is consulting engineer of the Harbor Commissioners of Montreal. He was born in Caledonia, Ontario, in 1863. He received his B.S. from McGill University in 1886 and was then appointed assistant engineer under the late Sir John Kennedy, a noted port engineer, and at that time chief engineer of the Montreal Harbor Commissioners. Since that time Mr. Cowie has continuously devoted his service to this very important branch of engineering work. Having had the advantage of training and association with Sir John Kennedy, Mr. Cowie was made consulting engineer of the Commission when the former died.

Mr. Cowie is recognized as a harbor-engineering authority and has recently been appointed as expert adviser of the Hampton Roads (State) Port Commission, where his duties will consist in aiding the State Commission to prepare a report and recommendations to the next General Assembly of Virginia, visualizing the future of Hampton Roads as a state asset.

Included in recent work Mr. Cowie has done on the Atlantic seaboard are surveys and reports with recommendations on the harbor of Boston, and a comprehensive plan on the development of Savannah as the State port of Georgia. In 1914 the Council of the Institution of Civil Engineers (Great Britain) awarded Mr. Cowie the coveted Telford gold medal for his paper on The Transportation Problems in Canada and Montreal Harbor. He is a member of the Engineering Institute of Canada.

* * * * *

Carroll R. Thompson, assistant director of the Department of Wharves, Docks, and Ferries of the City of Philadelphia, contributes an article on Material-Handling Problems in Pier Design. Mr. Thompson was born in Philadelphia, Pa., in 1885, and is one of the youngest executives to fill such a position where his duties combine those of chief engineer and supervisor of new construction and the maintenance of the existing port equipment. He deserves a very considerable part of the credit for the recent rapid development of Philadelphia's waterfront facilities and the consequent growth of the port.

CARROLL R. THOMPSON

Mr. Thompson is well qualified to write on his subject for his previous experience includes six years with the American Bridge Co., one year with the Pennsylvania Steel Co and eleven years in the engineering office of the department in which he is now employed. While connected with this department he had unusual opportunities to become familiar with the port and terminal conditions of other seacoast cities, and has served on a number of committees to investigate and report on them. He is a member of the American Society of Civil Engineers, and of the Society of Terminal Engineers and an associate member of the American Association of Port Authorities.

* * * * *

Alfred Cotton, whose paper on The Determination of Chimney Sizes is included in this issue, was born in Southport, England, in 1871. While serving an apprenticeship from 1885 to 1892 in marine engineering, he received his technical education through university-extension courses and by private tuition. He was then engaged by Thomas Henderson, of Liverpool, for whom he worked in designing mechanical stokers and grates until 1894, when he entered the Port Sunlight Soap Works of Lever Brothers, Ltd., as engineering assistant to the works manager. Here he designed one of the first, if not the first, double-stage centrifugal pumps, which operated with fairly high efficiency and entire satisfaction.

In 1898 Mr. Cotton became assistant chief engineer for Meldrum Brothers, Ltd., working on the design and adaptation of mechanical stokers and forced draft, and collaborating in the development of destructors for generating steam from municipal refuse. He came to America in 1903 and developed the Cotton furnace, which embodied a system of steam-jet forced draft. He manufactured and installed these furnaces and allied apparatus until the war, when he entered the employ of Colt's Patent Fire Arms Manufacturing Co. In 1918 he became chief engineer in the combustion department of the Sterling Blower Co., and in 1919 he took his present position as chief of the research department of the Heine Boiler Co.

ALFRED COTTON

Coming A.S.M.E. Events

The third A.S.M.E. Regional Meeting and the first among the Southern Sections of the Society is scheduled for October 23-24, 1923, at Chattanooga, Tenn. Three technical sessions are being arranged, the first on welding, planned to give practical information to engineers and executives, the second on power problems, and the third on management. The latter is especially appropriate as the week of October 22-27 is Management Week, in which some fifty-odd A.S.M.E. Local Sections and about twenty-five sections of other societies will participate.

Making America Independent in the Air

The Inception of the National Advisory Committee for Aeronautics, Its Organization for Research, and the Results It has Achieved at the Langley Field Laboratory

When the United States went into the World War in 1917 the importance of aircraft from a military point of view was fully realized, not only abroad where they had had ample experience with it, but also in this country. As a result of this realization a huge appropriation for aircraft, amounting to $640,000,000, was passed practically without discussion by Congress. To build an airplane, however, it is necessary to have money, factory facilities, raw materials, brains, and a knowledge of the laws governing the design and operation of its novel machinery.

This knowledge at that time was entirely lacking in this country and the United States had to go to England, France, and Italy and borrow from them the complete designs of the planes in which our young men were to fight the enemy. The DH-4, the Bristol, and practically all other types except training planes were all copies of foreign products, and there is good reason to believe that they were not improved in their American adaptation.

Since the armistice, however, a different spirit has appeared in American aviation. While appropriations for building airplanes by the Army and Navy have been reduced to a limit which is considered dangerous by the enthusiasts of the new service, a vast amount of research work has been done, with the result that today America may be considered as being practically independent of Europe as far as knowledge of aerodynamics and airplane design is concerned. And much of the credit for this achievement is due to the National Advisory Committee for Aeronautics.

The National Advisory Committee for Aeronautics

This body was established in 1915 for the purpose of supervising and directing the scientific study of the problems of flight with a view to their practical solution, the determination of problems which should be experimentally attacked, and their investigation and application to practical questions of the aeronautics

The Committee consists of twelve members appointed by the President. The law provides that its personnel shall consist of two members from the War Department, from the Office in Charge of Military Aeronautics; two members from the Navy Department, from the Office in Charge of Naval Aeronautics; three members representing respectively the Smithsonian Institution, the U. S. Weather Bureau, and the U. S. Bureau of Standards; and five additional members appointed by the President, all serving without compensation. These five, who may be called expert members, are Jos. S. Ames, Director of the Physical Laboratory, Johns Hopkins University, Baltimore, Md., Wm. F. Durand, Mem. A.S.M.E., Professor of Mechanical Engineering, Leland Stanford Jr. University, Cal., Samuel W. Stratton, Mem. A.S.M.E., President of the Massachusetts Institute of Technology, Cambridge, Mass., D. W. Taylor, Rear Adm. U. S. Navy, Retired, and Orville Wright, Hon. Mem. A.S.M.E., one of the two brothers who originated the airplane. These eminent and busy men could not have been induced by salary considerations to do the work of the Committee, consuming as it does a large amount of time and requiring their frequent presence in Washington, but have undertaken it from patriotic motives for the good of the country.

The task the National Advisory Committee for Aeronautics has set for itself is that of collecting the information necessary to design aircraft of all classes intelligently and to test them reliably. Only those cognizant of the deplorable lack of knowledge regarding aircraft design and operation can have any conception of the magnitude of this task, and when they are made acquainted with the achievements of the Committee they will realize how truly remarkable is the work done by its engineers, especially considering the scanty means at their disposal.

The National Advisory Committee for Aeronautics

From Left to Right:

Dr. S. W. Stratton, President, Mass. Inst. Tech.
Orville Wright, Dayton, Ohio
Major T. H. Bane, Chief Engineering Division, Army Air Service
Dr. John F. Hayford, Northwestern University
Hon. Paul Henderson, Second Asst. Postmaster General (Guest)
Rear Admiral Wm. A. Moffett, Chief, Bureau of Aeronautics, U. S. N.
Prof. Charles Marvin, Chief, United States Weather Bureau
Dr. M. I. Pupin, Columbia University
Rear Admiral D. W. Taylor, Chief Constructor, U. S. N.
Dr. Charles D. Walcott, Chairman, Secretary, Smithsonian Institution
Major General Mason M. Patrick Chief of Army Air Service
Dr. Joseph S. Ames, Chairman Executive Com., Johns Hopkins Univ.

The New Spirit in Aero Engineering

The history of design in aeronautics strikingly resembles that in bridge engineering. The earliest bridges were the work of families of carpenters or stone masons who passed on a few very general and untested rules from generation to generation. They were built by certain rules of thumb without any regard to or analysis of the stresses to which they would be subjected. If the stresses happened to be within the capacity of the bridge, well and good; but if for some reason too great a load was placed on the structure, it collapsed; and while some may have become sadder they seldom became wiser through this experience, and the next bridge was built in substantially the same manner and trust reposed in Providence.

While aeronautics does not cover as many generations as bridge building, it has been but little more scientific. Airplanes were designed at first by inspiration. Sometimes this inspiration was right and a better machine resulted, but exactly why even its designer could not show. At other times inspirational design failed and the machine was abandoned, but not in many cases until it had caused the death of one or more fliers. However, there was no way of telling exactly why and in what respect the proposed design failed. To all practical purposes engineers were "wildcatting" in airplane design.

The testing of airplanes was practically as unsatisfactory as their design. Models could be tested in wind tunnels, but there was no way of determining to what extent the results of a wind-tunnel test would apply on a full-scale model, the so-called law of "dynamical similarity" being one on which entirely too little precise information is available.

In full-flight tests absolute reliance had to be placed on the impressions obtained by the test pilot, which were likely to be tinctured by his changeable state of mind, his ability to report observations exactly, and possibly his personal prejudices for or against the given design. The report of a test to all practical purposes resolved itself into the opinion which the test pilot formed, a purely qualitative conclusion not based on exact scientific data and arrived at by one not trained in the art of exact observation and operating under conditions which did not insure satisfactory precision. It is only natural for an aviator flying a new, unfamiliar, and untested plane to be more concerned with his own safety than with the precise extent to which the plane responds to his maneuvering. All of this created an uncertain, unsatisfactory, and highly unscientific situation. The National Advisory Committee for Aeronautics undertook to remedy it, and the amazing part of it is that while the work is not yet completed, enough has been done to place airplane design and testing on a sound basis and to insure proper precision in the taking of observations.

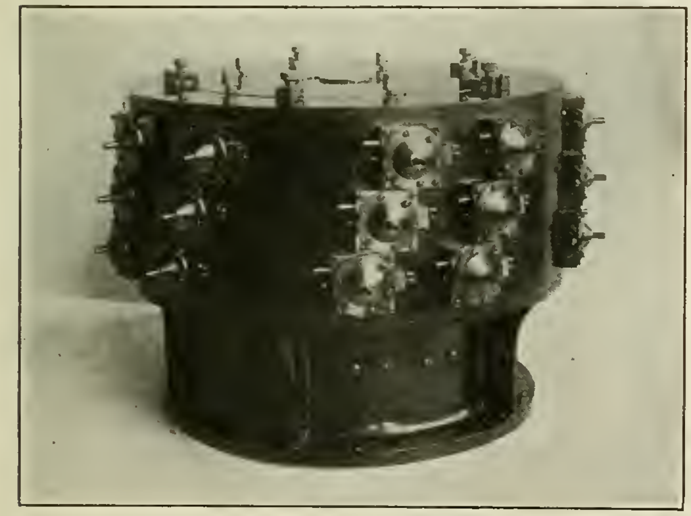

Fig. 5 Multiple Recording Manometer Used in Obtaining the Distribution of Pressure Over Airplane Wings and Surfaces of Dirigibles

To accomplish this required the creation of a research organization unlike anything previously in existence, the design of novel and ingenious research methods and instruments, and the carrying out of thousands of tests in the laboratory, on the ground, and in flight.

Organization of Aeronautical Research by the N.A.C.A.

We shall discuss the organization of research first, which is primarily a management problem that differs from the organization of an industrial plant in many ways.

Organization of research is basically unlike the organization of a manufacturing plant and approaches that of a jobbing machine shop in that, instead of production being essentially a repetition of a given set of operations, every job presents an individual problem entirely novel in its main aspects and one that has to be handled in its own way.

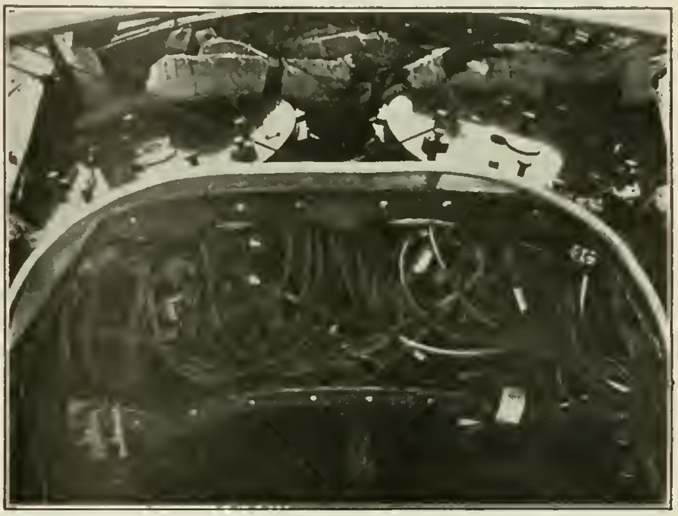

Fig. 6 Multiple Recording Manometer (Fig. 5) Mounted on Cockpit

(This shows also the tubes leading to pressure buttons on various parts of the airplane wing by which the pressure at a given spot is communicated to the manometer.)

In the National Advisory Committee as it is organized, problems may arise in several different ways. A problem may be proposed by the Committee itself or by one of its members; it may be suggested by an outsider or an outside organization, perhaps in connection with an invention submitted to the Committee for consideration; or the Committee may be requested by a Government department, such as the Army or Navy or Post Office, to undertake a research.

Each problem as it arises is referred to one of the three main sub-committees of the Committee and this sub-committee determines broadly the extent to which the problem should be investigated and the organization which should handle it, and submits its recommendations to the main committee. It may thus be handled at Langley Field or at the Bureau of Standards, which latter has a standing arrangement with the National Advisory Committee for Aeronautics for this purpose; or it may be referred by special arrangement to an outside organization such as the Massachusetts Institute of Technology, the University of Illinois, the Leland Stanford Jr. University, or the like, this being done when an outside organization has the proper equipment and personnel to handle the given problem.

It should be clearly understood, however, that the sub-committees of the National Advisory Committee for Aeronautics mark out the program for each given investigation only on very broad lines, especially when the work is to be done in the Committee's own laboratory at Langley Field or at the Bureau of Standards.

The research man is preëminently one venturing into unknown fields. Like David of old he may go out to look for lost asses and find a kingdom. Quite often, however, the contrary happens to be the case. In research it is not unusual to find that apparently minor problems to which scarcely any attention has been paid at the beginning of the work rapidly develop into major ones, and it is not unusual also to find that the problem for which the given research was originally undertaken proves on closer consideration to be no problem at all. Because of this a certain clas-

ticity in instructions is imperative, the governing body, such as one of the main sub-committees, keeping in close touch with the work of the laboratories through progress reports and occasionally through personal observation.

When the problem reaches the Langley Field research laboratory it is then considered at a conference of the engineer-in-charge with such heads of divisions as may be interested in it. For example, a given problem may deal with the determination of the aerodynamic properties of a new wing. In the conference with the engineer-in-charge would be the head of the Wind Tunnel Division, the head of the Instrument Section, and possibly the head of the Flight Test Division. At this conference the general problem of how this piece of research should be carried on is considered, as well as the research facilities available and the new instruments or appliances that have to be provided. A tentative time schedule is established and an estimate of the cost of the given investigation drawn up. Such a conference is usually quite informal, no minutes being kept and each member present taking notes as to what his group should do and when it may call upon other groups to assist in the new undertaking. In addition to this brief conferences of all the heads of the technical divisions and sections are held every week, at which progress reports are made as to work in hand so that all can keep track of what is going on. The general organization of the laboratory may be seen from the chart in Fig. 1.

The laboratory is equipped with a small instrument shop capable of doing work of high precision. As far as possible all heavier and rougher machine work is done by outside contract, although facilities therefor are available in the laboratory if the need is urgent. When it is decided to build a new instrument or piece of apparatus, the practice is to carry the design work in the drafting room only to the extent necessary to establish a proper basis for the construction of the first model. No attempt is made to produce a full set of shop drawings, a complete idea of the design often being present only in the brain of the engineer. As the parts are being completed, it takes shape. Sometimes changes have to be made either on parts already produced or by making entirely new parts. In case the new device is an addition to the family of recording or indicating flight-test instruments, it is tested out first in the laboratory and then in flight. If it is found that its operation approximately meets expectations, changes are incorporated and further tests are made until the performance of the apparatus fully satisfies the requirements or its limitations are determined. While this does not at first appear to be a very scientific or logical procedure, experience has demonstrated that it does lead to the production of satisfactory apparatus with the minimum of delay.

When the apparatus has been definitely completed and tested out by use, complete working drawings are made. This is made particularly necessary by the fact that the research laboratory is not a production shop and ordinarily does not build duplicates of the instruments designed in it, since this can usually be done at somewhat less cost by properly equipped outside shops.

In this connection it may be mentioned that methods have been developed by engineers of the laboratory for handling this work in outside shops. It would have been obviously impossible to write complete specifications for each apparatus. Therefore in the several years of its existence, the laboratory has compiled what might be called a "white" list comprising shops that experience has shown can be relied on to do the work satisfactorily, and it is to such shops that the production of instruments from complete drawings prepared at the laboratory is farmed out. This method, while somewhat informal, has been found to be most productive of results.

Research Personnel at Langley Field Laboratory

As regards the personnel of the laboratory, the engineer-in-charge has stated that experience has shown that the best plan is to employ good men directly after they have been graduated from college and before they have been engaged in any production work. While they may be lacking in practical experience, it has been found easy to instill into them the true spirit of research, a matter somewhat more difficult in the case of engineers who have been taught to concentrate on "getting the work out."

Naturally the turnover in the ranks of the researchers is quite high. After the young men have been at the laboratory a few years they find themselves in possession of a considerable amount of valuable engineering experience and training, and to obtain their services commercial organizations offer them pay far greater than the modest salaries with which the Government compensates its scientific men.

In a way this handicaps the work of the laboratory, but no serious objection can be made, partly because of the gratification natural in seeing men leaving the laboratory to occupy responsible positions in the outside world, but especially since in this way the laboratory comes to occupy the position of a school sending out its missionaries into the industry to teach respect for aeronautical research and methods for bettering American aeronautical products. The industry badly needs such a school, and in training the research force of future American aircraft factories the Langley Field laboratory and its allied organizations are performing a valuable service to the cause of national preparedness.

On a visitor to the laboratory this feature produces a strong impression. Aeronautics from the beginning has been a young man's game, and as one passes from one building of the laboratory to another he constantly meets keen young men with the latest information on their respective subjects at their finger tips. And the amazing thing about it all is that these young men with but scanty financial means at their command are achieving results which are rapidly revolutionizing the industry and converting it from one of unadulterated guesswork into an exact science.

Wind-Tunnel Testing

The Wind Tunnel Division has two tunnels, one of conventional design built of wood, and the other of the so-called "high-pressure" type and of radically novel construction.

The art of testing various wing, airplane, and propeller shapes in wind tunnels has been brought within the last twelve years to a high state of perfection and the instruments developed in this time make it possible to measure and record the performance of a model in a wind tunnel with great reliability and precision. The trouble begins when an attempt is made to interpret the data obtained in a wind tunnel in reference to their application to full-scale machines. There is the so-called law of "dynamical similarity" which purposes to express the relation between results obtained on models and the performance of full-scale machines, but the extent to which and the precise way in which this law should be applied is still a matter of considerable uncertainty.

The compressed-air tunnel, Figs. 2, 3 and 4, represents an interesting attempt to apply a novel principle to the testing of model shapes. Briefly and without going into aerodynamic intricacies it may be said that a model of a length, say, of 6 in. in an air stream having an absolute pressure of 5 atmos. behaves in the same manner as a model 30 in. long would behave in air at atmospheric pressure. In other words, an increase in the pressure of the ambient medium in which a model is tested is equivalent to an increase in the size of the model at approximately the same rate as the increase in pressure.

This is a rather novel departure in testing airplane shapes and not enough work of the kind has been done to show its exact value. It is fortunate, however, that at the Langley Field laboratory sufficient equipment is available to obtain precise data as to the behavior of various wing shapes when incorporated in full-size airplanes in flight, and it may be expected that a comparison between data obtained from the normal-pressure tunnel on the one hand and from the compressed-air tunnel on the other, when compared with data obtained from wings of the same shape in actual flight, will throw a vivid light on the still obscure but highly important law of dynamical similarity.

As shown in Fig. 2, the compressed-air wind tunnel known in the laboratory as Wind Tunnel No. 2 is essentially a riveted tank of quite respectable dimensions, 15 ft. in diameter by 36 ft. long, built of steel plate $2^1/_8$ in. thick, which is none too much considering that the apparatus is designed for working with a maximum pressure of 300 lb. per sq. in.

Inside the tunnel is a propeller which circulates the air and creates the necessary air stream; spy windows are provided to observe the instruments, which latter may be controlled from the outside by the observer.

Instruments for Determining the Magnitude and Distribution of Stresses in Aircraft

One of the most important problems in the design of either an airplane or a dirigible is the determination of the magnitude and distribution of the stresses in the structure. It is obvious to any engineer that before he can design a piece of machinery he must know what the stresses are in the entire machine and particularly

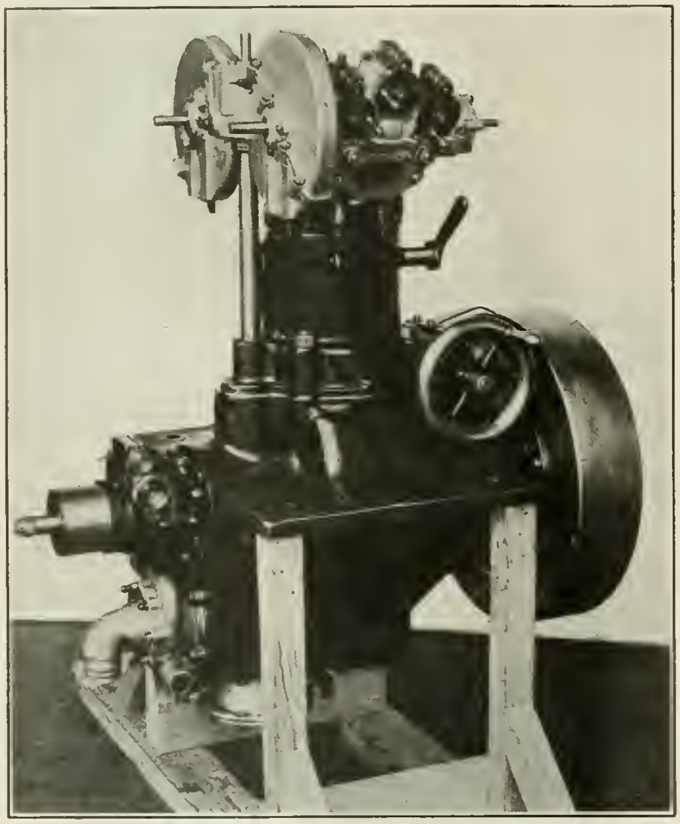

Fig. 13 A Universal Test Oil Engine
(Conditions of operation, such as valve timing, compression pressure, clearance, etc., may be varied while the engine is running.)

the stresses in the parts. This is why we can use a material like cast iron in the foundations, but have to employ steel forgings, possibly special heat-treated alloy steels, in parts rotating at a high speed or subjected to severe vibration. Both airplanes and airships have hitherto been designed in the utter absence of such important data.

While designers for a number of years have known the general nature of the distribution of air pressure over wing surfaces and have been able to apply this knowledge in "sand testing" airplane structures, this mere approximation was found to be untrustworthy when applied to modern high-speed racing and fighting craft, several of which have been the victims of unexpected accidents which were later explained by a more thorough knowledge of the air loads on airplane wings and control surfaces and on airship hulls. The collapse of the Italian-built semi-rigid airship *Roma* in this country and the British-built rigid airship *ZR-2* in England were probably due to lack of adequate load information. The National Advisory Committee for Aeronautics was the first body to undertake a thoroughly scientific investigation of these loads and their distribution, and to carry it through to a successful conclusion.

To do this a new instrument was devised (Figs. 5 and 6) called the multiple manometer, chiefly remarkable for the fact that within a space slightly smaller than a man's silk or stovepipe hat there were crowded thirty diaphragm-type registering manometers. These were connected by small tubing to small brass pressure buttons located at various points of the surfaces of the airplane wing or control surface. The tiny points on the airship in the illustration on the cover of this issue are special "pads" for the same purpose. The pressure at each of these points was transmitted through the rubber tube to the corresponding registering manometer while the aircraft was in actual flight. This permitted recording the variation of distribution of air pressure over the surfaces during various flight maneuvers reliably and without in any appreciable way affecting the behavior of the aircraft itself.

The idea seems to be very simple, but it required an immense amount of thought and engineering design in order to carry it through successfully, and it gave truly amazing results. In the first place, it was found that the distribution of load over the wing of an airplane flying at high speed was decidedly different from what had been anticipated. There have been cases, especially after a rapid dive, where the fabric on the upper side of the wing was actually torn off at the forward edge. There did not seem to be any reasonable explanation for this as the loads were supposed to be of the order of 50 lb. per sq. ft., which was considerably less than the fabric was capable of withstanding.

In the tests of the National Advisory Committee for Aeronautics it was found that the loads reached a maximum of 210 lb. per sq. ft. instead of 50 lb., or were more than 300 per cent greater than hitherto supposed. This means that the forward edge of the wing will have to be reinforced in some way. It will also probably mean that a complete and intelligent redesign of the shape of the wing must be effected to avoid this undersirable localization of the load; and in any event it will mean a more intelligent handling of flight problems themselves.

Another entirely unexpected result of these tests was the discovery of unsuspected extreme load concentration at the wing tips, which explained several instances where the wings had buckled and fliers had been killed. Here the solution of the problem has already been found, namely, altering the wing-tip shape and giving to the wing a negative angle at the rear, a simple matter which

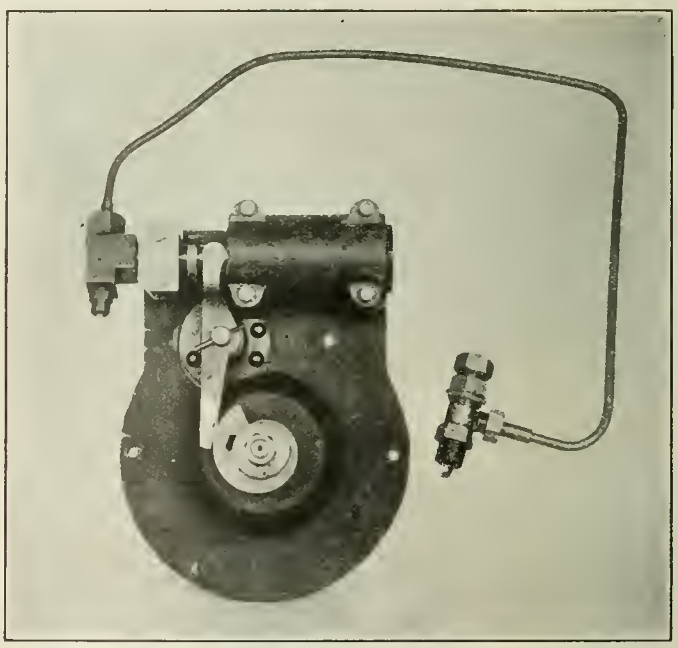

Fig. 14 Fuel-Injection Pump Developed for Use with the Special Single-Cylinder Test Liberty Engine Shown in Fig. 15

will save many valuable lives; and yet it could not have been arrived at without some such methodical and scientific investigation as the Committee and its engineers applied and are applying to the problems of aeronautical design.

While space does not permit going into this matter more fully, the cover illustration shows that the same methods have been employed in the design of airships. Without revealing any military secrets, it may be stated that the results of this investigation have been already taken into careful consideration in the design of the huge Navy dirigible *ZR-1* now under construction at Lakehurst, N. J., and because of this there is reason to hope that it will escape the fate of the *ZR-2* and the *Roma*.

In general, it is the aim of aerodynamical experts of the National Advisory Committee for Aeronautics to place the design of an airplane on the same scientific basis as that which has been employed for a long time in bridge design, where it is possible to know before-

hand the stresses to which not only the entire structure but every one of its members will be subjected. The ability of the materials used to withstand these stresses being known, it becomes possible to specify such factors of safety as will insure the proper functioning of the structure under all but absolutely unforeseeable conditions. This is an undertaking of great difficulty and importance, so difficult, in fact, that no practical attempt at it has been made anywhere outside of this country; and it is a matter regarding which American engineers may feel proud that conclusive results have been obtained within a period of less than three years of work, and with the expenditure of an extremely modest sum of money.

(This apparatus is used in connection with work of developing a fuel-injection oil engine for aircraft.)

Flight Testing of Airplanes

"The proof of the pudding is in the eating," but this does not mean that all who eat the pudding will agree as to its qualities. There is presumably about as much variation in the ability of different test pilots to judge of the performance of an airplane, because of the personal element of the flier. Furthermore, there are good grounds for believing that even a reliable test pilot will not always report things as they have actually occurred, no matter how honestly he may try.

In any event, impressions of a test pilot, and that is practically what a report of the ordinary test flight amounts to, are too indeterminate to make a comparison possible. As a result of this there has been in the past no reliable way of determining the qualities of an airplane in flight, in particular its controllability and maneuverability.

To solve this problem the National Advisory Committee has developed a series of instruments which give exact information as to what the pilot does in flight at any given time, and show beyond cavil just what happens as a result of a given action of the pilot.

The most interesting of these instruments are those designed to record the actions of the pilot in controlling the airplane. Many of the controlling operations of the pilot are very nearly automatic in about the same way as are those of an expert automobile driver threading his way through congested traffic. They consist of a series of slight movements of the steering wheel, light pressure on the accelerator, and possibly a shift of the brake, all of these being instantaneous reflexes to the state of traffic ahead as viewed at each succeeding moment by the driver. The airplane pilot "feels" his machine, and by slight movements of the control elements keeps it on the desired course. Not every pilot controls his machine in the same way, since not all have the same quickness of reflex or the same "feel" of the machine.

A new instrument has been developed called a control position recorder, by means of which every movement of the "joystick" is recorded and timed. This is not all, however, because in addition to recording what has actually been done, it is necessary, in order to judge of the controllability of an airplane, to know how much of an effort a pilot has had to exert to obtain a given result. This again can now be recorded and timed by means of a control force recorder, the two instruments together giving a complete record of what the pilot has done.

The next problem was to find out to what extent the airplane responded to the control operations of the pilot—whether it made the turns, dives, "zooms," etc., demanded of it, and how rapidly it did so. For this purpose an interesting series of instruments were developed. These are shown in Figs. 7 to 11, and the stability of an airplane, its ability to take turns, to accelerate, etc., is, or rather may be, recorded synchronously with the "position" and "force" records of the control apparatus. A comparison of the two records will show exactly and independently of any personal element of the test pilot just what had to be done to keep the airplane on its prescribed course and what its ability was to stay on that course and to respond to such changes as might be demanded of it. In this way it now becomes possible to obtain what may be called an index number of the controllability and maneuverability of an airplane, which enables one to compare two given machines fairly, reliably, and intelligently—something which has never been done before and cannot be done without a set of instruments of the type developed by the Committee.

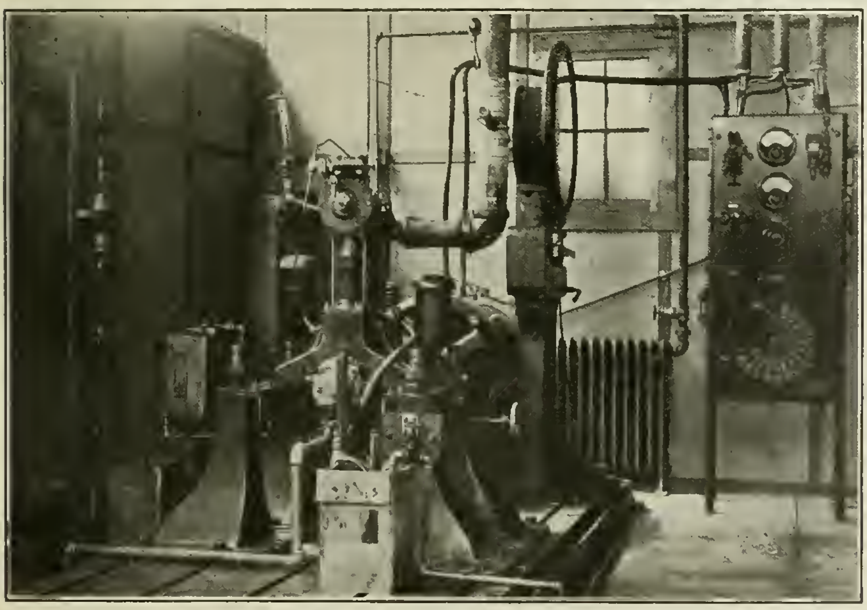

Fig. 15 General Set-Up for Testing a Liberty Single-Cylinder Special Unit When Operating on Fuel Injection and Autoginition

Test Airplanes

In this connection it may be mentioned that at the Langley Field research laboratory the Committee maintains a rather interesting assortment of airplanes. There are thirteen machines of ten different types ranging from single-seat Bee Line racers capable of making better than 180 m.p.h. to a huge torpedo carrier that looks like an aerial truck and carries about as heavy loads. The Committee has the services of two pilots, and it is the belief of the engineering personnel that work such as is done by the laboratory in the air should be performed by test pilots specially selected and trained for it rather than by ordinary flight pilots. The reason for this is that test pilots are more inclined to obey strict instructions as to what they should do than are ordinary flight pilots. Of course, when it is necessary to have extra machines in the air, arrangements are made to borrow the necessary personnel and equipment from either the Army or the Navy.

With thirteen machines in the hangar and extremely elementary facilities for handling the work, the laboratory manages to get along with two pilots and six mechanics in the hangar. In the two years that heavy flying has been done the laboratory has a record of close to 500 hr. in the air in all kinds of weather without a single smashup.

In addition to the flying work in heavier-than-air machines, which is practically all done at Langley Field, a certain amount of experimental work on lighter-than-air machines is performed at the Navy Base at Norfolk, Va. This is being done with the regular Navy personnel, the engineers of the National Advisory Committee for Aeronautics directing the actual tests and acting as observers.

Oil-Engine Design

One of the many problems that are interesting today every aeronautical power-plant engineer is that of the design of an oil engine for aircraft. The National Advisory Committee for Aeronautics is devoting a good deal of attention to this problem at its laboratory at Langley Field and is going about it in a way that is certain to result in greatly broadening our knowledge of medium-compression engines. This work is being carried forward in three directions. In the first place, tests are made on a dynamometer outfit with a single-cylinder Liberty engine, and while some interesting results have been obtained, a great handicap exists in the fact that this engine was not initially designed as an oil engine and, therefore, no matter how much it may be tinkered with, it will not give high efficiency as such.

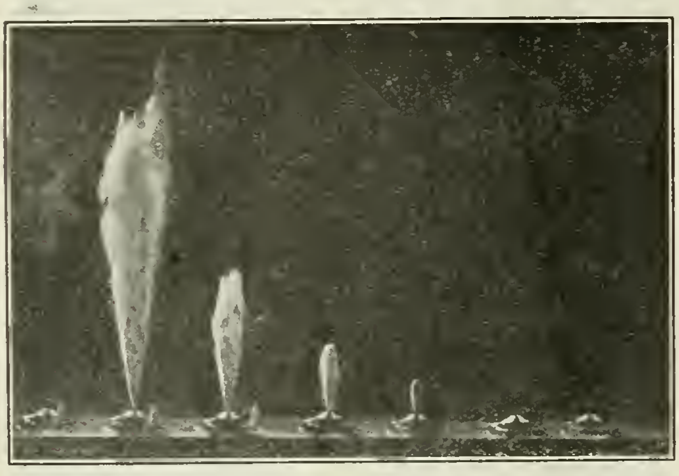

Fig. 17 Instantaneous Photographs of Fuel Sprays
(As noted in the text, these photographs were taken with an earlier type of apparatus and not with that shown in Fig. 16.)

From this point of view a good deal more may be expected from the unusual single-cylinder "universal" oil engine shown in Fig. 13. One of the features of this engine is that the compression ratio can be changed while the engine is running, as can also the timing and lift of both inlet and exhaust valves, as well as the fuel-injection characteristics.

This experimental work on actual engines is of course of great value, but after all so many variables enter into the operation of an engine that it is practically impossible to determine completely the influence of each one of them, and yet without taking them into consideration it is impossible to perfect a truly scientific design.

Because of this the laboratory undertook what appears to be a highly original research, namely, that of learning the behavior of various jets as affected by each of the several variables that enter into the determination of the character of the spray. Among these may be mentioned the shape and size of the nozzle, the pressure of the fuel, the temperature and viscosity of the fuel, the temperature and pressure of the gaseous medium into which the spray is injected, turbulence, etc.

The only practical way to investigate the various kinds of sprays appears to be by securing a photographic record of their gradual development. An apparatus (Fig. 16) was therefore built which made it possible to take photographs at the rate of 1350 per sec. Some of these photographs are shown in Fig. 17. Illumination for these photographs was provided by means of electric sparks, but in the initial installation the illumination proved to be insufficient to give the desired clarity of the pictorial image. The apparatus was therefore completely redesigned and is now practically completed. With it photographs may be secured at the rate of 5000 per sec., and the illumination has been increased so that it is now about tenfold what it was initially. From eight to twelve photographs may be taken during the period a jet is developing from its beginning to full size. It is easy to see what a light will be thrown on the process of jet formation by an accumulation of such photographs.

This, together with other developments at the research laboratory, may be taken as an indication of a determined tendency on the part of the Committee to organize its research so as to obtain data that will be as free as possible from errors introduced by the personality of the experimenter. In the case of jets this is done by photography, and in flight tests by means of the several recording instruments which tell exactly what the pilot and the airplane did. The behavior of the airplane itself is written down by kymograph, gyro turn indicator, single- or three-component accelerometers, gyro position recorder, angle-of-attack recorder, etc. To know by record and by measure is a good rule to follow, especially in a science as young and unorganized as aeronautics.

International Air Congress

THE following are brief extracts from two timely and informing addresses delivered before the International Air Congress held in June of this year in London on invitation of the British Government.

The Duke of Sutherland, who acted as Chairman of the Main Committee of the Congress, in delivering his inaugural address, said that the present time was full of great possibilities in the realm of aeronautics. We were on the eve of far-reaching advances in aviation, which might within the next decade or two bring about a partial or complete readjustment of our manner of living. To achieve the desired objects it was, however, essential that the results of research work and the experience derived from the Congress should be properly applied by means of the continued support of governments, and by the business initiative, and patriotism, of private citizens and companies of wealth and influence. The day had gone by when we could leave these things to develop themselves and work out their own salvation. The stakes were too great for us to stand negligently by, while the world's greatest secrets were almost within our grasp. The development of civil and commercial aviation between all countries on a scale hitherto unrealized and the evolution of a popular, cheap light airplane for the public use were both essential factors for the future, and were undoubtedly the forerunners of the world's entry into an aerial age.

J. D. North, in his address on The Technical Development of the Aeroplane, spoke as follows:

"Mechanical flight in the brief twenty years of its existence has passed through four phases, each of an approximately equal period, and which are defined sufficiently clearly to be marked by the observer. There are indications that we are now entering on a fifth phase in the art and practice of aviation, the trend of which forms a legitimate field for speculation.

"Let us take stock of our technical assets. We have a large amount of incompleted work which requires sifting and developing to its proper conclusion. We cannot expect to develop the aeroplane on the heroic lines, the achievement-at-any-price methods, which were proper to the war period. Probably we shall be compelled to concern ourselves mostly with small matters out of the multitude of which great things may come. First, there is the development of the aeroplane from the economic standpoint, the improvement of the ratio of the useful load to the gross weight, and the improvement of fineness whereby for given horsepower this gross weight may be given a better performance. These may be attacked either by systematic improvement of detail or more speculatively by radical changes in design." (*The Engineer*, June 29 and July 6, 1923, p. 682, and p. 5.)

The Port of Montreal

Factors Contributing to Its Development—The River St. Lawrence Ship Channel—Mechanical Handling in Montreal Harbor—Electrification of the Harbor Terminals—Floating Drydocks, Standard Piers, Etc.

By FREDERICK W. COWIE,[1] MONTREAL, QUEBEC

THE PORT OF MONTREAL is essentially a national port. It has been developed upon a national principle, namely, that of coöperating with production in its completest sense for marketing, for warehousing, for collecting, for manufacturing, and for shipping—the principle of a truly modern port.

The total land area of Canada is 3,600,000 square miles; the density of population is less than $2^1/_4$ per square mile as compared, for instance, with 30 per square mile in the United States. This vast area, the tremendous distances, and the distribution of the sparse population make the problem of transportation one of vital importance. Canada, with four times the present population, may produce, for export, one billion bushels of the finest wheat in the world.

The fundamental difficulties in the way of production and marketing in Canada are population, climate, and distance. From the center of production in the Canadian Northwest, in the vicinity of Moose Jaw, or Saskatoon, the transportation distance, by rail and water, to Montreal is over two thousand miles. Further, there is also the desire on the part of the farmer to market his products before the winter sets in, when the Great Lakes and St. Lawrence routes are closed. The transportation problem, therefore, is a serious one, and one of the factors in connection with that problem is the port terminal.

The development by Canada of navigation on the St. Lawrence, reaching a thousand miles into the interior of the continent; the development of the port of Montreal; and the improved canal navigation between Montreal and the head of the lakes, have been recognized as national necessities and have been promptly carried out to the credit of, and by the credit of, Canada. For a young country with such a small population and limited financial resources, the record is respectfully submitted as being a most excellent one. Not long ago a writer in *Collier's Weekly* summed up matters as follows:

> Within the past decade Canadian enterprise has been building at Montreal one of the most modern and efficient harbors in all the world. Yet the harbor of Montreal is a thousand miles from the sea, and for five months of the year is closed by ice. It has always struck us that the development of the port of Montreal is one of the most daring and sportsmanlike pieces of commercial enterprise that ever has come before our eyes.

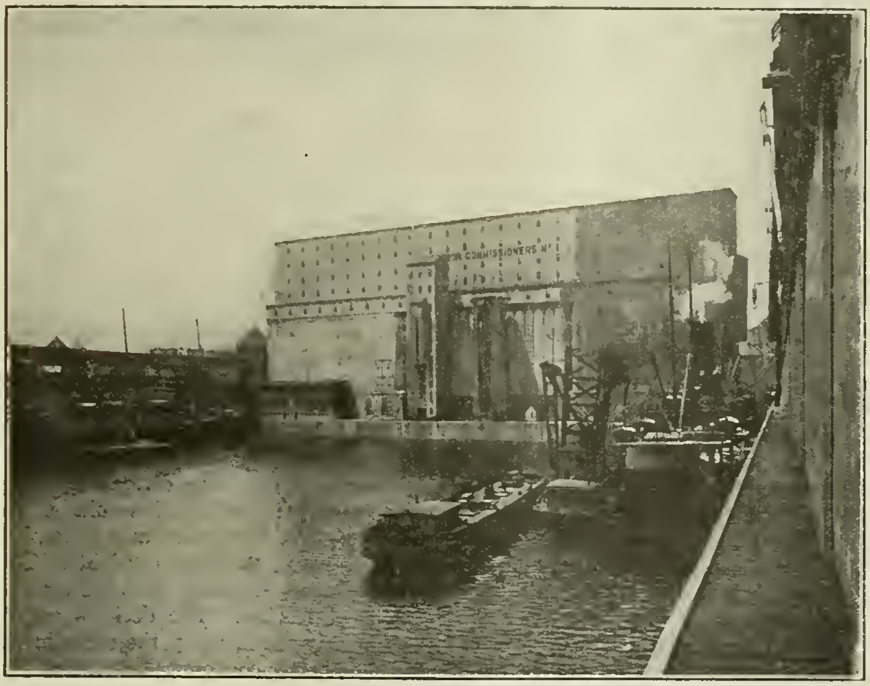

Fig. 1 Harbor Commissioners' Grain Elevator No. 1
(Storage capacity, 4,000,000 bushels.)

Factors Contributing to the Development of the Harbor of Montreal

One hundred years ago the city of Montreal had a population of less than 20,000. Quebec was the great Canadian St. Lawrence seaport, and the depth of water in the channel to Montreal was, during the low-water season, only 11 ft. The total ocean freights by ship, to and from Montreal, one hundred years ago could have been carried in one of the several modern ocean steamships which may be seen in Montreal today.

There were then no railroads, and no canals. As the brig of 250 tons represented ocean navigation in Montreal, so the batteau, a flat-bottomed boat, pointed bow and stern, 35 to 40 ft. long, the usual freight being from four to five tons, represented the entire system of transportation to a rapidly developing Ontario, then called Upper Canada or Canada West, as well as to a large section of the United States bordering on the Great Lakes.

In the meantime, while the two provinces, Upper and Lower Canada, could not agree upon financial arrangements, the enterprising citizens of the United States discovered that remarkable pass, the Mohawk Valley, through the Alleghenies, and built their own "St. Lawrence" from Buffalo to the Hudson River, opening it in 1825, one year before Canada opened her first Lachine Canal.

The first Lachine Canal was opened in 1826. Its locks of masonry construction, remarkable at that time, were $6^1/_2$ ft. wide, and had a depth over the sills of $4^1/_2$ ft. They were specially constructed for navigation by Durham boats, vessels of 20 to 30 tons. In the meantime Montreal became the point of transfer between ocean navigation and inland transportation, and has retained that position now for one hundred years.

The first harbor commission having in view the improvement and development of the port of Montreal was established in 1830. Montreal at that time had just emerged from being a walled town, and the only port accommodation consisted of the beach extending from the river wall to the water. There were originally five gates from the river to the town, but with the introduction of the river steamer in 1812 from Quebec, and the necessity of more economy in discharging the brigs of that day, wharves were required.

The new harbor commissioners having before them only a sketch plan, decided with wisdom upon obtaining the advice of that eminent civil and mechanical engineer, Peter Flemming, of Albany, N. Y., who had just achieved fame by the successful completion of the locks of the Erie Canal.

Peter Flemming's first report outlined the difficulties, and suggested wharf structures estimated to cost £39,000. He recommended rock quay walls, and his estimate was based upon this type

---

[1] Consulting engineer, Harbor Commissioners of Montreal. Mem. Eng. Inst. of Canada.

Contributed by the Materials Handling Division and presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

of structure. Another engineer, whose name has not lived in history, suggested a timber-piling type of structure, and as this was found to save £10,000 it was adopted. Unfortunately, however, when the spring ice shoves swept down upon this timber structure, the inevitable happened.

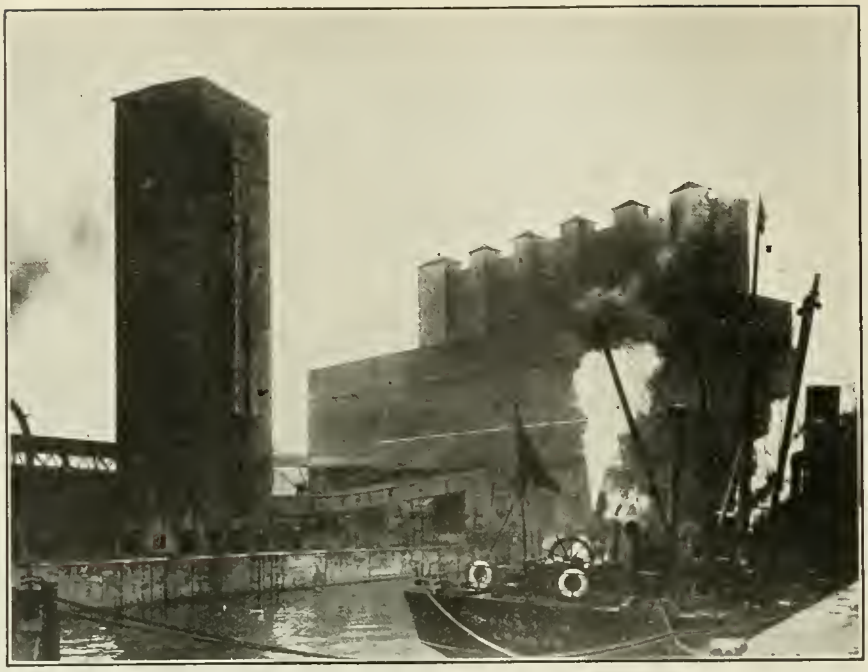

Fig. 2 Harbor Commissioners' Grain Elevator No. 2
(Storage capacity, 2,622,000 bushels.)

The River St. Lawrence Ship Channel

It was the genius of the mechanical engineer that made possible that great achievement, the River St. Lawrence ship channel from Montreal to the sea.

The first dredge was built in Montreal in 1838, the machinery having been brought from Scotland. From 1840 to 1844 various preliminary works—experimental and otherwise—were carried out, and it was only in 1840 that actual progress was commenced. The author was first identified with this great work in 1886 when it was considered a wonderful and successful enterprise.

Two types of dredge were then in use, the elevator dredge and the dipper dredge. It was soon apparent that the latter, though effective, could not coördinate with continuous navigation, and the elevator dredge, floating and held in position by "crab" moorings so that it could quickly haul itself out of the way of passing ships, was adopted.

From Montreal to Murray Bay the total distance by river is 220 miles. In this distance dredging for deepening the natural channel has been required over a distance of more than 70 miles.

Fortunately, owing to the settling basins, the Great Lakes, there is practically no sediment in St. Lawrence water, so that the dredged channel once completed remains permanent. The material varies from a soft blue clay of the consistency of a cream cheese to hard shale rock, almost as hard as ledge limestone. The quantity of material dredged has nearly reached the enormous total of 100,000,000 cu. yd.

It was at Montreal that the elevator dredge was first adapted to dredge shale rock; immense cast-steel buckets with forged special steel teeth, operated by the necessarily powerful machinery, were successfully designed to dredge this hard rock at a depth of 48 ft. in a strong current; and to carry on at a rate of 2500 cu. yd. per day, working day and night; at a cost of 40 to 50 cents per cu. yd.

Immense boulders covering the bed of the river, many of them weighing 50 tons, had to be lifted and removed; all of which was successfully accomplished without blasting.

In Lake St. Peter, where the depth had been originally 11 ft., 18 miles of solid dredging was required. For this work several types of dredges were designed. The late Sir John Kennedy, a mechanical genius, improved the ladder dredges to such an extent that one dredge vessel was capable of dredging and having removed by scows 6000 cu. yd. per day at a cost of 3 cents per cu. yd.

When the project for widening and deepening the channel was undertaken in 1900 under the direction of the author, it was evident that a new departure was required for speed as well as economy. The suction dredge was investigated, but it was found quite impracticable to pump the sticky blue clay of Lake St. Peter by the suction principle. Mr. A. W. Robinson, Mem. A.S.M.E., a mechanical engineer of Montreal was consulted, with the result that the dredge *J. Israel Tarte* was designed, constructed, and put into operation. This dredge, having a rotary cutter and working on the suction plan, was capable of dredging and removing by pipe the mud of Lake St. Peter at the rate of 12,000 to 20,000 cu. yd. per day.

The cross-section of the 8-mile Culebra Cut of the Panama Canal was originally designed at 8000 sq. ft. The cross-section of the St. Lawrence in the three miles of rock cut is 80,000 sq. ft.

The Port of Montreal

Montreal Harbor today represents a capital cost of $35,500,000. It is hard to believe that the sixth port in the world, or the second in America, could have been developed, including harbor dredging; wharves, piers and basins; warehouses; grain elevators and equipment; real estate; railways and electrification; permanent sheds; with all plant and equipment, at such a modest price. Port authorities throughout the world may obtain much valuable information by analyzing the principles and methods adopted by the Montreal Harbor Commissioners and which have resulted in such an almost unparalled achievement.

Mechanical Handling in Montreal Harbor

It is admitted that only such mechanical handling has been adopted in Montreal Harbor as has been found absolutely necessary and as has been demonstrated to be desirable and economical.

Some years ago, by the direction of the Harbor Commissioners of Montreal, an exhaustive study was made of harbor freight-handling devices by several eminent engineers. These men unanimously agreed that it would be unwise to equip the Montreal docks at that time with any general system of freight-handling devices, except for special freights. The "forest" of cranes which is in evidence in many European ports is therefore not seen in Montreal Harbor. The decision regarding mechanical handling was greatly modified by the recommendations of the author that equal or better economical results could be obtained in the harbor by special correlation between the railways and the docks, the concentration and use to full capacity of facilities, and the extension of the grain-elevator system of delivery of grain to all berths in the central harbor.

Electric hoists were designed, for the first time, to make equally valuable the upper as well as the lower stories of the transit sheds. This design, so very successful, was adopted when team transporting was the rule. At the present time when motor-truck transport is feasible on an 8 per cent grade, there is room for difference of opinion. Practically the whole of the Montreal Harbor system of transit sheds, having a total floor area of 60 acres, is specially well adapted for the use of the storage-battery truck and trailer, and for the new system becoming so general in American ports, namely, the supporting warehouse.

For general cargo, therefore, as may be seen by actual demonstration, Montreal Harbor is sufficiently equipped, in coördination with the splendid freight equipment of the ships, for speedily, economically, and with great satisfaction to all concerned, turning around ships and their cargoes.

Special Freight Handling. While there is satisfactory equipment for the handling of coal in the harbor, Montreal is not an outstanding coal port.

The handling of live cattle is conducted with great rapidity and satisfaction from railway cars through the sheds to the gangways

of the ships, without any special equipment and without requiring the ships to move from their berths.

For the storage and handling of flour special facilities have been under consideration, and it is expected that this feature will require similar study and similar accomplishment as exemplified by the design and installation of facilities for the storage and handling of grain.

The Storage and Mechanical Handling of Grain. In America the areas of export production are at a great distance from the seaboard. Grain has to be transported over great distances and handled many times as compared with the producing areas in competing countries. Moreover it is difficult to realize the magnitude of the quantities of grain produced in America. In North America the production of grain annually is in excess of six billion bushels. At least five hundred million bushels are exported, and, let us say, three hundred million more are shipped to some local market, the remainder—two and a half billion bushels—being consumed on the farm.

In America, as a rule, export grain is handled at a country elevator, at the head of the lakes, at a lower lake port, at an ocean port, at a port in Europe, and at the final milling point. The cost of this handling for the export business may be estimated at 8 cents per bushel and amounts to $40,000,000 annually. The three billion bushels of local grain are handled at least twice, at an estimated cost of, say, 2 cents per bushel; a further amount of $60,000,000 annually. That is, the cost of handling the grain grown in America amounts to something like $100,000,000 annually. What a prize if the cost could be decreased 25 per cent, or even 10 per cent!

The port of Montreal is one of important handling ports for export grain in America and last year handled over 155 million bushels. Without the grain business and profits on handling, Montreal would not be the second port in America.

When it is considered that on the opening of the Canadian Pacific Railway in the West in 1886 there were no facilities and no organization of any kind for the handling of grain, one is profoundly impressed with the successful mechanical development which has resulted in the handling of the present production with one-sixth of the Canadian Northwest agriculturally developed; and with the requirements of the future, when five-sixths will be sending their streams of export to the markets of the world.

It may be asked, "Is there anything left in the way of possible improvements?" But when it is considered that grain may be received, weighed, stored, reweighed, and delivered to a ship at her berth half a mile from the elevator at about 50 cents a ton, why not rest satisfied?

During the war, when labor was so scarce and shipments required to be urgent, it was found almost impossible to unload promptly the railway cars containing grain into the elevators. The author accordingly undertook an investigation into the possibility of the mechanical unloading or dumping of cars. This investigation was later continued by the John S. Metcalfe, Co., Ltd., of Montreal and Chicago, who finally succeeded in designing a grain-car dumper which has solved the problems of labor, time, and cost in a most satisfactory manner.

When it is considered that the old method of unloading grain cars by shoveling required from four to five men for half an hour, while, with the new dumper, it takes a similar gang only six minutes, its value will be appreciated. A feature of the car is that it may be installed in a separate building, thus greatly minimizing the danger from dust explosions.

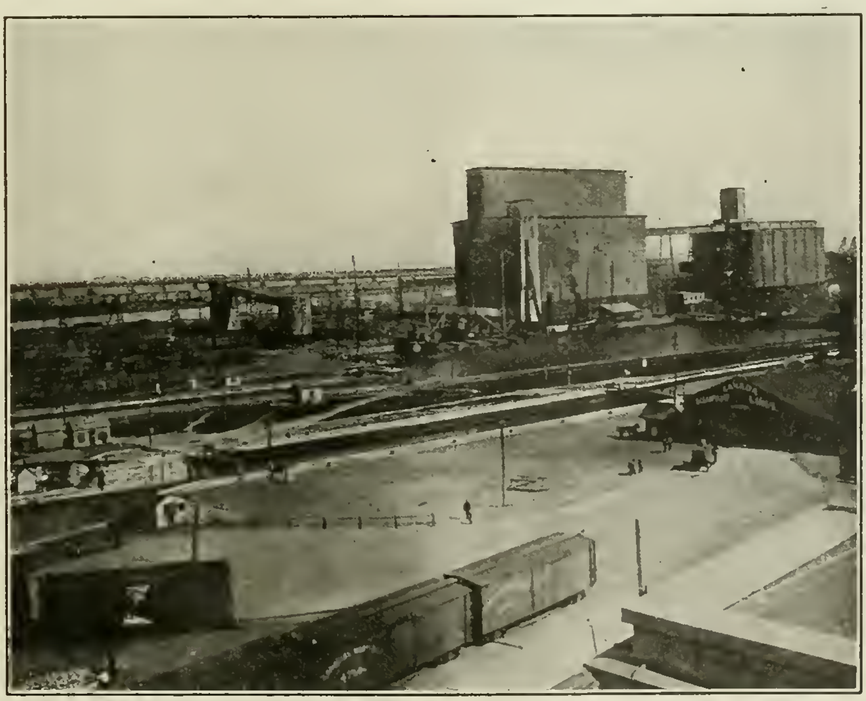

Fig. 3 Grand Trunk Railway Grain Elevator
(Showing in foreground locks at entrance to Lachine Canal; storage capacity, 2,100,000 bushels.)

There remain, however, serious problems requiring solution, such as the trimming and shoveling of grain in vessels in America, and particularly in the European ports.

The Mechanical Handling of Flour. As wheat unmanufactured is exported in great quantities, so manufactured wheat or flour is now becoming a very important item of American commerce. Who can solve the problem of a "container" more rapidly transportable and economical of space than the barrel and less wasteful and better than the sack, and thus make flour shipment compete with that of bulk wheat?

The Cold-Storage Warehouse. Last year there was opened for business in the harbor of Montreal a cold-storage warehouse, which was built to aid the producer in the preservation and marketing of his products and to lengthen the season for the consumer for many articles of daily consumption. This first example of this phase of harbor development is only a beginning, and modern ports are in many cases now considering this type of harbor enterprise.

Electrification of the Harbor Terminals

The Montreal Harbor railway terminals consist of surface lines situated between Victoria Bridge and the Imperial Oil Wharf, a distance of 10 miles, and have a total trackage of over sixty miles.

For several years nine standard locomotives have been in operation. Recently, however, it appeared that if the service was to be maintained to its highest efficiency, additional locomotives would be required to maintain a prompt service.

After investigation and study, electrification has been found to be not only economical but more efficient than the use of steam locomotives, especially during the winter months, the price of coal having in recent years advanced 300 per cent as against an increase of only 8 per cent for hydroelectric power. Further, through the Canadian National Railways' electrified terminal the Harbor Commissioners have a marginal harbor railway terminal connecting all railways and all plants on the river front with the harbor docks.

Floating Drydocks

Opposite Maisonneuve a tract of land 30 acres in extent was reclaimed from the harbor and leased to Canadian Vickers, Ltd. A shipbuilding and repairing plant was installed here and the floating dock *Duke of Connaught*, built in England, was towed to the same location from across the ocean. This drydock is capable of accommodating the largest existing vessel of the British Navy and has the following dimensions:

- Length, 600 ft.
- Width, 135 ft.
- Length of side walls, 470 ft. 6 in.
- Height of side walls, 59 ft.
- Draft of vessel for dock, 30 ft.
- Lifting capacity, 25,000 tons

Standard Piers in Montreal Harbor

A standard pier in Montreal Harbor is 1200 ft. long and 300 ft. wide. The interior filling of the pier is solid, so that the ground-floor or pier cargo weights are not limited.

The pier area is laid out with one standard railway track on the quay front. Closely adjoining this track there

is a two-story transit shed 100 ft. wide and 500 to 600 ft. long, built of steel and concrete and fireproof throughout. The lower floor is elevated to the height of a freight-car platform.

In the pier center, adjoining the shed, there is a 6-ft. trucking platform, two standard railway tracks, and a roadway. For the inner sheds and also for the outer sheds there is a vehicular elevator. These elevators carry two trucks at a time up to the upper-story level, and at each elevator a transverse bridge connects with the two sheds.

The marginal railway required to feed this pier, assuming shunts to be made every six hours, day and night, has been found to necessitate two standing tracks for waiting cars, two through-running tracks, and two other tracks partially for waiting cars and partially for teaming, the length required for each pier being at least 1000 ft. This is in addition to the holding yards at various points in the terminals.

The upper stories of the transit shed are designed to carry a floor weight of 600 lb. per sq. ft. They are used almost entirely for imports, but also to some extent as collecting warehouses for export freights.

Grain is delivered to these berths from overhead conveyors entirely separate from other cargoes. Ships may receive grain from two belts at a time at the rate of 15,000 bushels per hour each, the grain being spouted directly from the belt into the hold under a head, which with goosenecks eliminates to a great extent trimming in the vessel. Outside of the ship there is ample room for lighterage.

The four berths at each of these piers are designed after long experience for American traffic, and are based on each berth being able to unload an average cargo of 5000 to 6000 tons, and load an average of 8000 to 12,000 tons per week. These berths are used to capacity throughout the season of over seven months.

The St. Lawrence Deep Waterway

For many years the organization known as the Harbor Commissioners of Montreal has been recognized generally as a public trust. Important public interests relating to navigation, to the St. Lawrence route, to maritime commerce, as well as to the harbor of Montreal have been entrusted to them, not only for development but for guarding inviolate the rights, obligations, and interests of Canada in the River St. Lawrence district.

The commissioners have declared officially that their policy must be commercial development; their duty, to guard and improve navigation. They submitted for the consideration of the International Joint Commission their opinion that approval of every important project connected with the St. Lawrence should be withheld until a properly developed plan has been prepared, taking in the whole river from Lake Ontario to Montreal, that will fully safeguard for the people of the United States and Canada their heritage in connection with:

1 Navigation
2 Hydroelectric power
3 Regulation and flow.

Why, it may be asked, is the St. Lawrence deep-waterway project more acutely before the public today than it was ten years ago? Ten years ago steam coal was available in Ontario and Quebec at $3 per ton, and the supply was ample. Today the price is two and a half or even three times higher and the supply unreliable. Ten years ago the price of transportation of a bushel of wheat from the farm to the United Kingdom market was 15 cents. Today it is double that.

Before the war Canada was not the equal of other countries as regarded engineering and industrial works and variety of industrial output. Today, however, she can build any or all of the parts needed in hydraulic and electric developments, and much that was not known ten years ago about ice control and low-head power has been learned and successfully applied in practice.

What equal project in the world, therefore, now offers an equal return to man from the generous resources of nature?

For navigation purposes alone the St. Lawrence deep waterway may be admitted as of doubtful economy. The Harbor Commissioners of Montreal, however, representing not merely the interests of Montreal but of all Canada, have taken an eminently fair attitude upon this question. In their excellent annual reports they have stated that they do not believe that ocean vessels, except specials, are either fitted for inland navigation or can compete with the Great Lakes type of vessel, including a transfer at Montreal.

They would welcome and have reserved harbor accommodation for the 10,000-ton lake vessel, but they specifically state that, in their view, public money at the present time, if available, will yield better returns if applied to improving proper port terminals.

Navigation improvements and the development of hydroelectric power may come hand in hand. The latter may pay for the former. But before such a scheme may be considered, it should have, and it is worthy of, the most profound consideration and the most careful investigation.

A Montreal Bridge Project

Seventy years ago, when railroad transport had proved its success, a bridge was projected and later built to carry railway trains across the St. Lawrence. Today it is a question of the requirements of a bridge for motor transport.

In 1919 the limits of Montreal Harbor, placed by the Canadian Government under the jurisdiction, control, and management of the Montreal Harbor Commissioners, were extended to include the beach and bank of the south shore of the River St. Lawrence to high water mark, and to include both sides of the river down as far as Bout de l'Ile. The object of this enlargement was the coordination of all units of harbor development into one scheme.

A Montreal bridge scheme, and there are several, with its possibilities for industrial developments, its harbor connections, its possible connection with the island and the south shore and its location so near the center of the City of Montreal, offers attractive possibilities. The Harbor Commissioners' construction work and administration have received the approval of the public, and taking the point of view of navigation and other administrative requirements, it is believed that they could operate this bridge in the public interest.

Discussion

In the discussion which followed the presentation of the paper the author, replying to a question asked by W. S. Jacobs[1] regarding the unsuitability of ocean vessels for inland-waterway and lake transportation, said that ocean ships were built at very great cost, with very great strength, and with special features for safety. The result was that they had very small rudders and in going into ports, docks, locks and narrow channels, tugs were invariably required. On the other hand, the lake vessel was built very cheaply, with small engine power, a flat bottom, and no keel, but with a tremendously large rudder. The result was that it could go into the Chicago River, the Buffalo River, or any lock in the country without a tug. The cost of construction and operation of the ocean vessel was so high as compared with the lake ship that it was considered that the lake ship could handle the bulk type of cargo that originated in the territory between the head of the lakes and Montreal or some other port where it would be transferred to the ocean vessel, cheaper than if it was carried all the way by ocean vessel.

In reply to a question asked by Augustus Smith[2] as to whether the port charges for the wharf service and for elevator service were sufficient to defray the interest charges and operating charges of the magnificent structures he had described, or whether any portion of such expenses had to be borne by taxation, the author said that the Harbor Commission of Montreal had been in existence for almost one hundred years and had never failed to meet all interest charges and all cost of operation, and that usually they had a tidy surplus. The Commission could always get their projects put through, in spite of the financial situation of Canada, the reason being that Montreal Harbor paid so well and had been found so essential to the requirements of production and industry. In 1906, the year after he had been appointed chief engineer of the Commission, the total gross revenue was less than $450,000 and the total debt almost $14,000,000, nearly half of what it was now. At present the gross revenue was $3,500,000.

Material-Handling Problems in Pier Design

A Review of the Proceedings of Several Material-Handling Symposiums Held by The A.S.M.E. To Discuss Material-Handling in Its Relation to Port Development

By CARROLL R. THOMPSON,[1] PHILADELPHIA, PA.

TWO very important factors influencing the plans and policy of improvement and development of our ports which seem to preclude the possibility of substantial standardization of harbor facilities, are

1 The control and operation of the port facilities, and

2 The local conditions of the port.

both of which have a direct bearing upon the character and amount of freight-handling equipment that are justifiable on the pier or wharf.

No material-handling problem is more complex than that of the transferring of freight between land and water carriers at the pier. It is also one that requires diverse consideration of every element involved in the functions of a port, and as these transfer operations center at the pier, the importance of its proper design, layout, and equipment cannot be overstressed.

Control and Operation

In some of our ports where the port administration body owns and operates the facilities there is a greater tendency to experiment with and develop equipment than where the freight movement is entirely in the hands of the pier operators. There is no hesitancy in equipping the facilities with labor-saving devices. The cargo-handling problem is under the direct control of the harbor commission. Accounts, cost data, efficiency records, and maintenance are under constant observation. Inefficiencies can be immediately corrected, whether they be due to faulty equipment or to lack of proper coördination.

At most of our older ports, railroad and private ownership and operation of facilities is more extensive than public ownership, and the handling of freight through the terminals is generally done by shipping companies or stevedoring organizations. The publicly owned facilities are usually leased to private concerns and the *direct* control of freight handling is therefore not under the supervision of the port authority, which would naturally hesitate to equip its facilities with many forms of cargo-handling devices of doubtful efficiency, believing the installations, particularly equipment of the portable type, to be a matter for the operating companies. A harbor authority cannot afford to invest money in freight-handling machinery that may not be used—unless as a means of advertising the port to attract new business. Then again, this policy of port administration brings up the question of responsibility for the maintenance of the publicly owned equipment—which is subject to more or less abuse. Pier operators in their eagerness to turn around a ship in the least possible time often resort to "emergency" repairs in order to speedily overcome a breakdown and put the apparatus in operation while ship loading is under way; and these so-called "emergency" repairs are frequently made by unskilled mechanics who have a very limited knowledge of the construction and design of the apparatus, with the result that more damage is caused and later on serious trouble is encountered and complete overhauling may be necessary. Disputes naturally arise between the tenant and the landlord over the question of responsibility. With public operation this difficulty is eliminated and proper maintenance can be assured.

Some of our port authorities also have functioned very successfully under a policy of constructing pier facilities to attract commerce. In such a policy, however, the specific character of business that may come to the pier cannot be anticipated previous to its construction, and there is the possibility of installing apparatus not adapted to meet such problems of freight handling as may ultimately arise. Under present-day conditions, steamship lines will not wait until pier facilities are built for their particular accommodation but will seek the ports that already have them. A port-authority problem becomes more complicated in attempting to build piers to suit any steamship company's business, and port authorities properly hesitate to expend large sums for extensive

Contributed by the Materials Handling Division and presented at the Spring Meeting, Montreal, Canada, May 28 to 31, 1923, of The American Society of Mechanical Engineers. Abridged. All papers are subject to revision.

freight-handling machinery that may remain idle and in the last analysis prove to be a handicap and burden rather than an asset.

Local Conditions

Undoubtedly the most important consideration which enters into the general layout of a port and its freight-handling facilities is the rail and inland-waterway service. One port may be free from the lighterage problem, or comparatively so, while at another it may be practically the only means of interchange between railroad car and steamship. The freight-handling problems of two such ports would therefore differ. In the one case transfer of freight between car and ship is confined almost solely within the pier; in the other a considerable amount of freight would not come in contact with the pier facilities, transfer being made direct between ship and lighter. With the inland waterway service, the port facilities must of necessity be equipped for loading or unloading barges, which do not as a rule carry freight equipment.

Trade in bulk commodities may be the principal commerce of some ports—they may have been developed especially for trade in grain or other bulk cargoes such as coal and ore. The material-handling proposition for such commodities demands that facilities be designed for a particular trade.

Coastwise trade requires a different terminal design from that for foreign trade. The loading or unloading of freight through the side ports of coastwise ships is an entirely different proposition than loading transoceanic ships over the side through deck hatches. Tidal conditions of a port are a very important factor in the design of a pier to be used by "side port" ships; wharf drops or movable gangways are essential for loading operations at all stages of the tide. In coastwise trade a great amount of local freight is brought to the pier by teams and motor trucks—the transportation units that cause the greatest amount of confusion and congestion in pier sheds. The upper story of a two-deck pier shed would be useless for a coastwise terminal operating with side-port ships.

The character of the intercoastal commerce also influences the design. Local deliveries by team and motor truck are very important factors in this trade.

Some ports may be developing for all three of the principal trades—the foreign, coastwise and intercoastal. It is entirely feasible to construct a general cargo pier that will admirably serve any of these trades, although there would be features incorporated in the design of such a combination structure that would prove useless for some of the trades. For example, wharf drops, which are necessary for the coastwise ships, would not be used by transatlantic ships. The upper story of a two-deck pier, which is essential in some ports for the foreign trade, would not be of service in the coastwise trade. A depressed wagonway would be of great advantage on a wide pier for either the coastwise or intercoastal business, while the space it occupies might be used to better advantage for cargo area in some of the foreign trades. Wharf cranes might prove to be valuable equipment for loading export freight but a great disadvantage on a pier used in the coastwise trade owing to the space they would occupy.

It would seem, then, that no one ideal plan of improvement would be feasible for every port and that each port must solve its own problem to satisfactorily meet its own conditions, taking all elements into account.

In speaking of What Constitutes a Modern Port, the late B. F. Cresson, Jr., also considered the effect of local conditions upon the railroad service and pier layouts in the following statements:

> Where railroad cars can be brought direct to the ship's side, piers should generally be built considerably wider than when the service must depend upon lighterage movement between the railroads and ships.
>
> Where there is plenty of undeveloped land it is believed that for economy the initial development should be of the quay type, looking forward to piers if the demands of commerce increase beyond the capacity of the terminal under quay development.

Mr. Cresson also suggested zoning by trade routes as a solution to overcome the disadvantages of equipping piers to accommodate any of the general cargo trades.

Bulk Cargoes

Bulk cargo, such as grain, ore, coal, etc., does not present as complicated a problem in handling as the great variety of commodities which form general cargo. Equipment for this class of cargo has been developed to a very high degree of efficiency. Generally shipments are made in full cargo lots and the equipment can be designed exclusively for loading, unloading, or the storage of a uniform product, which greatly simplifies this particular phase of the material-handling problem. Also, such commodities are invariably handled at piers equipped and built especially for the purpose.

Miscellaneous Cargo

The problem of efficiently and economically handling miscellaneous freight or general cargo over piers is the most difficult to satisfactorily solve of any of our port problems; it is most complex and one that demands the utmost flexibility of freight movement. It also requires the introduction of mechanical equipment.

In dealing with the subject of freight-handling machinery on the pier, it must be constantly borne in mind that while the general cargo shed is only a single unit in port-terminal operation, it must be designed to function properly with every other port facility. Coördination of the port's various facilities must be adhered to. Proper conception of the duties of the general cargo pier must not be lost sight of. For quick dispatch of freight between land and water carriers with the many attendent problems in connection with cargo, the wharf should not be permitted to perform ware-

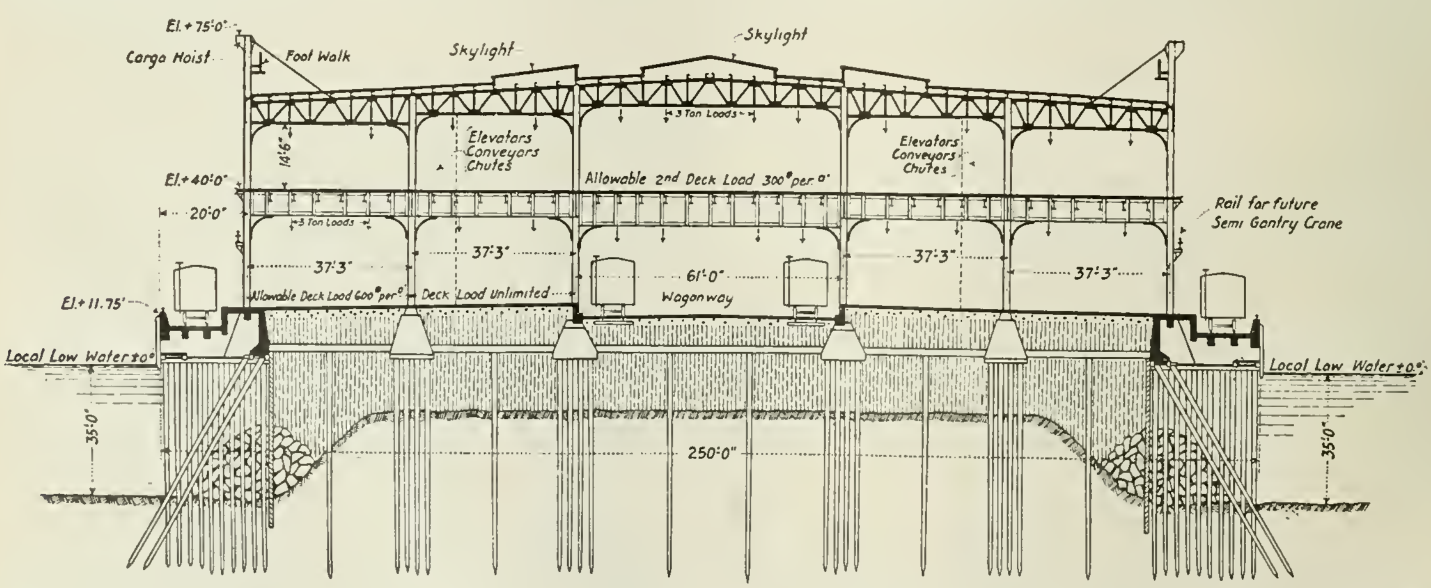

Fig. 2 Typical Cross-Section of Municipal Pier No. 78, South Wharves, Philadelphia, Showing Depressed Apron Tracks, Depressed Center Tracks and Wagonway; Also Provision for Future Installation of Semi-Gantry Cranes

house duties; that is another phase of the general port problem, and while of very great importance to the successful operation of any port, should be treated as a separate unit and coördinated with the pier as well as other facilities.

General cargo comes to the pier shed in many varieties of forms, sizes, and weights, and packed in all sorts of containers, to or from a multitude of consignees and shippers, and over any of the transportation systems entering the port. The first essential purpose of the shed is to provide ample, unobstructed cargo deck space—protected from the elements—for the sorting and assembling of this cargo for delivery to the ship, or to the railroad car or motor truck for removal. General cargo must be spread out on the pier: it must be sorted, classified, checked and weighed, and arranged for proper sequence of loading.

The run in and out of a ship for a few hours may be bagged stuff, the next run of cargo may be boxes or cases that weigh a ton, and then again in the same hold of the ship there may be a class of freight measuring a foot or two in diameter and ten or twelve feet in length, and so on. In loading cargo the various consignments from a great number of shippers must be kept separate, while import cargo must be handled in a specific manner for customs weighing and inspection. This further complicates the problem.

In modern pier operation it is impracticable to tier goods to any great height. Dr. R. S. MacElwee has pointed out that for short-time storage it is not economical to pile above five feet high.

Ample deck area is the first essential for a modern-day pier. In addition to the space required for cargo purposes, space is also needed for railroad tracks—which in a modern port are as necessary to the pier as the berth for the steamship—and considering the importance of freight delivery by motor truck and team, additional width of pier should be provided for that purpose. Adequate space for handling all of the operations connected with general cargo is a prime factor in reducing congestion—the most serious cause of delay and expensive handling cost.

Every effort should be used to eliminate obstructions to the free movement of freight. Where columns are required for the support of the shed structure, the number should be reduced to a minimum. The location of any stationary freight-handling equipment should be carefully considered, with the view of permitting the utmost flexibility of freight movement.

Unless the wide-pier terminal with ample, unobstructed cargo decks is constructed, the handling of cargoes of large ships can be done only at excessive cost and considerable delay. The wide transit shed with its railroad tracks and wagonways for drays and motor trucks has in many respects greater influence upon the expeditious interchange of freight between marine and land carriers than some types of freight-handling devices that cannot be properly adapted to the disposal of the various forms of freight in the general-cargo trade.

At the meeting of the Materials Handling Division of the A.S.M.E. in Philadelphia in December, 1921, a very interesting discussion brought out some of the advantages of two-story pier sheds.

Fig. 3 Pier No. 27, North Wharves, Philadelphia, Showing Bridge for Second-Deck Tracks

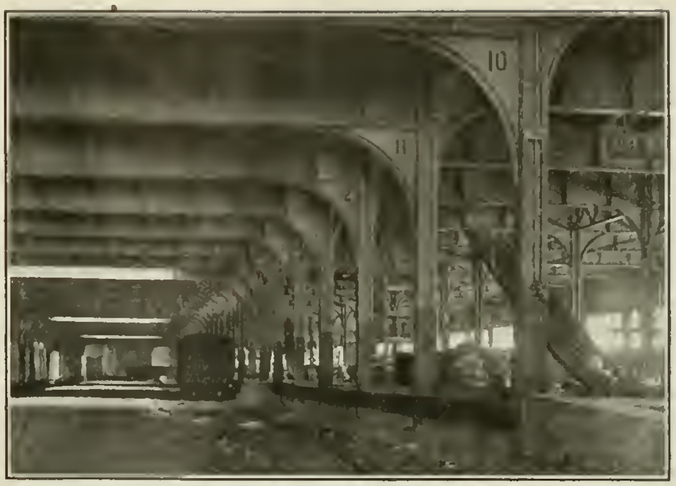

Fig. 4 Center Car Tracks and Depressed Wagonway on Municipal Pier No. 78, South Wharves, Philadelphia

Col. Fred Jaspersen explained the reasons leading up to the building and continued use of double-deck piers at Philadelphia as follows:

> When the first pier was built on these lines, the idea was that the lower floor would provide space for the collection of the ship's cargo, which arrived at the terminal at intervals; the merchandise was stored and classified on the lower floor. This left the second floor or upper deck, as it was termed, free to receive the ship's inbound cargo. Tracks on the upper deck of these piers make it as convenient to handle cargo from the upper deck as from the lower. The inbound cargo is classified and loaded into cars on the second floor and as soon as space is available in the ship, the stevedores start loading from the lower floor.
>
> We have found the cost. . . .to be lower in operating this type of pier, because the placing of cargo from the ship's hold to the upper deck was accomplished much quicker than it could have been done if the inbound cargo had been placed on the lower floor. It was found that *an average of three drafts could be placed on the second floor while two were being placed on the lower floor.* This scheme permitted better distribution of the men and employment of greater numbers without interfering with each other, which resulted in greater speed in the discharging and loading of cargo.

The bulkhead shed (which is usually a one-story head house flanking the inshore end of the pier) should prove to be an advantage with a more extensive use of tractors and trailers delivering freight to loading platforms of the shed along the street. It will keep many drays and motor trucks out of the pier altogether and tend to reduce congestion in the pier shed.

Large motor-truck elevators at the street end of the two-story pier shed that will enable local delivery to reach the upper deck direct from the marginal way to receive freight that has been discharged there, will greatly increase the usefulness of this type of structure. This will also avoid the necessity of many teams going on the first deck of the pier.

Railroad Tracks

The solution of securing the quickest dispatch of freight between railroad car and ship is to run the tracks directly on the pier. Depressed tracks (Fig. 4) in the center of the pier form a natural barrier to separate cargo space allotted to each steamship berth and in a sense divide the pier in half, which is a distinct advantage when the pier—or the double pier, as it might be called—is leased to two steamship lines. Two tracks are essential, one for each berth; but in the case of a pier long enough to accommodate two or more ships on each side, one additional running track along the center—or three in all—with crossover connections to the other two about midway in the length of the pier, is desirable to permit of car service to the outshore berths without interfering with cars assigned to, or interrupting the loading or unloading opposite, the inshore berths. Furthermore, the center location of tracks in an emergency, or when one side of the pier is not in use, will permit cars on all the tracks to be loaded or unloaded with freight from the steamship berths on either side of the pier by merely trucking through one line of cars after they have been properly spotted. Another advantage of center tracks is that they permit loading or unloading of cars under cover of the pier shed. In connection with these tracks, it is also desirable to provide a means of attach-

Fig. 5 Depressed Apron Track on Municipal Pier No. 78, South Wharves, Philadelphia

ing tackle equipment to the overhead structure to facilitate the loading or unloading of heavy parcels of freight from open or gondola cars. Many similar accessories of this character will add greatly to the economy of handling freight in the pier shed.

Apron tracks outside of the pier shed are always desirable, but where the pier width is limited it is questionable whether the covered cargo-deck area should be reduced to permit of their installation. The disadvantage of not having apron tracks for loading or unloading heavy commodities direct between car and ship may be far less serious than the congestion and confusion that would result from the restricted cargo-deck area in a narrow pier shed.

Some difference of opinion exists as to whether apron tracks should be depressed or laid flush with the pier deck. So far as the loading or unloading between ship and cars on the outside tracks is concerned, there is no particular advantage in either method. On the other hand, while the loading or unloading between ship and pier deck is underway, the tracks should be clear of cars, and this would lead to the belief that the tracks should be flush with the pier deck, in order to provide a deck-level place of deposit over the entire width of the apron for the drafts of cargo and also to facilitate trucking in and out of the shed. However, in the case of depressed tracks (Fig. 5), the sunken area outside the shed is not a very serious handicap if a platform space not less than 6 ft. in width and flush with the main pier deck is provided between the sunken pit and the pier shed for the handling of drafts of cargo. In any event, portable platforms laid across and spanning the width of the depression, in line with the loading operations, will provide the deck-level apron for its full width when required. The one great advantage of the depressed apron tracks is their use for bringing freight to the pier, or vice versa, when the berths are not occupied by the ships. When apron tracks are installed they not only can be, but invariably are, used to the greatest extent for transporting car shipments to and from the pier when the ship berths are unoccupied. In fact, their use for this purpose seems to greatly exceed that for loading direct between car and ship, and the importance of the car floors' being level with the main pier deck is obvious and offsets the slight disadvantage of a partially depressed apron for ship-loading operations, which may be readily overcome to a considerable extent, as discussed before.

For unloading or loading open cars on the apron tracks, the equipment installed on the pier for loading the ship would be available.

Vehicular Traffic

The other means of bringing goods to and from the pier, particularly the local deliveries, is by motor truck and teams. Ordinarily they cannot be confined to any particular location on the cargo deck, although the tendency is to follow a line of travel adjacent to the center car tracks, especially if the same entrance to the pier is used for both teams and cars. Congestion caused by drays and trucks could be reduced to a great extent by constructing bulkhead sheds, as discussed before.

Where the pier can be built wide enough, a depressed wagonway (Fig. 4) extending into the shed about three-fourths of the pier length will greatly facilitate team and truck delivery to and from the pier. It will not only keep many teams off the cargo deck but will permit loading or unloading of these units from a cargo deck built at wagon-floor height.

Another distinct advantage of the depressed wagonway, particularly with respect to a pier long enough to berth two or more ships, is that it affords a means of team traffic reaching the outshore berths without interfering with the working of freight on the cargo decks at the inshore berths. One car track laid along each side of such a wagonway will preserve the desirable feature of center car tracks—the space between tracks affording a thoroughfare for teams to reach the cargo decks at the outshore berth. When these tracks are not occupied by cars, either totally or partially, the teams can back up to the cargo-deck platform. With a layout of this character, however, it is essential that the pier be not only wide enough to accommodate the depressed wagonway—due to the fact that the space can be used for no other purpose—but, also, it must be wide enough to allow apron tracks to be installed, because the two tracks in the wagonway extending only three-quarters of the length of the pier will not permit of sufficient car service on a four-berth pier.

Loading and Discharging Ships

The importance of quick loading and unloading of ships, which in turn results in quick turn-around, cannot be overestimated, and any improvements in the existing methods that will at the same time satisfactorily meet the many complexities involved in handling freight at a general-cargo pier, will be a step in the right direction and one that will be welcomed.

As a rule, any discussion of loading or discharging general cargo centers around the efficiency of ship's gear in comparison with wharf

Fig. 6 Burtoning of Cargo to the Lower Deck of a Pier While Coaling Operations Are Under Way with Ship Breasted Off

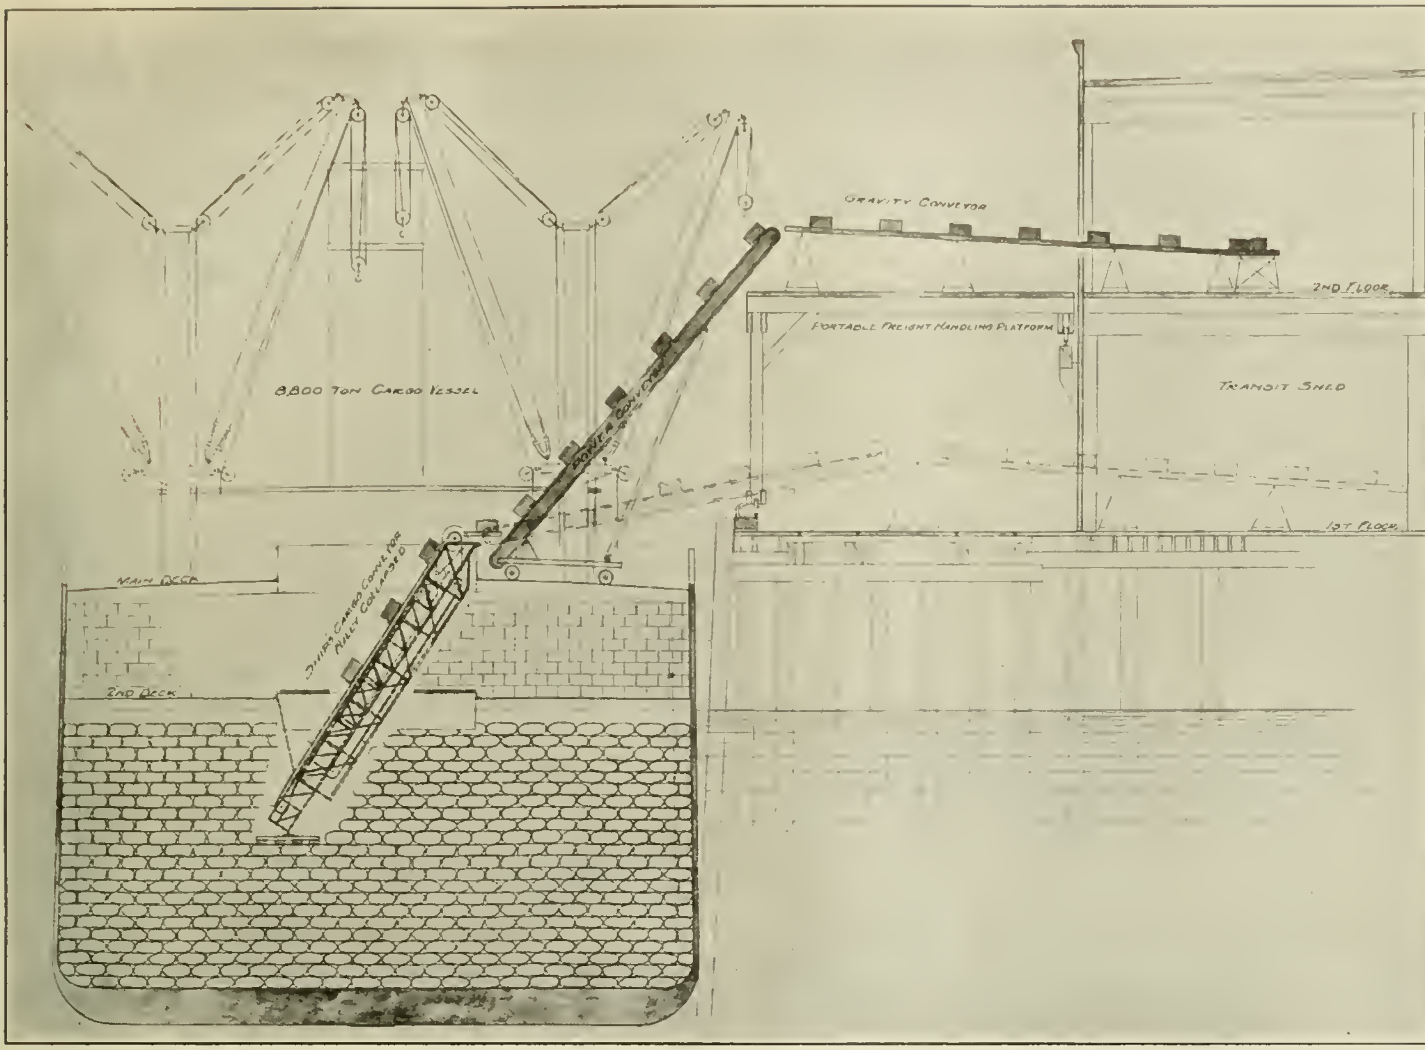

Fig. 7 Ship's Cargo Telescopic Conveyor, Port of Seattle, Wash.

cranes. It seems doubtful whether the wharf crane will displace the use of the ship's gear for handling general cargo until the operating and economic advantages of the crane have been demonstrated to be superior to the ship's winches by results of actual tests of each method conducted under working conditions.

Ship's gear forms one of the most flexible methods now in use that will meet all of the requirements for ship loading. It has one distinct advantage of being located on the ship and not on the pier, where space is valuable for other purposes. Its use is well understood and it can be worked over a narrow apron, thus permitting a maximum area of the wharf to be covered over.

Cargo masts on the pier will greatly increase the flexibility of loading with ship's gear in that it can operate by "Burtoning" over a wide apron or when the ship is breasted off (Fig. 6), and also over a greater length of the pier apron. The initial cost of cargo masts is small and there is practically no maintenance expense as there is nothing to get out of order.

In designing the side construction of a pier superstructure to permit of loading operations to be conducted at any point along the ship's berth, continuous door openings should be provided along the full length of the pier, and of a height sufficient to form no interference with the operation of the ship's gear. Generally, it is found that a clear opening of door height should be not less than 20 ft. for the first story. In the second story of the pier shed this height may be reduced, and door openings in alternate bays should provide sufficient access to the second deck for loading or unloading operations.

Remote-control, portable electric dock winches at some piers are desirable for furnishing power to supplement the ship's gear, although cases are known where pier operators have requested the port officials to remove publicly owned winches from the piers on account of the space they require.

Wharf cranes will generally accomplish all of the loading or unloading operations of the ship's gear, but their economy and speed still seem to be questioned. The pier must be built for their support and free operation, and unless the speed of ship loading and discharging is reduced, it is doubtful if they are able to control any more of the wharf area than the ship's gear. A wide apron is necessary, and besides skilful operation is required to avoid the ship's rigging. One drawback to providing wharf cranes on covered general-cargo piers is the high cost of installation and maintenance; another—in some cases—is the additional width of pier that is necessary for their operation.

In the case of a pier where apron tracks are built outside of the shed, it may be good policy to design the foundations and the superstructure for the future installation of semi-portal cranes, in the event of their use being warranted.

Other methods of loading ships, such as the portable conveyor systems, have proven successful at some of our West Coast ports for full cargoes of a uniform character such as bagged flour, but it is very doubtful if stevedores would set up such machines for loading parcel lots and then turn to the ship's gear or cranes for other freight that could not be handled on conveyors. The main objection to any equipment of this kind is the room it takes up on the pier when not in use, and also the necessity of changing to other kinds of equipment in loading miscellaneous cargo.

Freight Handling Within the Shed

The first essential for the economical movement of freight in the transit shed is a large area of unobstructed cargo-deck space. Stationary or semi-stationary equipment will generally prove to be obstructions in the way of flexibility of movement. Speaking on this subject, J. A. Jackson has said:

Industrial trucks and tractors with trailers provide to the fullest extent

that extreme flexibility so necessary and desirable for cargo handling on piers, the industrial truck being the more flexible of the two. If sufficient aisle space can be provided the tractor train is more desirable as it can handle a ton at lower cost than an industrial truck on account of the lower labor charge and due to the fact that the tractor—representing the major part of the investment—can be kept almost constantly at its legitimate work of hauling if sufficient trailers are provided.

The loading and unloading of trailers and trucks is still a job for manual labor and it must be admitted that in respect to this one problem the old hand truck has about everything beaten. It is for this reason that for very short movements the hand truck can make a better showing than either electric trucks or trailers.

Other methods such as overhead traveling cranes and telpher systems usually can operate only within certain restricted areas, particularly in two-deck structures where necessary columns form an obstruction, and the various movable units of either of these systems will invariably interfere with each other. Furthermore, the portable equipment before mentioned—in the event of its not proving satisfactory either generally or for particular purposes—does not represent an exorbitant initial cost and can be very readily removed from the pier if it proves to be unsatisfactory.

For interchange of freight between the first and second decks of a two-story pier shed, the large standard platform elevator and the automatic elevator and lowerator for handling packages of the size and weight for which it is particularly adapted, are the best means of communication; however, in the case of lowering goods from the second deck to the first, full advantage should be taken of the gravity type of equipment, such as chutes. In this connection it is believed that the straight chutes possess more advantages than the gravity spiral conveyors, in that the entire operation of lowering freight can constantly be seen by the operator stationed on the second deck.

Many other minor details in the design of piers, if given proper attention, will facilitate the general freight movement in the pier shed.

If the overhead girders and roof trusses are designed to allow for a moving load of, say, three tons at any point along the bottom chords, there need be no alarm over lifting occasional heavy loads from the pier deck level by means of tackle attached to these structural members; swivel tackle links built on them for such purposes—particularly over the railroad tracks—will prove very helpful in saving time in rigging tackle and at the same time result in such attachments being made to the structure at points where provision has been made in the design for it.

This particular allowance for loading in the design of the pier would also provide for future installations of overhead mechanical equipment that might prove serviceable in specific cases.

Tackle links built along the stringpiece of the apron will permit of easy tackle attachment to the pier for ship-loading operations with dock winches and will also go a long way to prevent lashing to columns, which invariably results in bent and battered door guides.

Links built in the side walls of depressed car pits have proved to be valuable for moving railroad cars with dock winches or other power equipment.

Dr. MacElwee, in a very commendable discussion on The Relation of Wharves and Warehouses in the Economical Handling of Materials, compares the advantages and disadvantages of terminal freight movement in "the pier and warehouse system" with "the quay and warehouse system," and offers the huge pier, or "quay pier," with its transit shed, warehouses, teamway, and railroad tracks as a solution of our water-front terminal problem with respect to the handling of "general" cargo, its chief advantages being the decrease in congestion and the shorter trucking movement.

The adoption of the wide transit shed, with its large, unobstructed cargo-deck area—whether the terminal is of the pier, double-pier, quay or quay-pier type—is obviously the fundamental essential for a successful and economical terminal facility for handling general cargo, and also the feature that will sooner or later permit of more extensive freight handling with mechanical equipment.

The success of any mechanical means of improving our freight-handling problem will be dependent upon the whole-hearted co-operation of all those who have any connection with terminal operation: the mechanical and electrical engineer must play just as important a part as the stevedore, the railroad or steamship operator, the port authority, or the terminal engineer.

Discussion

G. F. Nicholson[1] wrote that on the Pacific Coast freight was handled direct to and from vessels, and while gantry cranes, shearleg derricks, and locomotive cranes were used to handle large-tonnage export commodities such as lumber, iron and steel, both in the raw and manufactured state, when it came to handling imports consisting of boxed, baled, and sacked goods, light portable equipment such as tractors and conveyors were employed.

Ports like that of New York, where a large barge and lighterage business was carried on, should be well equipped with cranes, the straight-line roof type being the best for such work.

In addition to its heavy handling equipment the port of Seattle had a varied assortment of light portable equipment consisting of electric and gasoline tractors and trailers, incline conveyors, stacking elevators, etc. With a view to improving their service the port authorities were now constructing a ship-cargo telescopic conveyor which they had designed themselves, and it was expected that this machine would handle boxed, baled, and sacked goods weighing up to 500 lb. per package twice as rapidly as the equipment now used for that purpose. This conveyor, shown in Fig. 7, it was believed, would do away with the use of slings and the damage often resulting therefrom; permit of much better sorting of cargo to the hold of the vessel, as it could be handled by gravity conveyors to the main conveyor equipment; increase the speed of handling, as a continuous line of freight would be transferred from the hold of the vessel to the pile on this conveyor equipment; and reduce the cost of handling freight, as it would be carried to its destination on the wharf by the conveyor without rehandling.

J. A. Shepard,[2] who opened the oral discussion, called attention to the fact that one of the greatest difficulties in connection with materials handling today was the lack of adequate cost data. His mature opinion regarding the application of machinery to the handling of miscellaneous cargoes was that it could be made sufficiently flexible and could be installed in moderate but sufficient variety to meet all of the reasonable requirements of miscellaneous cargo handling. Too little had been said about cargo-handling machinery in the pier shed, which Mr. Shepard believed was destined to exercise perhaps a greater influence on the total economy than the use of machinery outside the shed. The traveling crane, able not only to hoist its load but to travel in all directions and cover absolutely a large area, he predicted, would in course of time be the solution of the handling problem within the pier shed.

H. E. Birch,[3] referring to the unloading of incoming freight to the upper deck of a double-deck pier, asked whether the cost of rehandling that freight on to the cars on the lower deck was taken into account; also what influence the type of stevedore labor available in any particular port had on the selection of the types of machinery or pier design.

Augustus Smith[4] said that the box car was a tremendous obstacle to any practical crane system, and a great step forward had been taken by the New York Central recently with its container car. The railroad rate system was based on the weight and value of freight and was unscientific. If it were only possible to have it based on the cost of handling, it would be easy to induce, through the Inter-State Commerce Commission, the roads to recognise convenient sizes of packages; and if manufacturers and shippers could be prevailed upon to use standard containers by a freight differential in their favor, a long step forward would be taken in facilitating the handling of such freight.

H. V. Coes,[5] chairman of the Materials Handling Division, who presided over the session, said that in his opinion, it ought to be possible, with the use of high-grade steel, to build a freight car from which the roof could be lifted; this would permit the use of containers of larger size and the tiering of freight, and immediately open up the use of cranes or other material-handling devices. It would also make loading a great deal easier than it was at the present

The Determination of Chimney Sizes

By ALFRED COTTON,[1] ST. LOUIS, MO.

In this paper the author presents a simple and orderly system, based on accepted characteristics, for determining the sizes of chimneys. He has found that certain essential relations exist between capacity, draft, diameter, and height when connected in the manner described in the text.

Under any specific conditions there is a definite static draft for a given height and a definite "maximum capacity" for any given diameter. These are connected by a fundamental curve which is applicable to all chimneys under all conditions.
